The most commonly reported side effect of mycophenolate mofetil is gastrointestinal upset and diarrhea. Mycophenolate sodium causes fewer gastrointestinal symptoms than mycophenolate mofetil. In the aforementioned pilot study, Kreuter et al. reported one patient with elevated liver transaminases that reverted to normal once the medication was stopped. Mycophenolate is a relatively new medication, and the long-term ramifications of infection and malignancy risk are unknown.

CONCLUSIONS

There is insufficient evidence to support the use of mycophenolate at this time.

Is Dapsone Effective in the Treatment of Cutaneous Lupus?

We found no randomized-controlled trials of dapsone in the treatment of CLE.

We found three case series assessing the use of dapsone in CLE.⁷¹⁻⁷³ These series make up a combined 55 patients, thirty of whom reportedly improved. We found case reports showing improvement in patients with SCLE, Lupus profundus, DLE, and bullous lupus⁷⁴⁻⁷⁸. Dapsone doses ranged from 25 mg per day to 150 mg per day.

Toxicity

Dapsone can cause a rare hypersensitivity reaction, which results in agranulocytosis. Dapsone causes hemolysis, and therefore some degree of anemia, in all patients. Patients with a deficiency in glucose-6-phosphate dehydrogenase (G6PD) are particularly sensitive to dapsone-induced hemolysis. For this reason, patients should be tested for G6PD deficiency prior to starting the medication. Those patients with G6PD deficiency should not be prescribed dapsone. Dapsone is also known to cause a reversible motor neuropathy. Patients should be monitored for this side effect.

CONCLUSIONS

There is insufficient evidence for the use of dapsone in CLE. Dapsone is anecdotally considered first line therapy in bullous lupus, but this is not supported by any clinical trials.

Are other Systemic Agents Effective in the Treatment of Cutaneous Lupus?

Azathioprine

We did not find any randomized-controlled trials assessing the usefulness of azathioprine in the treatment of CLE.

We found three case reports totaling nine patients with CLE treated with azathioprine. Tsokos et al. reported one patient with generalized DLE who improved with azathioprine.⁷⁹ Ashinoff et al. reported two patients with refractory DLE of the palms and soles who improved with azathioprine.⁸⁰ Callen et al. reported a series of six patients with CLE treated with azathioprine. Three of the six cleared; however all three necessitated cessation of the medication secondary to side effects (drug fever, pancreatitis, and nausea).⁸¹

Rituximab

We found four case reports in the literature documenting improvement of CLE after treatment with rituximab.⁸²⁻⁸⁵

IVIG

We found five case reports in the literature documenting improvement of CLE after treatment with IVIG.⁸⁶⁻⁹⁰

CONCLUSIONS

There is insufficient evidence to support the use of azathioprine, rituximab, or IVIG in the treatment of CLE.

Are Topical Steroids Effective in the Treatment of Cutaneous Lupus?

We found one randomized controlled trial comparing a high potency steroid with a low potency steroid in the treatment of CLE.

Roenigk et al. conducted a 12-week randomized-controlled crossover study comparing 0.05% fluocinonide cream to 1% hydrocortisone cream in the treatment of CLE. Seventy-eight patients were enrolled. Fifty-nine completed the entire 12-week study. A single lesion was chosen for treatment in each patient. A numeric scale from 1 to 5 was used to assess improvement (1 represented worsening and 5 represented clearing). At 6 weeks excellent response was seen in ten of the 37 patients (27%) in fluocinonide arm and four out of 41 patients (10%) in hydrocortisone arm.⁹¹

Ullman et al. conducted a double blind randomized placebo controlled study of R-salbutamol in the treatment of DLE. They enrolled 37 patients with at least one new active lesion of DLE. The primary outcome was change in an invalidated modification of the CLASI, and intention to treat analysis was not carried out. After eight weeks of treatment, the change in the modified CLASI scores in

treated and untreated groups was equivalent. The change in the following secondary outcome measures did reach statistical significance: scaling, hypertrophy, induration, pain, itching, and patient global assessment.⁹²

Barikbin et al. conducted a double-blind prospective comparison of pimecrolimus 1% cream and betamethasone 17-valerate 0.1% cream in the treatment of 10 patients with DLE. The primary aim was comparison of the changes in means of an invalidated skin score. There was no statistically significant difference between the two groups. Using each patient as their own control, each group mean showed a statistically significant improvement.⁹³

Björnberg and Hellgren used a half side of body comparison study to assess the efficacy of fluocinolone acetonide ointment in the treatment of DLE. They enrolled twenty patients. Seventeen of the patients had improvement of the treated half of their body in comparison to the untreated half of their body.⁹⁴

We found two observational studies showing improvement in CLE lesions with topical steroid treatment.^{95,96}

Toxicity

Potent topical steroids are known to cause skin atrophy and telangiectasias, particularly on the thin skin of the face.

CONCLUSIONS

There is good evidence supporting the use of potent topical steroids in the treatment of DLE. Pimecrolimus 0.1% cream is not inferior to betamethasone 17-valerate 0.1% cream.

Are Calcineurin Inhibitors Effective in the Treatment of Cutaneous Lupus?

We found one randomized-controlled trial comparing the use of topical 0.1% tacrolimus ointment with 0.05% clobetasol propionate ointment.

Tzung et al. conducted a randomized-controlled double-blind bilateral comparison study of 0.1% tacrolimus ointment and microdermabrasion versus 0.05% clobetasol propionate ointment and microdermabrasion in 20 patients with CLE (thirteen with ACLE, four with DLE and one with SCLE). The patients were instructed to apply tacrolimus twice daily to one-half of their face, and clobetasol propionate twice daily to the other side of their face for 4 weeks. Improvement was assessed on a seven-point scale each for erythema, desquamation, and induration. The agents were equally effective in obtaining a partial response over a 4-week time course with the addition of microdermabrasion. Clobetasol was noted to cause a statistically significant increase in post-therapy telangiectasias compared to tacrolimus. The results of this study are difficult to interpret given the unconventional addition of microdermabrasion.⁹⁷

Several open label trials were conducted to evaluate the effectiveness of topical calcineurin inhibitors.^{98–103}

Yoshimasu et al. treated nine patients with CLE with 0.1% tacrolimus ointment once daily for 4 weeks and reported improvement in four of their patients.

Kanekura et al. designed a half face comparison study in 3 patients with ACLE. Patients were instructed to apply 0.1% tacrolimus ointment to half of their face twice daily for three weeks. The authors report resolved erythema of the treated side in all three patients.

Lampropoulos et al. treated twelve patients with CLE with 0.1% of tacrolimus ointment twice daily for 6 weeks. Eleven of their twelve patients completed the study. Six patients were reported to have improved based on clinical photographs, clinician opinion, and patient opinion.

Heffernan et al. treated five patients with DLE with 0.1% tacrolimus ointment. Two lesions were chosen in each patient for treatment. Patients were instructed to apply the ointment twice a day for a total of 12 weeks. A clinical scoring system based on diameter, erythema, scarring, and thickness was constructed by the authors. Only three of the five patients completed the study. Using the last observation carried forward they reported that all five patients improved. Based on their scoring system, mean improvement ranged from 32% (reduction in erythema) to 56% (reduction in lesion thickness).

Tlacuilo-Parra et al. conducted an open label trial of twice daily pimecrolimus 1% cream in patients with CLE. Again, a clinical severity score was used to assess clinical improvement in the ten enrolled patients. They report a mean improvement in severity score of 52%.

We found one retrospective cohort study comparing the efficacy of 0.3% tacrolimus ointment combined with 0.05% clobetasol propionate ointment compared to 0.1% tacrolimus alone in the treatment of CLE. Madan et al. reviewed the charts of thirteen patients with CLE who were treated with a combination of 0.3% tacrolimus ointment and 0.05% clobetasol propionate ointment. They report that eleven of the thirteen patients treated with this combination improved (85%). They compared this to five patients who were treated with 0.1% tacrolimus ointment alone. Of the tacrolimus only group, only one patient improved (20%). Two patients in the 0.3% tacrolimus ointment combined with 0.05% clobetasol propionate ointment group developed acne and telangiectasia.

Multiple case reports and case series have also been published showing improvement of CLE when treated with topical calcineurin inhibitors.^{101,102,104,105} A total of eighteen patients have been reported in this manner with 16 reported to have improvement in their cutaneous lesions.

Toxicity

The most commonly reported side effect was a burning sensation. Calcineurin inhibitors have a black box warning for increased risk of lymphoma. There is significant debate

if this is a warranted label for the topical formulations of these medications.

CONCLUSIONS

There is evidence that 0.1% tacrolimus ointment is as efficacious as a potent topical steroid in the treatment of DLE, with less risk of cutaneous side effects.

Is Smoking Cessation Effective in the Treatment of Cutaneous Lupus?

We found no randomized controlled trials assessing the efficacy of smoking cessation in treatment of CLE.

Moghadam-Kia et al. performed a prospective cross-sectional analysis of 114 patients with CLE. Eleven out of the 114 patients had refractory disease, defined as active inflammation in the setting of aggressive systemic therapy. Within this subset of refractory patients, there was a statistically significant increased rate of smoking.¹⁰⁶

We found three retrospective cohort studies.

Rahman et al. performed a retrospective cohort study of 36 patients with CLE whose smoking status was documented in the medical record. All 36 patients were treated with a year-long course of antimalarials. Seventeen smokers and 19 nonsmokers were evaluated after 6 months and 12 months of antimalarial treatment. The primary end point was resolution of CLE. They found a statistically significant difference in the two groups. Three of the 17 smokers (18%) had resolution of their CLE, whereas nine of the nineteen nonsmokers (47%) had resolution of their CLE.¹⁰⁷

Jewell and McCauliffe reviewed the records of 61 patients with CLE who were previously treated with an adequate trial of antimalarials (defined as 8 weeks of hydroxychloroquine or 5 weeks of chloroquine) and whose smoking history was documented. A two-by-two table analysis was performed to compare the response rates of smokers versus nonsmokers. They found a statistically significant difference in response to antimalarials in smokers (40%) versus nonsmokers (90%).¹⁰⁸

Kreuter et al. retrospectively reviewed 36 patients with tumid lupus who were treated with antimalarials. They performed a retrospective CLASI as their outcome measure. They report that 28 of the 36 patients were current smokers (78%). The proportion of smokers in their study was much higher than expected, based on a cross-sectional analysis of an age and sex-matched population. The smokers had an increased CLASI score on presentation when compared to the nonsmokers, and had less improvement of their CLASI score during the course of therapy with antimalarials.²³

We found one case report describing clinical improvement in a patient with DLE when she decreased the amount she smoked.¹⁰⁹

CONCLUSIONS

Population studies suggest that patients with DLE are more likely to smoke than their age and sex-matched population cohorts. There is evidence suggesting that smoking decreases the efficacy of antimalarials. There are no randomized controlled trials assessing the benefit of smoking cessation on CLE.

Is Sunscreen Effective in the Treatment of Cutaneous Lupus?

We found one open-label study of the efficacy of broad-spectrum sunscreen in the treatment of CLE.¹¹⁰ Eleven patients with CLE that was inducible with photoprovocation were treated with three different commercially available sunscreens in 5 cm × 5 cm test spots, 20 minutes prior to irradiation. Photoprovocation was carried out with UVA and UVB devices. All three sunscreens prevented formation of CLE lesions within their respective 5 cm by 5 cm phototesting areas.

CONCLUSIONS

There is evidence that sunscreen use is an effective prevention measure in the development of UV-induced CLE.

Are Laser Treatments Effective in the Treatment of Cutaneous Lupus?

We found no randomized controlled trials assessing the efficacy of laser treatment in CLE.

There are three case series^{111–113} and five case reports^{114–118} assessing patient improvement after treatment with argon and pulse dye lasers. In total, 66 patients have been treated, and 44 of them were reported to have improved.

Toxicity

Pain, immediate purpura, and postinflammatory hyperpigmentation were reported as side effects of laser therapy in patients with CLE.

CONCLUSIONS

There is insufficient evidence to recommend pulse dye or argon lasers as a treatment in CLE.

ACKNOWLEDGEMENTS

This work was partially supported by the Lupus Foundation of America and in part by a Merit Review Grant from the Department of Veterans Affairs Veterans Health Administration, Office of Research and Development, Biomedical Laboratory Research and Development and by

What We Know

- There are few randomized-controlled trials for the treatment of CLE.
- Systematic reviews reveal obvious benefits of antimalarials in treating SLE.
- There are no randomized placebo-controlled trials assessing the efficacy of antimalarials in the treatment of CLE; however, antimalarials are historically accepted as the first line therapy for CLE. Chloroquine may have slightly greater efficacy than hydroxychloroquine, but chloroquine is less well tolerated. Addition of quinacrine appears to be helpful for refractory patients, but is limited by side effects. There is little evidence of harm from antimalarials.
- Thalidomide has been shown, in a summation of case series, to be successful in the treatment of more than 400 patients with CLE refractory to accepted first line therapies. Randomized controlled trials are needed to better elucidate the benefits of thalidomide in CLE, particularly given the well-documented risks of this medication.
- There is good evidence supporting the use of potent topical steroids in the treatment of DLE.
- There is good evidence to support the role of topical calcineurin inhibitors in the treatment of CLE.
- There is evidence that sunscreen use is an effective prevention measure in the development of UV-induced CLE.
- Population studies suggest that patients with DLE are more likely to smoke than their age and sex-matched population cohorts. There is evidence suggesting that smoking decreases the efficacy of antimalarials.

Treatment of Cutaneous Dermatomyositis

34

Ruth Ann Vleugels, M.D., and Jeffrey P. Callen, M.D.

INTRODUCTION

Dermatomyositis is an idiopathic inflammatory myopathy characterized by progressive proximal muscle weakness and pathognomonic or characteristic cutaneous manifestations. Management of patients with cutaneous lesions of dermatomyositis must begin with a systematic investigation for the presence of muscle disease, the presence of additional systemic involvement, particularly of the pulmonary, cardiac, and/or gastrointestinal systems, and for the possibility of an accompanying malignancy. Detection of any of these potentially associated features dictates the initial approach to disease management. Notably, management of cutaneous lesions in patients with dermatomyositis is often challenging and can require multiple sequential and/or combined therapies. Many patients with muscle and systemic disease will have continued problems with their skin, despite control of their systemic disease. Thus, the cutaneous manifestations of this disease can remain highly refractory to therapy and challenging to manage. In addition, in some patients with dermatomyositis, cutaneous disease exists in the absence of objective evidence of muscle weakness and elevated muscle-derived enzymes. These cases are referred to as amyopathic dermatomyositis and can be difficult to manage. For these reasons, the dermatologist has a unique role to play in caring for patients with this disease.

Very few prospective, randomized studies have been conducted on skin disease in dermatomyositis, requiring clinicians to rely on case reports and retrospective reviews in formulating their approach to treatment. In this chapter, we will review the evidence that exists regarding the therapeutic options for dermatomyositis, while specifically highlighting treatment options used for the cutaneous manifestations of this disease.

EPIDEMIOLOGY

A study published in 1990, by Oddis, et al. reported an incidence of dermatomyositis of 5.5 cases per million, with an increasing incidence noted over the two decades represented in the study period.¹ A recent population-based study published in 2010, found the incidence of dermatomyositis to be 9.63 per million, with an incidence of clinically amyopathic dermatomyositis of 2.08 per million.²

In addition, this study also found the incidence of dermatomyositis to be 13.98 per million in women and 4.68 per million in men, supporting previous epidemiologic data indicating that women are affected by dermatomyositis more often than men. In this population-based study, malignancy was present in 28% of participants², strengthening the best previously existing data that 18–32% of dermatomyositis patients have or will develop a malignancy.³ The incidence of the juvenile form of dermatomyositis (diagnosed up to age 16), has been estimated to be 1.9 per million, with a female-to-male ratio of 5:1, and median age of onset of 6.8 years.⁴ These patients have little to no increased risk of malignancy, but they are at an increased risk of calcinosis relative to the adult form of disease.

ETIOLOGY

Although the exact pathogenesis of dermatomyositis has yet to be elucidated, the disease is thought to result when varying factors, such as malignancy, infections, or drugs, trigger an immune-mediated process in a genetically predisposed individual.⁵ Serum antinuclear autoantibodies, as well as other myositis-specific autoantibodies, are often present. In addition, there is increasing evidence to support that autoantigens activate a humoral immune process in which complement is deposited in capillaries, resulting in capillary necrosis and ischemia.⁶ Finally, dermatomyositis is also known to be photoexacerbated.^{7–9}

DIAGNOSIS

The diagnosis of dermatomyositis often involves clinical recognition of the characteristic cutaneous manifestations along with a skin biopsy that is compatible. Cutaneous disease includes pathognomonic changes, referred to as the heliotrope eruption and Gottron's papules, as well as characteristic features, including photoexposed violaceous erythema, violaceous erythema on the extensor surfaces, malar erythema, nonscarring alopecia with or without scaly poikilodermatos changes, erythematous papules and/or plaques on the lateral thighs (Holster sign) and cuticular/periungual changes.¹⁰ Less common cutaneous lesions of dermatomyositis include mechanic's hands (hyperkeratosis of the lateral fingers and palms), panniculitis, urticaria, a flagellate erythema, follicular hyperkeratosis, erosive or

vesicobullous lesions, and an exfoliative erythroderma.³ Calcinosis and changes consistent with a cutaneous vasculopathy can also be present, particularly in cases of juvenile dermatomyositis.

Investigation for associated muscle disease and/or systemic disease is necessary in all patients, including those with no symptoms of muscle weakness or systemic involvement. Evaluation traditionally involves strength testing of the proximal muscles, serum levels of muscle-derived enzymes (creatinine kinase and aldolase), and often an electromyogram, magnetic resonance imaging study, or muscle biopsy. Investigations for interstitial lung disease (pulmonary function tests with diffusion studies and a chest x-ray or possibly a high resolution CT scan), for esophageal disease (barium swallow or manometry), and for cardiac disease (electrocardiogram), should be completed at the time of diagnosis. Additionally, the patient should undergo a systematic evaluation for an associated malignancy which is repeated annually as we have recently reviewed elsewhere.³ It is important to note, that patients with amyopathic dermatomyositis also may have an associated malignancy or may develop systemic manifestations such as fulminant pulmonary disease.¹¹ Therefore, investigations for malignancy and associated systemic disease must be conducted in this subset of patients as well.

SEARCH METHODOLOGY

A PubMed search was performed using the search term “dermatomyositis treatment AND.” Only articles available in English were included. Titles and abstracts were reviewed for relevance. References were also gathered from the cited studies and reports reviewed. Case reports and retrospective reviews were considered given the relative lack of prospective studies available on therapeutic interventions for cutaneous dermatomyositis.

RESEARCH QUESTIONS AND THEIR ANSWERS

There are multiple limitations in assessing the various therapeutic approaches to dermatomyositis. Most existing information regarding therapy for dermatomyositis is in the form of retrospective reviews. In fact, in a Cochrane review article, only four high-quality randomized controlled studies on dermatomyositis were identified, and none specifically focused on its cutaneous manifestations.¹² The low incidence of dermatomyositis, coupled with the fact that studies traditionally pooled cases of polymyositis and dermatomyositis when considering therapeutic regimens, further complicates the assessment of treatment options for this disease. In addition, given the refractory nature of the skin manifestations and the frequent association with muscle and/or systemic disease, data on true monotherapy is virtually nonexistent. Finally, until recently there were no

validated measures in assessing cutaneous disease severity in dermatomyositis.

Given these limitations, the purpose of this chapter is to provide care providers with the existing evidence behind various therapeutic options in order to allow more evidence-based treatment recommendations. (Please see Table 34-1 for a therapeutic ladder for cutaneous disease in dermatomyositis and Table 34-2 for existing evidence-based data for the treatment of dermatomyositis.)

Photoprotection

Studies have demonstrated that both UVA and UVB are involved in the elicitation of certain subtypes of cutaneous lupus erythematosus, and a similar phenomenon is thought to occur in dermatomyositis as well, although studies are lacking.¹³ It has been shown that patients with dermatomyositis, similar to those with lupus erythematosus, demonstrate a significantly reduced minimal erythema dose (MED) to UVB irradiation compared to healthy controls.⁸ Another study was able to reproduce skin lesions of dermatomyositis with solar-simulated radiation in 1 of 6 patients however, 5 of 10 patients indicated that light would worsen their existing cutaneous lesions.⁹

Patients should be counseled that their disease may be exacerbated by light even in very limited exposures.⁷ Given the photoexacerbated nature of dermatomyositis, year-round daily photoprotection with a broad-spectrum sunscreen with sun protective factor of at least 30 is recommended, and reapplication should occur every 3–4 hours.¹⁴ Wide-brimmed hats, sun protective clothing, and behavioral modification should also be encouraged as skin

TABLE 34-2—Existing Evidence-based Data for the Treatment of Dermatomyositis

	Muscle Disease	Cutaneous Disease
Level 1 Evidence (prospective randomized-controlled trial)	Oral corticosteroids High-dose IVIG Azathioprine In progress: rituximab, methotrexate, infliximab, etanercept, oral tacrolimus, methimazole, monoclonal antibody directed against the fifth component of complement, MEDI-545 Plasmapheresis and leukapheresis (*showing no benefit)	High-dose IVIG Plasmapheresis and leukapheresis (*showing no benefit)
Level 2 Evidence (retrospective study and/or large case series)	Low-dose methotrexate Mycophenolate mofetil Cyclosporine Cyclophosphamide Chlorambucil Rituximab	Hydroxychloroquine Low-dose methotrexate
Level 3 (small case series and/or case report/s)	Infliximab Etanercept Oral tacrolimus Sirolimus Total body irradiation Stem cell transplantation	Sunscreens Topical corticosteroids Topical tacrolimus Hydroxychloroquine or chloroquine plus quinacrine Mycophenolate mofetil Thalidomide Dapsone Adjuvant leflunomide Antiestrogen medications (tamoxifen, anastrazole) Infliximab Etanercept Efalizumab (prior to being removed from the US market in 2009) Rituximab Oral tacrolimus Sirolimus Total body irradiation Stem cell transplantation

manifestations are challenging to control without adequate photoprotection. Notably, there have been cases reported involving flares of internal disease following solar irradiation in patients with dermatomyositis, similar to this more recognized phenomenon in lupus erythematosus.⁷ Given the careful photoprotection warranted in patients with dermatomyositis, consideration should be given to vitamin D status and possible supplementation.

Anti-Pruritics

Pruritus, often a prominent feature of the skin disease of dermatomyositis, can significantly affect patients' quality of life.^{15,16} In addition, it can occasionally help clinically distinguish dermatomyositis from lupus erythematosus. Pruritus, in particular scalp pruritus, can be the initial presenting symptom in dermatomyositis. Because it can interfere with sleep patterns and overall quality of life, pruritus should be treated aggressively. Topical preparations used for symptomatic relief include topical antihistamines, pramoxine, menthol, camphor, and lidocaine.¹⁷

The addition of oral antihistamines (hydroxyzine or doxepin), amitriptyline, or other agents that can improve pruritus, and thereby quality of life, is often necessary.

Topical Corticosteroids

Topical corticosteroids of various strengths are often used to improve the pruritus and reduce the erythema associated with the cutaneous lesions of dermatomyositis.¹⁸ Class I topical corticosteroids are often employed to treat the dorsal hands, extensor surfaces, and scalp, while lower potency agents are often utilized for the heliotrope eruption and facial erythema. These topical agents can be used under occlusion for refractory hyperkeratotic lesions, particularly those on the dorsal hands.¹⁷ Intralesional corticosteroid therapy is occasionally used for refractory lesions or for the associated scalp dermatitis, however, this is often impractical given the extent of cutaneous disease.¹⁸ In many patients, photoprotection and topical agents alone are insufficient in controlling the cutaneous disease of dermatomyositis.

Topical Calcineurin Inhibitors

Given the refractory nature of skin lesions in dermatomyositis, topical agents other than corticosteroids have been tried in an attempt to improve cutaneous disease. There have been several cases and one pilot study in the literature regarding the efficacy of topical tacrolimus on skin lesions in dermatomyositis.^{19–22} Of note, in these reports, all patients were on additional therapeutic agents at the time of initiation of topical tacrolimus. In the pilot study, six patients (five adults and one juvenile dermatomyositis participant) were followed for 6–8 weeks after initiation of topical tacrolimus. Two had >90% improvement, one had 40–90% improvement, and three had 20–40% improvement during the follow-up period.²³ A side-by-side comparison in a different group of five patients, however, showed a lack of benefit with topical tacrolimus.²⁴ In a small group of pooled patients with both lupus erythematosus and dermatomyositis with facial lesions, one of the two patients with dermatomyositis had good response to topical tacrolimus, while the other did not improve with this intervention.¹⁹ Given these reports, topical tacrolimus is a reasonable agent to consider for refractory cutaneous lesions of dermatomyositis. There are currently no published reports on pimecrolimus for cutaneous dermatomyositis, however, the authors have anecdotally noted some limited success in patients using this cream.

Antimalarials

Antimalarials have been used in the treatment of the cutaneous disease associated with dermatomyositis for over 50 years. Traditionally, mepacrine was used as a first line agent, however given its increased risk of diplopia; a shift was made to the use of other antimalarials.

Although chloroquine and related antimalarials have been reported to be effective as first-line therapy in the treatment of the cutaneous manifestations of dermatomyositis, they are seemingly not beneficial for the associated muscle disease.²⁵ The lack of effect of hydroxychloroquine on muscle disease suggests that the beneficial effects of this medication on the skin may be a result of photoprotection rather than systemic immunomodulation, or that the pathogenetic mechanisms involved in dermatomyositis differ in skin and muscle disease, a concept supported by a study published in the *Lancet* in 2003.^{6,18}

Hydroxychloroquine in doses of 200–400 mg/day is effective in up to 75% of patients in partially or completely controlling the cutaneous disease and allowing a decrease in corticosteroid dosage. In an open study of seven dermatomyositis patients with cutaneous lesions that had not responded to topical therapy, the addition of hydroxychloroquine resulted in improvement in all seven patients, with total resolution of skin lesions in three patients and tapering of corticosteroid dosage in two patients.²⁶ Additional small studies similarly demonstrated favorable results with hydroxychloroquine used for cutaneous disease in adult

patients, including those with amyopathic dermatomyositis, and in pediatric patients with dermatomyositis.^{27–30} In one pediatric study, however, three of nine patients developed ocular side effects that mandated discontinuation of hydroxychloroquine.³⁰ In addition, another report indicated worsening of rash in two children with dermatomyositis after the initiation of hydroxychloroquine.³¹

It has been reported that patients with dermatomyositis have an increased risk of developing morbilliform drug reactions from hydroxychloroquine, and counseling patients regarding this possibility prior to initiation of therapy is helpful.³² Development of a morbilliform eruption often mandates discontinuation of hydroxychloroquine given that dermatomyositis skin disease has been noted to koebnerize in this situation. Counseling patients regarding smoking cessation is also essential as the efficacy of hydroxychloroquine appears to be reduced in patients who smoke.

Patients who lack adequate response to hydroxychloroquine can be switched to chloroquine therapy 250–500 mg/day, or can receive quinacrine 100 mg once or twice daily in addition to either hydroxychloroquine or chloroquine. Chloroquine is used more frequently than hydroxychloroquine in Europe given possible increased efficacy. It does, however, carry an increased risk of irreversible retinopathy and is therefore used less often than hydroxychloroquine in the United States. Quinacrine may be used as add-on therapy in conjunction with either hydroxychloroquine or chloroquine given that it lacks ocular toxicity (hydroxychloroquine and chloroquine should never be prescribed in combination given possible additive ocular toxicity). Quinacrine may not be readily available in all locations, however, and must be obtained at special compounding pharmacies. One published report has supported the synergistic effect of combination antimalarials in cutaneous dermatomyositis.³³ In this retrospective case series, 7 of 17 patients experienced at least near clearance in cutaneous disease with the use of antimalarial therapy alone (3 responded to antimalarial monotherapy while 4 required combination therapy of hydroxychloroquine-quinacrine or chloroquine-quinacrine). These findings suggested that a significant subset of patients might benefit from combination antimalarial therapy when antimalarial monotherapy has been ineffective.

Conventional precautions regarding antimalarial therapy should be taken, including a careful ophthalmologic examination prior to or within several months of initiation of therapy and annually thereafter in follow-up.³⁴ Quinacrine therapy requires blood count monitoring given the rare potential risk of associated aplastic anemia. Quinacrine can also cause gastrointestinal upset as well as a reversible yellow discoloration of the skin.

Corticosteroids

The mainstay of initial therapy for active muscle or systemic disease in dermatomyositis is the use of high-dose systemic

corticosteroids. Traditionally, prednisone is given in a dose of 0.5–1.5, mg/kg/day (maximum daily dose of 60 mg) as initial therapy.³⁵ Systemic corticosteroid treatment should continue at these doses for at least 1 month after the myositis has become both clinically and enzymatically inactive. At this point, the dose can be tapered slowly, generally over a period lasting 1.5 to two times as long as the period of active treatment.

It is crucial to emphasize that a slow taper of corticosteroids is necessary to prevent relapse of active disease. A dermatology-based case series supported the hypothesis that a significant number of patients (75–85%) can become muscle disease-free, off treatment, after a period of 2–4 years, utilizing a slow corticosteroid taper.²⁹ Long-term follow-up of cases of juvenile dermatomyositis also supported this conclusion.^{36,37} Despite these reports, there have been no controlled long-term studies assessing whether patients with dermatomyositis, unlike those with systemic lupus erythematosus, can achieve long-term remission off therapy.³⁸ In addition, there are no randomized controlled studies comparing various corticosteroid doses or taper rates in patients with dermatomyositis.

Intravenous pulse methylprednisolone has been used in multiple studies, both in adult and juvenile cases of dermatomyositis, most with favorable results.^{39–45} It may be most beneficial in rapid control of a fulminant disease process, usually myositis or pulmonary disease, associated with dermatomyositis.

There is known to be a discordant response to therapy between muscle and skin disease in dermatomyositis.²⁹ Even after the myositis and systemic disease are controlled, the cutaneous disease often remains recalcitrant to therapy and can be particularly challenging to manage. For these reasons, there are subsets of patients in which cutaneous disease becomes the primary component of disease management. This includes patients with postmyopathic dermatomyositis (patients with adequately treated muscle disease who continue to have active cutaneous disease),¹⁷ and those with clinically amyopathic dermatomyositis. In both of these subsets of patients, which lack active myositis, aggressive corticosteroid therapy is frequently not warranted.

Anecdotal experience supports the concept that systemic corticosteroids have varying degrees of efficacy for the cutaneous manifestations of dermatomyositis, with only a small subgroup of patients having excellent responses at doses that do not cause toxicity. In addition, many patients on toxic doses of systemic corticosteroids have little to no effect on their cutaneous disease or its associated symptoms. Therefore, treatment of amyopathic and postmyopathic dermatomyositis often differs significantly from that of classic dermatomyositis. In sum, given the host of potential side effects of long-term systemic corticosteroid therapy as well as the refractory nature of the skin lesions in dermatomyositis, systemic corticosteroids are not considered the mainstay in therapy for cutaneous disease.

Methotrexate

Approximately 25–43% of patients with dermatomyositis have muscle disease that will not respond to systemic corticosteroids or develop significant steroid-related side effects.^{46,47} In these patients, immunosuppressive agents may be necessary to induce or maintain disease remission.

Methotrexate is traditionally administered in an empiric dose of 25–50 mg/week for the muscle disease of dermatomyositis. Methotrexate is often used as add-on or alternative therapy when corticosteroids alone fail. It also is frequently used as a first-line agent in combination with prednisone. It can be used on a weekly basis, given either orally, intramuscularly, subcutaneously, or intravenously. The drug usually becomes effective in 4–8 weeks, and therefore is not recommended for rapid control of a fulminant disease process. In patients requiring adjunctive therapy, methotrexate induces response rates of 70–77%.^{46,48,49} Patients with juvenile dermatomyositis have also improved with methotrexate,^{50–54} with some also demonstrating steroid-sparing.⁵⁰

No randomized controlled study has been performed comparing methotrexate in combination with prednisone versus prednisone alone. There has been a double-blind, randomized controlled trial comparing methotrexate and azathioprine in a pooled group of dermatomyositis and polymyositis participants.⁵⁵ In this trial, efficacy was similar for both drugs, however methotrexate resulted in fewer side effects. In addition, another study demonstrated better response of myositis to methotrexate than to azathioprine in a group of patients with dermatomyositis, polymyositis, and inclusion body myositis.⁴⁸ Finally, a randomized cross-over study demonstrated a trend in favor of oral methotrexate combined with oral azathioprine over intravenous methotrexate in 30 patients with both dermatomyositis and polymyositis.⁵⁶

Retrospective reviews and open-label studies support the usefulness of methotrexate in doses between 10 and 40 mg/week specifically for the cutaneous manifestations of dermatomyositis. In a review of 22 patients treated with combined methotrexate and systemic corticosteroid therapy, 17 patients improved on methotrexate resulting in steroid-sparing.⁴⁹ Another review of 13 patients with little to no muscle involvement treated with 2.5–30 mg/week of methotrexate for refractory cutaneous dermatomyositis, demonstrated complete clearance in four patients, near complete clearance in four patients, and moderate clearance in all remaining patients. In addition, dose reduction and/or discontinuation of other therapies was facilitated.⁵⁷ There has also been demonstrated benefit for skin disease in juvenile dermatomyositis with the prevention of calcinosis formation. In one study, 12 pediatric patients with severe disease were treated with intravenous methylprednisolone in conjunction with methotrexate. Two of the six patients who initiated therapy greater than 5 months after diagnosis developed calcinosis, whereas none of the six patients treated within 6 weeks of diagnosis developed calcinosis.⁴³

Despite numerous reports indicating the potential efficacy of methotrexate, adverse effects including both liver and pulmonary toxicity must be considered. In one retrospective study, ten patients with dermatomyositis (7 with classic dermatomyositis and 3 with amyopathic disease) were treated with methotrexate. Improvement of cutaneous disease occurred in seven (100%) of the patients with classic dermatomyositis and in two (66%) of those with amyopathic dermatomyositis, while myositis improved in four (57%) of the seven patients with muscle disease. Systemic steroid-sparing was also enabled. Despite improvement in their disease, methotrexate-related side effects occurred in seven of the ten patients (in six patients with classic dermatomyositis and in one patient with amyopathic dermatomyositis). Of the four patients that underwent liver biopsy, two demonstrated mild hepatic fibrosis resulting in discontinuation of methotrexate. Notably, both patients with hepatic fibrosis on biopsy had preexisting steroid-induced diabetes mellitus.⁵⁸

In sum, both the myositis and cutaneous disease of dermatomyositis have demonstrated response to methotrexate. In fact, methotrexate is often considered first-line as a steroid-sparing agent in dermatomyositis although careful patient selection and monitoring for side effects is essential.

Azathioprine

Azathioprine is administered orally in doses of 1–2 mg/kg/day depending on results of thiopurine methyl transferase (TPMT) enzyme testing in order to achieve efficacy yet avoid bone marrow suppression. There has been a randomized-controlled trial comparing prednisone plus azathioprine to prednisone plus placebo for the muscle disease of polymyositis. Although there were no statistically significant differences between the two groups at three months, in the open follow-up period at 3 years, patients treated with azathioprine had greater muscle strength and required a significantly lower steroid dosage.⁵⁹ Given the now better-recognized differences in pathogenetic mechanisms for dermatomyositis and polymyositis, it is unclear how much scientific relevance this study has on dermatomyositis patients with muscle disease.

As noted in the section on methotrexate, there has also been a randomized controlled trial comparing azathioprine and methotrexate in patients with both dermatomyositis and polymyositis. Although efficacy of both agents was similar, azathioprine caused more side effects in this study.⁵⁵ Also, in a pooled group of patients with idiopathic inflammatory myopathies, methotrexate resulted in better response in muscle disease than azathioprine.⁴⁸ Given this data, azathioprine is often considered second line, after methotrexate, for the muscle disease of dermatomyositis.

There is less data for the use of azathioprine in juvenile dermatomyositis, however, steroid-sparing has been demonstrated in some pediatric cases.⁴⁷ Experience with

azathioprine and cutaneous disease in dermatomyositis is anecdotal, but does suggest that some patients respond to azathioprine resulting in steroid-sparing effects.

Mycophenolate Mofetil

Mycophenolate mofetil has been shown to be an effective therapeutic option for control of muscle disease in dermatomyositis.^{60–63} One series demonstrated both efficacy and steroid-sparing, however, also noted that opportunistic infections developed in three of ten patients.⁶¹ Retrospective reviews and open-label studies also support the efficacy of mycophenolate mofetil for the cutaneous disease of DM.^{62,64,65} One series of four cases demonstrated improvement in patients with refractory skin disease that had failed to respond to systemic corticosteroids, hydroxychloroquine, and/or methotrexate.⁶⁴ Another retrospective review of the effectiveness of mycophenolate mofetil in patients with refractory cutaneous dermatomyositis found improvement in 10 of 12 patients at doses of 500 mg to 1 g twice a day. In this review, most patients tolerated mycophenolate mofetil without side effects; however, one patient developed a central nervous system B-cell lymphoma and another developed elevated liver function tests and urinary symptoms. These side effects resolved upon discontinuation of mycophenolate mofetil in both cases.⁶⁵

Cyclosporine

Several studies have supported the use of cyclosporine in both adults and children as a steroid-sparing agent to control either muscle or lung disease in dermatomyositis.^{66–72} In one prospective study, ten patients with dermatomyositis who received cyclosporine achieved remission more quickly than controls.⁶⁷ Cyclosporine plus prednisone has been compared to methotrexate plus prednisone in a randomized controlled fashion for the muscle disease of both dermatomyositis and polymyositis.⁶⁹ Both groups improved on therapy, and patients treated with methotrexate demonstrated a mildly improved response compared to patients treated with cyclosporine, however, this difference was not statistically significant. Cyclosporine should be considered for rapidly progressive interstitial lung disease (ILD) associated with dermatomyositis. Once patients have developed respiratory failure, however, cyclosporine is ineffective.^{73,74}

In terms of its use for the cutaneous disease of dermatomyositis, there is a report of refractory skin necrosis responding to cyclosporine.⁷⁵ Other than this report, however, experience with cyclosporine for the skin manifestations of dermatomyositis is anecdotal.

Tacrolimus

Oral tacrolimus (FK-506) has been reported to be effective in the treatment of refractory ILD associated with

dermatomyositis (both classic and amyopathic) and polymyositis.^{76–79} In these reports, patients had progressive disease despite conventional therapies, such as high-dose corticosteroids, cyclosporine, and/or pulse cyclophosphamide, yet improved clinically with oral tacrolimus. In the largest series of adult patients with anti-aminoacyl-transfer RNA synthetase (anti-aaRS)-associated ILD and idiopathic inflammatory myopathy, all 13 had improvement of their pulmonary disease, while 10 had improvement in muscle disease as well.⁷⁸ Despite these results, there was no data provided from this series on the effect of oral tacrolimus on skin disease. Additional reports have specifically highlighted improvement in muscle disease recalcitrant to other therapies on oral tacrolimus.^{77,80}

Although reports in adults are lacking, several cases have demonstrated improvement of skin disease in children with juvenile dermatomyositis treated with oral tacrolimus.^{81–83} Myositis also responded to oral tacrolimus in some of these reports, while demonstrating lack of response in others.

Chlorambucil

When used alone or in conjunction with other agents, chlorambucil has demonstrated benefit on the muscle disease of dermatomyositis in case reports.^{84–86} However, these reports noted either little or no improvement in cutaneous disease with this medication.

Cyclophosphamide

Multiple reports have demonstrated improvement in the ILD associated with dermatomyositis on cyclophosphamide, particularly fulminant or rapidly progressive lung disease.^{87–90} In terms of its effects on the skin manifestations of dermatomyositis, there has been one case of refractory cutaneous vasculitis resulting in ulcers that responded completely to repeated intravenous cyclophosphamide pulse therapy without adjunctive high-dose corticosteroids. Repeat biopsy after treatment with cyclophosphamide confirmed complete remission of vasculitis, and no adverse effects were noted in the patient.⁹¹

Dapsone

Oral dapsone has shown to be beneficial in refractory cutaneous dermatomyositis in case reports and a small series.^{92,93} In the series of two patients with cutaneous dermatomyositis unresponsive to combination therapy with prednisone, hydroxychloroquine, quinacrine, and immunosuppressive medications, both had rapid improvement in cutaneous disease with the addition of dapsone to their therapeutic regimens. Both patients also experienced exacerbation of their skin disease after discontinuation of dapsone as well as subsequent improvement after reinitiation of this medication.⁹³ Other reports, one involving a case of drug-induced amyopathic dermatomyositis⁹⁴ and

another a case of postmyopathic dermatomyositis with residual cutaneous disease,⁹⁵ did not respond to dapsone.

Thalidomide

Cutaneous dermatomyositis recalcitrant to other therapies has anecdotally responded to thalidomide.⁹⁶ In addition, the case of drug-induced amyopathic dermatomyositis mentioned above, which was unresponsive to dapsone as well as oral corticosteroids, antimalarials, and methotrexate, was treated with initial marked success with thalidomide; however, no long-term follow-up was provided.⁹⁴

Intravenous Immunoglobulin

There are numerous cases in which the muscle disease of the idiopathic inflammatory myopathies has responded to intravenous immunoglobulin (IVIG).^{97–100} In a retrospective study, patients treated with prednisone, cyclosporine, plus IVIG had an increased remission rate when compared to patients treated with prednisone and cyclosporine alone.¹⁰¹ IVIG was also demonstrated to be a safe and effective steroid-sparing agent when added on to mycophenolate mofetil for severe and refractory myositis in another retrospective study.¹⁰² In addition, a small series highlighted potential efficacy in ILD associated with dermatomyositis, with improvement demonstrated in two of five patients.¹⁰³ Several reports and series have demonstrated benefit in cases of juvenile dermatomyositis as well,^{97,104–107} including in a subset of children who had never received systemic corticosteroids.¹⁰⁸ Recently, an ad hoc committee of the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM) considered the rational use of IVIG for various neuromuscular disorders. Class evidence I, the strongest category, was found to support the use of IVIG for dermatomyositis.¹⁰⁹

It has been reported that patients with amyopathic dermatomyositis may respond to one-tenth the usual dose of IVIG.¹¹⁰ There has also been a case described of cutaneous disease refractory to prednisone, methotrexate, and hydroxychloroquine that responded to IVIG. In this case, new cutaneous ulcerations stopped developing 1–2 weeks after initiation of IVIG therapy.¹¹¹

Unlike for many agents in dermatomyositis, the efficacy of high-dose IVIG has been investigated in a randomized, placebo-controlled clinical trial.¹¹² In this trial, fifteen patients were dosed with 2 gm/kg of IVIG versus placebo monthly for 3 consecutive months with the option of crossover for an additional 3 months. Of the 11 patients receiving placebo, none had major improvement, three had mild improvement, three had no change, and five had disease worsening, whereas nine of 12 patients who received IVIG after crossovers had major improvement with near return to normal function. Those patients who received IVIG also had improvement in their cutaneous disease. Despite these promising results, the improvement

in strength noted with IVIG often lasts for only 1–2 months, indicating that IVIG therapy may need to be continued for longer-term effects.¹¹³ Although ongoing therapy is often beneficial, the high cost of this therapeutic intervention can present a challenge.

Not all studies involving IVIG and its effect on dermatomyositis have demonstrated favorable outcomes. In fact, one study of high-dose IVIG on molecular expression in muscle tissue of patients with inflammatory myopathies demonstrated limited benefit.¹¹⁴ In this pooled study of 13 patients with idiopathic inflammatory myopathy, five had either adult or juvenile dermatomyositis. Three of these five patients demonstrated dramatic improvement in cutaneous disease with IVIG. In terms of muscle disease, however, serum creatine kinase (CK) levels decreased significantly in only five of the 13 patients. In addition, only three of the thirteen patients improved their Functional Index (FI) in Myositis score by greater than 20%. Therefore, clinical improvement based on FI score was limited although statistically significant. Although some patients in this study demonstrated either clinical improvement or decreased serum CK levels, there was no significant improvement of inflammation in muscle tissue based on numbers of T-cells or macrophages, expression of MHC class I and II antigen on muscle fibers, or endothelial cell activation.¹¹⁴ In spite of these results, which call into question the role of high-dose IVIG as an immune-modulating therapy for idiopathic inflammatory myopathy, IVIG remains the only therapeutic agent that has demonstrated beneficial results in the treatment of cutaneous dermatomyositis in a randomized-controlled trial.

PLASMAPHERESIS AND LEUKAPHERESIS

A placebo-controlled study has demonstrated that plasmapheresis and leukapheresis are no more effective than sham apheresis in corticosteroid-resistant dermatomyositis.¹¹⁵ Despite significant reductions in the levels of serum muscle enzymes with plasma exchange, no significant differences were found in either the final muscle strength or the functional capacity of the patient groups in the trial. This study also demonstrated no benefit in muscle strength or functional capacity from leukapheresis despite significant decreases in lymphocyte counts.

Another study found that plasmapheresis did not offer any advantage to patients being treated with other immunosuppressive medications.¹⁰¹ Although the main finding of this study was that patients receiving prednisone, cyclosporine, plus intravenous immunoglobulin had a significantly higher probability of maintaining complete remission at the end of a 4-year follow-up period than those treated with prednisone and cyclosporine alone, the authors also noted that there was no additional benefit observed from the addition of plasma exchange in these patients. In sum, plasmapheresis and leukapheresis are not considered effective therapeutic options for dermatomyositis.

ANTI-TUMOR NECROSIS FACTOR-ALPHA MEDICATIONS

Numerous case reports have indicated benefits from anti-tumor necrosis factor-alpha (TNF-alpha) medications on both refractory adult and juvenile dermatomyositis.^{116–126} Although most of these reports focus on the myositis component of disease, several also report improvement in cutaneous disease on anti-TNF-alpha therapy.^{117,123,124,126}

Despite numerous beneficial case reports, a pilot study of infliximab for patients with refractory idiopathic inflammatory myopathies demonstrated both radiologic and clinical worsening of muscle disease, as well as activation of the type I interferon system in several cases.¹²⁷ In addition, a series of patients with dermatomyositis treated with etanercept all had worsening of muscle disease.¹²⁸ Finally, an open-label trial of weekly methotrexate plus infliximab in new-onset dermatomyositis and polymyositis was terminated prematurely because of a high drop-out rate secondary to disease progression and infusion reactions in some participants, as well as an overall low inclusion rate.¹²⁹ The few patients who remained in the study until a primary endpoint did have improvement in muscle disease activity and serum CK levels.

In addition to the concern of exacerbating a patient's myositis with anti-TNF-alpha therapy, there have also been cases reporting the development of dermatomyositis-like cutaneous eruptions in patients on anti-TNF medications for other diseases such as rheumatoid arthritis.¹³⁰ One report also details the onset of dermatomyositis, with muscular, pulmonary, and mild cutaneous changes, occurring in a patient being treated with etanercept for seronegative rheumatoid arthritis.¹³¹

Efalizumab

Efalizumab has been reported to be of benefit in one case of refractory dermatomyositis.¹³² After failing to improve on methotrexate and prednisolone, the patient in this report had improved skin disease after being started on efalizumab 1 mg/kg/week combined with prednisolone 40 mg/day. In particular, the patient had decreased facial edema and upper chest erythema, whereas the erythematous-violaceous discoloration on the upper lids demonstrated only modest improvement. After 1 month on this therapy, the patient was also started on azathioprine 50 mg/day, along with a dose increase of efalizumab to 1.8 mg/kg/week and a dose reduction of prednisolone to 10 mg/day. At 1 year of follow-up, this patient was still doing well clinically. Efalizumab was removed from the market in the United States in the spring of 2009, for a potential increased risk of the demyelinating disease progressive multifocal leukoencephalopathy (PML), and is therefore no longer available as a therapeutic option for dermatomyositis.

Adjuvant Leflunomide

Case reports have demonstrated improvement in muscle disease in patients on leflunomide for polymyositis or dermatomyositis.^{133,134} More recently, a small case series demonstrated improvement in the cutaneous manifestations of dermatomyositis with adjuvant leflunomide in three patients refractory to multiple other systemic therapies.⁹⁵

Rituximab

A national randomized, placebo-controlled trial of rituximab for inflammatory myopathy (RIM) is currently underway. Until these results become available, clinicians must rely on the somewhat contradictory information available in case reports and three open studies utilizing rituximab for dermatomyositis.

Many case reports have shown improvement in the muscle, pulmonary, cardiac, and/or skin manifestations of dermatomyositis with rituximab.¹³⁵⁻¹⁴² One case demonstrated remission of both myositis and cutaneous disease for over 4 years.¹⁴² A series of three patients with postmyopathic disease, all with adequate control of their muscle disease on other systemic agents, utilized rituximab for deteriorating skin disease specifically.¹⁴³ Skin disease improved in all three patients in this series following rituximab. In particular, the heliotrope eruption and violaceous poikiloderma were the cutaneous manifestations of dermatomyositis that responded most effectively to rituximab. Benefit from rituximab was also reported in an open-pilot study of six patients with dermatomyositis.¹⁴⁴ In this study, patients had increased muscle strength, decreased muscle enzymes, improved forced vital capacity in three patients with ILD, and improved skin disease in all patients including hair regrowth in two patients with alopecia.¹⁴⁴

Despite the promising results of these cases and open-pilot study, the largest open trial to date of rituximab for dermatomyositis demonstrated modest improvement of muscle disease but limited effects on cutaneous disease.¹⁴⁵ Of the eight patients enrolled in this trial, three achieved partial remission, defined by a reduction in muscle deficit by at least 50% at week 24. All patients demonstrated sustained depletion of peripheral B-cells on rituximab, however, serum muscle enzyme levels and skin scores using the Dermatomyositis Skin Severity Index (DSSI) at week 24 were not significantly changed from those at baseline.

Another group of eight patients with presumed idiopathic inflammatory myopathy were also treated with rituximab, five in an open label trial, and three based on perceived medical need.¹⁴⁶ Within this group, an interesting subset of two patients with Jo-1 antibody-positive dermatomyositis demonstrated improved clinical response in myositis, as well as greater than 30% percent

improvement in serum CK levels. One of the two patients had normalized serum CK levels for 10 months, while the other had both normalized CK levels and stable pulmonary function tests for 3 years. In both patients, Jo-1 antibody levels fell modestly yet remained detectable.

In a retrospective review of four cases of juvenile dermatomyositis treated with rituximab, three patients, including one with positive myositis-specific antibody Mi-2 and two without positive myositis antibodies, improved following rituximab, while one patient failed to improve and went on to develop cutaneous vasculitis and ILD requiring cyclophosphamide.¹⁴⁷ In all three pediatric patients who responded to rituximab, improvements in both muscle and cutaneous disease were specifically noted and steroid-sparing was enabled.

Sirolimus

In the first case report utilizing sirolimus (rapamycin) in a patient with dermatomyositis, improvement was noted in both cutaneous and muscle disease within 4 weeks of initiating therapy and steroid-sparing ensued.¹⁴⁸ Although hypertriglyceridemia resulted in discontinuation of sirolimus after 3 months of therapy, the patient did not have worsening of skin or muscle disease for at least 4 months after discontinuing this therapy. Another case involved a patient with a history of refractory dermatomyositis who also underwent kidney transplantation for autosomal-dominant polycystic kidney disease. This report demonstrated benefit in using a combination of rituximab and sirolimus to not only treat the patient's posttransplant lymphoproliferative disorder, but also to maintain remission of the patient's dermatomyositis.¹⁴⁰

ANTIESTROGEN MEDICATIONS

The antiestrogen medications tamoxifen and anastrazole have been reported to improve the cutaneous manifestations of dermatomyositis in two patients. In addition, one of these patients had exacerbation of skin disease after tamoxifen was discontinued. One mechanism proposed for this improvement in skin disease on antiestrogen therapy is that tamoxifen has been found to have anti-TNF-alpha properties, and other therapies that down-regulate TNF-alpha have also previously demonstrated benefit in dermatomyositis in some cases.¹⁴⁹

TOTAL BODY IRRADIATION

Two patients with recalcitrant dermatomyositis were treated with 150 rad of total body irradiation over a 5-week period.¹⁵⁰ Both had rapid improvement in myositis with minimal side effects and remained in remission at 18 and 42 months after treatment. In addition, improvement in skin disease was also noted in both patients.

STEM CELL TRANSPLANTATION

There are increasing reports in the literature of the use of hematopoietic stem cell transplantation (HSCT) in the treatment of severe and refractory autoimmune diseases, including dermatomyositis.^{151–157} Although no data specific to patients with dermatomyositis exists, there is compiled data for HSCT for autoimmune diseases. Data from this pooled population indicated a long-lasting improvement off of immunosuppression in approximately half of patients who underwent HSCT for a severe and progressive autoimmune disease.¹⁵¹ All cases were refractory, having failed multiple systemic medications prior to HSCT. Of note, mortality related to HSCT has decreased in the past several years given improved initial patient selection and the use of better-tolerated conditioning regimens. Allogenic transplants are associated with increased morbidity and mortality, making autologous HSCT the preferred choice over allogenic HSCT when possible.¹⁵¹

With respect to dermatomyositis specifically, two adult patients with amyopathic dermatomyositis and associated refractory and progressive interstitial lung disease benefited from HSCT.^{154,156} A case of recalcitrant juvenile dermatomyositis in a preschool-aged child treated with HSCT has also been reported with improvement of both skin and muscle disease.¹⁵⁵ Two additional cases of refractory juvenile dermatomyositis in wheelchair-bound patients with contractures demonstrated dramatic improvement, including resolution of contractures, and sustained remission after autologous stem cell transplantation.¹⁵⁷ In one of these cases, there was no improvement in the child's skin disease after HSCT, while the other case does not specifically comment on the patient's cutaneous manifestations.

THERAPY FOR CALCINOSIS

Calcinosis associated with dermatomyositis can be particularly challenging to manage, particularly in cases of juvenile dermatomyositis in which calcinosis is more commonly associated than in adult dermatomyositis. Various therapies have been tried for calcinosis in the setting of dermatomyositis, including low-dose warfarin, colchicine, probenecid, diltiazem, aluminum hydroxide, alendronate, intravenous methylprednisolone, surgical excision, and electric shock wave lithotripsy (ESWL).^{158–169} Infliximab was beneficial in some patients with juvenile dermatomyositis and calcinosis in one study as well.¹²² Despite IVIG showing benefit in cases of calcinosis associated with connective tissue disease,¹⁷⁰ as well as specifically with dermatomyositis,^{170,171} another report describes two patients with dermatomyositis and progressive, extensive calcification despite several years of IVIG therapy.¹⁷² A child with debilitating contractures as well as calcifications demonstrated resolution of both following HSCT.¹⁵⁷

As mentioned above, cutaneous calcinosis can be particularly problematic in cases of juvenile dermatomyositis

and affects 29% to 70% of children with this disease.^{36,173,174} In children, aggressive and early intervention with systemic therapy seems to decrease the risk of development of calcinosis.^{36,43,167,175–178} Early aggressive therapy is often warranted in juvenile dermatomyositis given that another retrospective study demonstrated improved outcomes and sustained remission of disease in children treated with this approach.¹⁰⁷

EXERCISE AND REHABILITATION

The role of exercise and rehabilitation in the therapeutic regimen for patients with dermatomyositis should not be underestimated. Even in patients responding to pharmacologic interventions for myositis, a majority develop sustained disability.¹⁷⁹ Studies demonstrate that patients with inflammatory muscle disease who participate in exercise and rehabilitation programs have improved muscle strength and endurance, note reduced disease activity, and tolerate intensive resistance training.^{179–186} In addition, improvement in strength from using exercise regimens has been demonstrated even in the course of active disease, rather than inducing flares in muscle involvement.¹⁸⁴ In a study of children with juvenile dermatomyositis, muscle inflammation did not worsen after a single bout of exercise, suggesting that moderate exercise training is safe for patients with juvenile dermatomyositis as well.¹⁸⁷

HEALTH MAINTENANCE

In both adults and children, attention to general health maintenance principles and osteoporosis prevention is a key element of patient management. This can be accomplished by joint longitudinal care with an internist or pediatrician. In addition, adult patients with dermatomyositis should undergo rigorous malignancy screening annually for at least 3 to 5 years.

Children with juvenile dermatomyositis should be monitored by a pediatrician comfortable with monitoring their developmental milestones while on immunosuppressive therapy. Of note, lipodystrophy and metabolic abnormalities, including hypertriglyceridemia and insulin resistance, are increasingly being recognized as potential complications of juvenile dermatomyositis, and these metabolic derangements should be routinely screened for in pediatric patients with this disease.^{188,189}

CONCLUSIONS

Care providers face numerous challenges in selecting a therapeutic strategy for patients with dermatomyositis. Disease incidence is low and well-designed controlled clinical trials are relatively lacking. In addition, therapies that may prove effective in controlling a patient's myositis and/or systemic disease may make little to no impact

What We Know

- Dermatomyositis, particularly the cutaneous disease, is often refractory to therapy and can require multiple simultaneous or sequential therapeutic interventions.
- All patients presenting with dermatomyositis skin disease should undergo appropriate investigations for potential concomitant muscle disease, systemic involvement, and/or malignancy.
- Myositis and/or systemic involvement in dermatomyositis are traditionally treated with high-dose systemic corticosteroids plus/minus corticosteroid-sparing agents such as methotrexate, mycophenolate mofetil, azathioprine, or intravenous immunoglobulin, among others.
- Cutaneous disease mandates strict photoprotection and often requires topical corticosteroids. First-line systemic therapy is traditionally hydroxychloroquine. Add-on therapeutic options include quinacrine, methotrexate, mycophenolate mofetil, intravenous immunoglobulin, or thalidomide, among others.
- Most data regarding therapy for cutaneous dermatomyositis is in the form of small case series or retrospective reviews, however, well-designed, multicenter randomized controlled trials are necessary to better assess the effectiveness of therapeutic options for skin disease in dermatomyositis.

on their cutaneous disease, which is known to often be refractory and challenging to manage. Despite these limitations, care providers, particularly dermatologists, have a significant role to play in treating this patient population and improving their overall quality of life. A multidisciplinary approach should be utilized in caring for patients with dermatomyositis, and therapeutic selection should be made only after careful consideration of a patient's comorbidities, disease severity, presence of systemic involvement, and search for a potentially associated malignancy.

Treatment of Systemic Sclerosis

Rupa Pugashetti, M.D., and David Fiorentino, M.D., Ph.D.

INTRODUCTION

Systemic sclerosis (SSc) is a heterogeneous disease, which can affect multiple internal organs and lead to extensive cutaneous changes secondary to excess collagen and extracellular matrix deposition. Disease pathogenesis is multifactorial, including processes of vasculopathy, autoimmunity, and tissue fibrosis.¹ More extensive skin involvement is associated with poorer prognosis and, eventually, fibrosis of the skin, internal organs, and muscles can occur.² The natural course of scleroderma is highly variable as some patients improve spontaneously while others experience a progressive disease course. Skin involvement in SSc represents a therapeutic challenge as differing therapies attempt to target the inflammation, vascular changes and/or fibrosis implicated in the pathogenesis. Treatment options are currently limited and there is a need to develop new and effective therapies applicable for patients with SSc experiencing various degrees of cutaneous involvement.

Interpretation of data from clinical trials evaluating therapies for SSc is difficult because of the small numbers of patients and variable disease course among patients. Scleroderma is a rare disease and there is difficulty in obtaining adequate numbers of patients in order to achieve statistical power to demonstrate statistically significant results. Furthermore, while some patients experience a gradual progression in their skin disease, many others spontaneously improve. Thus, a significant placebo response is often seen and limits the statistical power for studies with drugs that might have only modest efficacy. Additionally, the appropriate disease marker to examine is unclear, as it is generally believed that clinical changes of thickening in the skin are downstream and later sequelae of cutaneous disease activity, and thus might not be readily reversible with therapy. In addition, even the clinical skin changes are multiple and involve skin thickening, tightening, fibrosis tethering, and atrophy. It is difficult to find a clinical measure that is able to distinguish between these findings.

METHODS

In this chapter, we present the evidence for a variety of therapies in the treatment of the cutaneous manifestations

of SSc. Only cutaneous sclerosis and digital ulcerations are considered here, while other cutaneous manifestations associated with scleroderma such as calcinosis, telangiectasias and pigmentary changes will not be discussed. Other manifestations of SSc including Raynaud phenomenon, pulmonary arterial hypertension, interstitial lung disease, and scleroderma renal crisis are not considered here, as they are generally not addressed by the dermatologist. This review addresses therapies for systemic sclerosis and not localized scleroderma (morphea). Medline database was searched for the terms 'systemic sclerosis'. Only the highest level of evidence data was considered and reviewed for a particular treatment modality.

ENDPOINTS

Measurements of skin involvement in SSc vary and differing techniques specifically measure different aspects of skin involvement. Currently, the modified Rodnan skin score is considered the most important, reliable and validated measure for measurement of dermal thickness. The modified Rodnan skin score has shown responsiveness to change in multicenter trials and demonstrates good interobserver reliability.^{3,4} This technique is an assessment of skin thickness in 17 or 22 body areas depending on the specific modifications used. A scale of 0-3 is utilized in which 0 = normal, 1 = mild skin thickness, 2 = moderate skin thickness and 3 = severe skin thickness. There is some concern that this technique is not sensitive enough to detect small but clinically meaningful changes, and that it accounts only for skin thickness as opposed to induration or tethering of skin.⁵

Other techniques are used less frequently than the modified Rodnan skin score but may represent useful measures of cutaneous involvement in SSc. The UCLA skin score is another skin assessment where 10 specific sites are measured, with a maximum score of 3 for tethering evaluated at each site.⁶ Durometry is a validated technique with good inter- and intraobserver reproducibility which measures skin induration and correlates well with ultrasound measured thickness and modified Rodnan skin score.^{7,8} Ultrasound using a 20-30 MHz probe is another valid and reproducible technique utilized to measure dermal

thickness.⁹ The plicometer measures thickness of cutaneous plica, folded areas of skin. Additional measurement devices include an elastometer to measure lineal extension and twistometer to measure skin rotation. Such techniques warrant further validation in multicenter trials.

The aforementioned techniques are used as measures of cutaneous involvement in SSc and utilized to measure improvement with investigational agents in clinical trials. Although controlled trials generally report statistically significant changes in such disease measures, the minimally important difference (MID), has also been used to represent ‘the smallest difference in a score that is considered to be worthwhile or important.¹⁰ This method helps associate changes in disease measures with clinical relevance, as measured subjectively by patients and clinicians. Khanna et al. examined the MID in a clinical trial examining the efficacy of low-dose and high-dose D-penicillamine, and the MID estimate for the Rodnan skin score improvement ranged from 3.2 to 5.3.¹¹

THERAPIES FOR SKIN SCLEROSIS

Results evaluating therapies targeting cutaneous sclerosis of SSc are reviewed. These are categorized into immune-modulating treatments, antifibrotic agents, vasodilators and other investigational therapies.

IMMUNE-MODULATING THERAPIES (TABLE 35.1)

5-Fluorouracil:

In a 6-month randomized, double-blind, placebo-controlled study, intravenous 5-fluorouracil was evaluated in the treatment of scleroderma.¹² Skin assessment included a modified Rodnan skin score, and flexion and extension indices between the third finger and palmar crease. In the group receiving 5-fluorouracil, statistically significant improvement was observed in total skin score and extension index. Notably, toxicities were common in the treatment group.

TABLE 35-1—Therapies for Diffuse Cutaneous Systemic Sclerosist

Therapy	Outcome Measurement	Efficacy	Level of Evidence	Comment	Reference
Rituximab	MRSS	0	4	Improvement in dermal myofibroblast numbers	13
Rituximab	MRSS	0	4	Mean change in skin score was not significant	14
Mycophenolate mophetil with methyl prednisolone	MRSS	+	4	Skin score improved significantly after 1 year	21
Anti-thymocyte globulin and mycophenolate mophetil	MRSS	+	4	Significant decrease in skin score throughout 1 year study	22
PUVA phototherapy	Dermal thickness measured	+	2b	Dermal thickness significantly decreased	34
PUVA phototherapy vs. UVA1	Changes in collagen fibril diameter	0	4	Changes in collagen fibril diameter occurred deeper in the dermis after PUVA therapy as compared to UVA1 therapy	35
Cyclophosphamide	MRSS	+	1b	Significant difference between cyclophosphamide and placebo treatment arms	37
High-dose cyclophosphamide without stem cell rescue	MRSS	++	4	Significant improvement in skin score in treatment group	38
Cyclophosphamide vs. azathioprine	MRSS	+	2b	Significant improvement in cyclophosphamide group	36
Azathioprine as maintenance treatment following cyclophosphamide	MRSS	0	4	Modified Rodnan Skin Score did not deteriorate significantly	39
Cyclosporine	MRSS	+	4	Improvement in cutaneous abnormalities in severe scleroderma	40

Therapy	Outcome Measurement	Efficacy	Level of Evidence	Comment	Reference
Cyclosporine	MRSS	+	4	Skin thickness significantly decreased	41
Low-dose cyclosporine	Plicometry	+	4	Significant reduction in plicometry score	42
Halofuginone	MRSS	+	4	5/11 patients had 25% reduction in skin score	45
Thalidomide	MRSS	0	4	No benefit in measured skin score	46
Etanercept	MRSS	+	4	4/10 patients had improvement in skin score	48
Autologous stem cell transplantation	MRSS	++	4	63% of patients had significant improvement in Rodnan skin score	49
Autologous stem cell transplantation	MRSS	+	4	15/19 patients had improvement in skin score, and 35% patients relapsed within 10 months	50
Allogeneic stem cell transplantation	MRSS	++	4	Rodnan skin score decreased from 30 to 13	52
Allogeneic stem cell transplantation	Skin biopsy	+	4	One patient had resolution of dermal fibrosis on biopsy	53
Allogeneic stem cell transplantation	MRSS	++	4	Rodnan skin score decreased from 25 to 9	54
Colchicine	Skin elasticity	0	4	Improvement noted in skin elasticity	58
Imatinib	MRSS	+	4	Rodnan skin score decreased from 44 to 33	67
Imatinib	MRSS Skin tightening	+	4	Rodnan skin score reduction in both patients	68
Intravenous 5-fluorouracil	MRSS Extension index between 3 rd finger and palmar crease	+	1b	Significant improvement in total skin score and extension index	12
Chlorambucil	MRSS	0	1b	No significant difference from placebo	15
Intramuscular methotrexate	MRSS	+	1b	At 24 weeks, significantly more patients in methotrexate group had favorable response compared to placebo	17
Oral methotrexate	MRSS UCLA skin score	+	2b	Significant difference in Rodnan skin score change, but not in UCLA skin score	18
Oral methotrexate	Clinically judged improvement	0	2b	No significant improvement in skin parameters	16
Mycophenolate mofetil	MRSS	0	2b	No significant difference	20
D-penicillamine in low and high dose	MRSS	Not determined	1b	No significant difference between low and high dose	23
Extracorporeal photochemotherapy compared to D-penicillamine	Skin severity score Percent surface area involvement	+	1b	Significant improvement in skin severity score	27
Extracorporeal photochemotherapy	MRSS	0	1b	No significant difference between active and sham photopheresis	28

(Continued)

TABLE 35-1—Therapies for Diffuse Cutaneous Systemic Sclerosist (Continued)

Therapy	Outcome Measurement	Efficacy	Level of Evidence	Comment	Reference
Plasma exchange with D-penicillamine vs. D-penicillamine	MRSS	+	2b	Significant improvement of skin score in combination treatment group	30
Low-dose UVA1 phototherapy	MRSS	0	1b	No difference between treated and untreated hands	32
Low-dose UVA therapy	Clinical palpation and inspection	+	2b	No significant differences between UVA dosages of 5, 10, or 20 J/cm ²	33
Oral type 1 collagen	MRSS	0	1b	No significant difference in skin score change. Significant reduction in skin score in late-phase SSc patients only	25
Recombinant human tissue plasminogen activator	MRSS	+	1b	Significant difference between placebo and treatment	55
Aminobenzoate potassium	Skin mobility and thickening scores	0	1b	No significant difference	56
Urokinase	Ultrasound transverse and longitudinal scans	0	2b	Improvement in skin thickness; did not report statistical significance	57
Recombinant human relaxin	MRSS	+	1b	Significant difference between 25 µg/kg/day and placebo	60
Recombinant human relaxin	MRSS	0	1b	No significant difference between treatment groups and placebo	61
Interferon-α	MRSS Collagen synthesis from skin biopsy	0	1b	No significant difference	63
Interferon-γ	MRSS	0	2b	No significant improvement in skin score in treatment or control	62
Anti-TGF β (CAT-192)	Rodnan skin score	0	1b	No significant difference	64
Low and high dose iloprost	MRSS	0	2b	No significant change in skin score in both groups	69
Iloprost and cyclosporine-A vs. iloprost	Total plicometer skin score	+	2b	Significant improvement in iloprost and cyclosporine-A group	70
Dipyridamole and aspirin	Clinical skin induration	0	1b	No significant improvement	71
Ketanserin	Clinical skin evaluation	0	1b	No significant difference	72
Ketanserin	Clinical skin evaluation	0	1b	No significant difference	73
Stanozolol	MRSS	0	1b	No significant difference	74
Glyceryl trinitrate	Skin elasticity	0	2b	No significant difference	75
Intravenous pulse dexamethasone	MRSS	+	1b	Significant improvement in treatment group	76
Daily paraffin bath and hand exercise	MRSS Stiffness and skin elasticity - visual analog scale	+	2b	Elasticity and stiffness improved significantly; differences in skin score not reported	77
Minocycline	MRSS	0	4	No statistically significant difference between patients treated with minocycline and patients from D-penicillamine trial	81

Therapy	Outcome Measurement	Efficacy	Level of Evidence	Comment	Reference
PVAC	MRSS	+	1b	Significant improvement in the 15 µg PVAC arm but worsening of skin score in 50 µg PVAC arm	78
Factor XIII	Clinical assessment	+	1b	Significant difference between placebo and treatment	79

MRSS, modified Rodnan skin score; PUVA, psoralen + ultraviolet A; UVA, ultraviolet A; PVAC, psoriasis vaccine.

with 96% of patients having gastrointestinal complaints, which generally responded to dose reduction.

Rituximab

The safety and efficacy of rituximab, an anti-CD20 monoclonal antibody that depletes mature B-lymphocytes, has been examined in scleroderma patients. There have been two open label trials with conflicting results. In the first, eight patients received an infusion of 1000 mg rituximab at baseline and again at day 15, along with 100 mg methyprednisolone. Both modified skin score and histopathologic evaluation of the skin were examined. Rituximab induced effective B cell depletion in all patients and there was a significant change in skin score by week 24 ($p<0.001$). Furthermore, there was improvement measured in dermal myofibroblast numbers and the dermal hyalinized collagen content.¹³ Overall, treatment with rituximab was well tolerated. In another open-label study examining the safety and efficacy of rituximab, 15 patients with diffuse cutaneous systemic sclerosis received two intravenous doses of rituximab 2 weeks apart.¹⁴ The primary outcome measure was modified Rodnan skin thickness score after 6 months compared to baseline. The mean change in skin score was not significant. Rituximab treatment did result in depletion of circulating B cells and depletion of dermal B cells, with little effect on SSc-associated autoantibodies. Treatment with rituximab did not have a significant beneficial effect on skin disease, although it appeared safe and well tolerated.

Chlorambucil

Chlorambucil was compared to placebo in a 3-year randomized double-blind study (n=65).¹⁵ Chlorambucil is an immunosuppressive agent and the treatment group developed significantly more decrease in white blood cell count, platelet count, and lymphocyte counts as compared to placebo. Semiquantitative skin scores showed no significant difference between treatment groups. Overall, 3 years of treatment did not show any significant benefit for patients with SSc.

Methotrexate

In a trial of 18 patients with systemic sclerosis, methotrexate versus placebo was tested for 18 months.¹⁶ Clinical improvement was observed but no statistically significant

improvement in skin parameters were seen in the treatment group. Anorexia, nausea, and vomiting were common side effects and nine patients (3 in the methotrexate group) total dropped out of the study due to noncompliance or toxicity.

In a randomized, double-blinded trial, methotrexate was compared to placebo using a 24-week treatment period followed by 24-week observation period.¹⁷ Scleroderma patients received weekly injections of 15 mg methotrexate (n=17) or placebo (n=12). Rodnan total skin score was assessed. By week 24, Rodnan skin score changes were -0.7 and 1.2 in the methotrexate and placebo groups, respectively ($P<0.06$). Six patients had methotrexate temporarily held because of elevated liver function tests and two patients in the methotrexate group withdrew from the study because of scleroderma renal crisis and persistent headaches.

In a multicenter trial (n=71) patients were treated with either methotrexate or placebo for 12 months.¹⁸ The primary outcomes measured were modified Rodnan skin score and the UCLA skin score. Methotrexate was begun at 10 mg/week and gradually titrated to 15 mg/week. When between-group differences for changes in score were studied using intent to treat analysis, methotrexate had a favorable effect on skin scores (-4.3 vs. 1.8 in placebo group, $p<0.009$). However, the differences in the UCLA skin score were not statistically significant, and the groups were mismatched at baseline in a manner that might favor methotrexate. The authors concluded that the between-group differences were small and there was not enough evidence to show that methotrexate is significantly effective for diffuse SSc. Interestingly, this trial was recently re-examined, and the results were reanalyzed using a Bayesian analysis.¹⁹ Three outcomes were studied including the modified Rodnan skin score, ULCA skin score, and physician global assessment of disease activity. The probability of beneficial treatment effect was computed. The probability that methotrexate treatment results in better mean outcomes than placebo was 94% for modified skin score, 96% for UCLA skin score and 88% for physician global assessment. The authors concluded that a Bayesian analysis for uncommon disease trials could allow for more clinically relevant conclusions.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) was studied in a retrospective trial of 172 patients.²⁰ MMF is an inosine

monophosphate dehydrogenase inhibitor which inhibits de novo guanosine nucleotide synthesis. It helps suppress proliferation of both T and B-lymphocytes. Data covering a 5-year period from the beginning of treatment was collected. While treatment with MMF was overall well tolerated, there was no significant difference between the treatment and control groups using modified Rodnan skin score.

Additionally, a pilot study was conducted evaluating the efficacy and safety of a treatment strategy combining mycophenolate mofetil, intravenous methylprednisolone and low-dose glucocorticoids.²¹ Nine patients were recruited based on their severe skin involvement (modified Rodnan skin score of at least 15) and received 3 consecutive daily methylprednisolone pulse treatments followed by 5 additional monthly methylprednisolone pulse treatments. Mycophenolate mofetil dosed at 0.5 g twice daily for 1 week then 1g twice daily and oral prednisolone at 5-10 mg/day were also administered for 1 year. Modified Rodnan skin score significantly improved at 1 year. Patients tolerated the triple combination regimen well and no patients suffered from renal impairment.

Another pilot study assessed the efficacy and safety of anti-thymocyte globulin followed by mycophenolate mofetil in the treatment of recent-onset diffuse scleroderma.²² Thirteen patients with recent-onset scleroderma were treated with antithymocyte globulin first for 5 days followed by mycophenolate mofetil for 1 year. Modified skin score was measured and decreased throughout the study from 28 at baseline to 17 following the 12-month treatment period ($p<0.01$). Interestingly, hand contractures worsened throughout the study. Overall, therapy with mycophenolate mofetil was well tolerated but five patients developed serum sickness after treatment with antithymocyte globulin.

D-penicillamine

D-penicillamine was proposed as a possible therapy for SSc because it interferes with molecular cross-linking of collagen and has immunomodulatory effects. In a double-blind, randomized study of 134 patients, high-dose D-penicillamine was compared to low-dose D-penicillamine in the treatment of cutaneous SSc.²³ Altogether, 68 patients with early diffuse cutaneous SSc completed 2 years of treatment. Using the modified Rodnan skin thickness score, there was no significant difference in skin score change between the two treatment groups. The skin score dropped by 4.8 ± 10.3 units in the high-dose group and 6.9 ± 8.4 units in the low-dose group. There were 20 withdrawals related to adverse events, 80% of which occurred in the high-dose group. Notably, in this trial, toxicity was increased in the high-dose group, therefore demonstrating a biologic response. However, this study demonstrated no differences in efficacy between a D-penicillamine dose of 125 mg every other day and a mean dose of 822 mg daily. The Authors concluded that

if D-penicillamine was to be used to treat SSc, there is no advantage to using dosages higher than 125 mg every other day. This argued in favor of using placebo controls in studies until an active control is found which is truly a disease-modifying agent. The authors explained that without using a placebo control, the efficacy of D-penicillamine remains unclear.

Bovine Type I Collagen

In patients with diffuse cutaneous SSc, the safety and efficacy of oral bovine type I collagen was examined (n=168).²⁵ Oral type I collagen at 500 µg/day or placebo was administered for 12 months. Authors sought to induce oral immune tolerance to type I collagen and assess its ability to improve skin thickness. The modified Rodnan skin score was assessed, and both intent-to-treat and modified intent-to-treat analyses showed no significant difference in the mean change of skin score between the two groups. However, patients with late-phase (disease greater than 3 years) diffuse cutaneous SSc experienced a significant reduction in skin score compared to placebo-treated patients when analyzed at 15 month follow-up ($p=0.0063$). This result was only significant, however, using an "as treated" analysis, while an intent-to-treat analysis revealed a nonsignificant improvement. The authors concluded that type I collagen treatment may provide benefit for patients with late-phase diffuse cutaneous SSc.

Photopheresis/Plasma Exchange

Photopheresis is a therapy combining ultraviolet A (UVA) irradiation with 8-methoxysoralen.²⁶ There is repeated extracorporeal exposure of peripheral blood lymphocytes to UVA light and lymphocytes are subsequently reinfused into the patient. In a multicenter, randomized, investigator-blinded clinical trial (n=79) extracorporeal photochemotherapy treatment administered monthly was compared with D-penicillamine in the treatment of SSc; patients had progressive skin involvement for the previous 6 months.²⁷ Blinded examiners evaluated skin severity score, percent surface area involvement and performed skin biopsies. Following 6 months of treatment, 68% of patients receiving photochemotherapy achieved significant improvement in skin severity score as compared to baseline skin score; as noted earlier, small, but clinically meaningful changes in skin score are not always statistically significant. For patients treated with D-penicillamine, no cutaneous disease measures improved significantly at 6 months, the difference in response rate between the groups was significant ($p=0.02$). Skin biopsies illustrated a correlation between clinical improvement and decreased dermal thickness. No patients required discontinuation of extracorporeal photochemotherapy.

Extracorporeal photochemotherapy was investigated in a randomized, double-blind placebo-controlled trial

(n=64).²⁸ These patients all had clinical scleroderma of less than 2 years duration which is thought to represent the group with the most aggressive clinical disease behavior.²⁹ Patients received either active or sham photopheresis monthly for 12 months. After 6 and 12 months, statistically significant improvement in modified Rodnan skin score was found in those who received active treatment ($p=0.0024$ and $p=0.008$ respectively). Between active and sham photopheresis groups, there was insufficient statistical power to reveal a difference in skin scores; a power analysis revealed that 60 patients per treatment arm would have been needed for a p-value of 0.05 or less. However, the authors noted a trend to a difference that did not reach significance ($p=.119$ at 6 months and $p=.129$ at 12 months).

Plasma exchange combined with D-penicillamine treatment was compared to D-penicillamine alone in the treatment of 29 patients with SSc.³⁰ Total skin score was measured. Following six plasma exchange treatments, total skin score showed significant improvement in the group receiving both plasma exchange and D-penicillamine. The most common side effect was hypotension, which resolved following transfusion.

Ultraviolet A1 Phototherapy

UVA1 irradiation induces apoptosis of T-cells, which infiltrates the skin and can reduce collagen deposition in the dermis.³¹ Ultraviolet A1 treatment (UVA1) ranging from 340-400 nm was tested in an investigator-blinded, controlled trial of 9 patients with acrosclerosis.³² A modified Rodnan skin thickness score was used and cutaneous thickness assessed on each hand after clinical palpation of both palmar and dorsal sides. Low-dose UVA1 treatment was used 3 times weekly for 14 weeks. While the mean skin score improved, the improvement was not different between treated and untreated hands.

UVA Phototherapy

Low-dose UVA phototherapy was examined in a trial of 15 patients with SSc.³³ Patients were allocated randomly into three treatment arms receiving 5, 10, or 20 J/cm². Patients were judged clinically by inspection and palpation (non-blinded). There was clinical improvement in all groups after 20 sessions, but no comparable differences were noted between the different UVA dosages. The authors concluded that lower doses of UVA are just as effective as the higher dose of UVA (20 J/cm²) for the treatment of cutaneous SSc.

PUVA Phototherapy

PUVA treatment (photochemotherapy) refers to combining UVA light, at a wavelength of 320-400 nm, with the use of 5- or 8-methoxysoralen, which helps sensitize cells to light. Psoralens are thought to intercalate between DNA,

and form crosslinks, which can prevent replication of DNA following exposure to UVA light. Photochemotherapy was studied with quantitative echography in patients with SSc.³⁴ The dermal echo intensity and dermal thickness were measured before and after treatment. Thirteen patients with SSc were studied, randomly receiving either oral photochemotherapy with 20 mg methoxysoralen or topical 0.3% methoxysoralen. UVA irradiation was started at $\frac{1}{2}$ minimal phototoxic dose. Overall, the dermal echo intensity significantly increased compared to baseline while dermal thickness significantly decreased. Authors concluded that photochemotherapy was more likely to improve dermal edema, not fibrosis.

In a recent study of three patients with diffuse SSc, two patients were treated with PUVA and one treated with UVA1 irradiation.³⁵ UVA1 therapy began with a single dose of 10 J/cm² and the exposure dose was gradually increased to 60 J/cm². For PUVA therapy, topical 0.3% 8-methoxysoralen was applied to the patient's skin and a single dose of 0.6 J/cm² was used first, and the exposure dose was gradually increased to 2.4 J/cm². The total cumulative dose in the two patients was 65 J/cm² and 164 J/cm². Skin specimens were taken from the forearms of patients before and after treatment. In the patient treated with UVA1 therapy, alteration of collagen fibrils was seen in the upper reticular layer and the number of large collagen fibrils decreased. The patients treated with PUVA therapy demonstrated similar changes in the upper reticular to the middle reticular layer. The median collagen fibril diameter decreased by 10 nm. Furthermore, spaces between collagen fibrils widened in all patients. Overall, changes in collagen fibril diameter occurred deeper in the dermis after PUVA therapy as compared to UVA1 therapy.

Cyclophosphamide

Cyclophosphamide, a cytotoxic immunosuppressive medication which modulates lymphocyte function, and the immunosuppressant azathioprine were compared in a randomized unblinded trial for 18 months (n=60).³⁶ Patients also initially received a course of prednisolone during the first 6 months of the trial. This trial evaluated patients for 18 months with 30 patients receiving oral cyclophosphamide at 2 mg/kg daily for 12 months followed by a maintenance dose of 1 mg/kg daily, and a comparison group of 30 patients receiving azathioprine at 2.5 mg/kg daily for 12 months followed by 2 mg/kg daily. Following treatment there was a statistically significant improvement in the modified Rodnan skin score in the cyclophosphamide group ($p<0.01$), but not in the azathioprine group (no trend towards improvement or worsening). The difference between the two groups in modified Rodnan skin score was statistically different ($p<0.001$). Despite its limitation as an unblinded trial, authors concluded that cyclophosphamide might be a potential disease-modifying agent for cutaneous SSc.

In a multicenter, randomized, placebo-controlled trial, the effect of oral cyclophosphamide was evaluated in 158 patients with scleroderma.³⁷ Patients received oral cyclophosphamide at <2 mg/kg body weight/day or placebo for 1 year and were followed for a subsequent year. In the 85 patients who had diffuse cutaneous sclerosis, modified Rodnan skin score at 1 year showed a significant difference between the two groups and favoring the cyclophosphamide treatment arm (-3.06 , $p=0.008$), although this is on the borderline of clinical significance.

High-dose cyclophosphamide without stem cell rescue was investigated in an open-label uncontrolled study for patients with diffuse cutaneous scleroderma.³⁸ Patients were treated with intravenous cyclophosphamide (at 50 mg/kg) for four consecutive days followed by granulocyte colony-stimulating factor (5 µg/kg/day). The primary endpoint was modified Rodnan skin score. The percentage reduction in Rodnan skin score in 5 evaluable patients 1 month following treatment was 60%, 55%, 41%, 31%, and 0%. Three patients demonstrated sustained improvement for 12, 12, and 24 months, while the other two patients relapsed. There was one patient death as a result of infection after neutrophil count recovery. The authors concluded that the use of high-dose cyclophosphamide could lead to a significant improvement in skin score.

Azathioprine

Azathioprine has also been investigated in the treatment of systemic sclerosis. After 1 year of treatment with low-dose pulse cyclophosphamide in patients with early diffuse systemic sclerosis, 13 patients underwent treatment with azathioprine 100 mg/day in a prospective 1-year study.³⁹ Overall, authors concluded that the improvement from a year of cyclophosphamide therapy was maintained with azathioprine treatment. The modified Rodnan skin score did not deteriorate significantly and azathioprine may have a role in maintaining improvement, which is induced by low-dose pulse cyclophosphamide although controlled studies have not been pursued.

Cyclosporine

Cyclosporine is an immunosuppressant agent, which was first used in organ transplant recipients. Cyclosporine binds to cyclophilin, leading to calcineurin inhibition and a blockade subsequently resulting in decreased levels of inflammatory cytokines such as interleukin-2. In an open-label pilot study, the efficacy of cyclosporine was investigated in eight patients with severe scleroderma.⁴⁰ Cyclosporine was initiated at 5 mg/kg/day and then adjusted to a mean dosage of 4.3 mg/kg/day. Following 6 to 12 months of treatment, cutaneous abnormalities improved in seven patients and no serious side effects were observed. No information described exact magnitude of skin score change, but authors concluded that cyclosporine is mainly

effective in skin involvement of scleroderma and possibly in other organ manifestations as well.

In an open-label study evaluating the safety and efficacy of cyclosporine for 48 weeks, ten patients were treated with cyclosporine and the skin score at entry and after treatment were compared.⁴¹ Skin thickening was significantly decreased ($p<0.001$) in the treatment group and adverse reactions were usually transient and associated with a cyclosporine dose of at least 3-4 mg/kg/day.

In a long-term study of low-dose cyclosporine, 9 patients who received cyclosporin treatment for diffuse systemic sclerosis with treatment periods ranging between 3-5 years at a mean dosage of 2.5 mg/kg/day were examined.⁴² Plicometry was used as a measurement of skin disease, and statistically significant reduction in the mean score was noted at 2 and 3 years after treatment with cyclosporine was initiated. Overall, low-dose long-term treatment with cyclosporine was well tolerated and no renal impairment or increases in blood pressure were observed throughout the 3 years.

In a routine immunology clinic, 16 patients who had been given cyclosporine (13 of which had been treated specifically for skin tightness) were identified.⁴³ Half of the patients noticed significant skin softening during cyclosporine treatment. However, side effects, particularly hypertension, were common and contributed to withdrawal in 12 of the 13 patients identified.

Halofuginone

Halofuginone acts by blocking the activated of Smad3 protein, interfering with the synthesis of TGF-β and potentially reducing collagen synthesis by fibroblasts.⁴⁴ Topical 0.1% halofuginone ointment appears to be safe and well tolerated. A treatment regimen for 6-months resulted in significant reduction of collagen type I in affected skin of patients with cutaneous sclerosis.⁴⁵

In a phase II trial designed to assess the safety and efficacy of halofuginone for diffuse SSc, the modified Rodnan skin thickness score was used as primary endpoint. Thirteen patients were treated once daily with topical 0.01% halofuginone (randomly assigned to either the right or left upper extremities) and 11 patients completed a 6-month treatment course. The most frequently reported adverse event was dermatitis of varying degree that did not result in cessation of treatment. Five patients met responder criteria of a 25% reduction in total skin score on the treated arm and the average time for response was 2.6 months. Halofuginone is being further investigated for the treatment of dermal fibrosis.

Thalidomide

Thalidomide was investigated in a prospective, nonrandomized open-label study in 11 patients with systemic

sclerosis.⁴⁶ Initially, thalidomide was administered at 50 mg/day up to a final dose of 400 mg/day. This led to complete healing of digital ulcers, but there was no benefit reported in modified skin score after 12 weeks of treatment. Furthermore, there was some development of extremity edema and dry skin in the patients receiving thalidomide. However, histologic comparison of skin biopsies did show changes in skin fibrosis in patients treated with thalidomide, and plasma levels of IL-12 and TNF- α were also increased in treated patients.

Etanercept

Etanercept is an inhibitor of tumor necrosis factor- α , (TNF- α) which is a proinflammatory cytokine produced by T-cells, which stimulated the synthesis of many other inflammatory cytokines such as IL-1, IL-6 and IL-8. Etanercept is a fusion protein of a soluble TNF receptor joined to human immunoglobulin.⁴⁷ In a pilot open-label study, 10 patients with early diffuse SSc were treated with etanercept at a dose of 25 mg subcutaneously twice weekly.⁴⁸ Following 6 months of therapy, four patients experienced an improvement in skin score, six patients experienced no improvement, and all patients tolerated the injections well.

High-Dose Immunosuppressive Therapy Followed By Autologous Stem Cell Transplantation

Two groups, one in the U.S. and one in Europe, have reported on their experience with the largest cohort of patients to be treated with this modality. An open-label multicenter trial of 34 patients with diffuse cutaneous SSc in the U.S. evaluated the efficacy of high-dose immunosuppressive therapy and autologous CD34-selected hematopoietic cell transplantation.⁴⁹ The immunosuppressive treatment included total body irradiation, cyclophosphamide at 120 mg/kg and anti-thymocyte globulin. Of the 27 evaluable patients, 63% had sustained response at a median follow-up of 4 years with a major improvement in modified Rodnan skin score (a decrease by 22 points, $p<0.001$). This equates to skin improvement of approximately 70%. Biopsies also confirmed a statistically significant decrease of dermal fibrosis as compared to baseline ($p<0.001$). During the study, there were 12 deaths of which eight were related to transplantation and four related to scleroderma progression. The estimated 5-year progression-free survival was 64%. Overall mortality at 5 years was 36% and the treatment-related mortality was 23%; relapse rate was not discussed.

Another group reported the results of a multicenter study in Europe using autologous hematopoietic stem cell transplantation in 57 patients.⁵⁰ Differing conditioning regimens, which included cyclophosphamide, were used,

and, unlike the U.S. study, most of the patients did not undergo total body irradiation. Hematopoietic stem cells were CD34-selected or further T cell-depleted. Fifteen out of 19 patients had an improvement in Rodnan skin score by at least 25% at 2 years. Overall, 35% of patients with initial partial response ($n=13/32$) or a complete response ($n=3/14$) relapsed within 10 months after stem cell transplant. Five patients died from treatment-related complications and eight from disease progression. Authors of this report concluded that the response seen in two-thirds of patients overall following transplantation was durable with an acceptable transplant-related mortality. Based on these data, there are currently two prospective randomized phase III studies to evaluate autologous stem cell transplantation in North America and Europe.⁵¹

High-Dose Immunosuppressive Therapy Followed By Allogeneic Stem Cell Transplantation

Compared to the autologous setting, there is scant experience using allogeneic stem cell transplantation for SSc. This methodology is proposed by some in response to the high relapse rate seen using the autologous transplantation, and it is proposed that a “graft versus autoimmunity” response might be a major benefit of the allogeneic transplant protocol, resulting in a lower relapse rate. At this time, there are only case reports of success in a handful of patients. A 40-year old patient with diffuse scleroderma and interstitial pneumonia was treated with an allogeneic peripheral blood stem cell transplantation from an HLA-identical sibling following conditioning with total-body irradiation and fludarabine.⁵² Cyclosporine and mycophenolate mofetil were also used as prophylaxis for graft-versus-host disease (GVHD); the patient tolerated transplantation well with no infection or GVHD. One year following transplantation, the patient’s skin score had decreased dramatically from 30 to 13. The patient did develop membranous glomerulopathy caused by chronic GVHD treated successfully with prednisolone.

Nash et al. evaluated the safety and efficacy of allogeneic hematopoietic stem cell transplantation after myeloablative conditioning in two patients.⁵³ The conditioning regimen included treatment with cyclophosphamide, antithymocyte globulin, and busulfan. Cyclosporine and methotrexate were used for GVHD prophylaxis. Bone marrow was transplanted from siblings who were HLA-identical. For the first patient, 5 years after stem cell transplant the patient had near complete resolution of scleroderma with resolution of dermal fibrosis from serial skin biopsies. The patient had no complications of GVHD. Patient two had skin toxicity from the initial conditioning regimen, and the patient experienced an improvement in scleroderma, but died from a fatal opportunistic infection 17 months following stem cell transplant.

Loh et al. reported a patient with diffuse cutaneous SSc who successfully underwent allogeneic hematopoietic stem cell treatment from an HLA-identical sibling.⁵⁴ The patient's baseline Rodnan skin score was 25. The conditioning regimen consisted of 200 mg/kg of cyclophosphamide and alemtuzumab; cyclosporine and mycophenolate were used for prophylaxis of GVHD. Rodnan skin score decreased to nine at 26 months following transplantation, and the patient tolerated treatment well with no development of GVHD.

ANTIFIBROTIC AGENTS (TABLE 35.1)

Fibrosis is an important component of the progression of skin disease in scleroderma, consisting of deposition of newly synthesized connective tissue such as collagens. Antifibrotic therapies are aimed to reduce the synthesis and polymerization of collagen, or to enhance collagenase activity.

Recombinant Human Tissue Plasminogen Activator

Low-dose (10 mg) recombinant human tissue plasminogen activator was one of the first antifibrotic agents examined in a double-blinded, placebo-controlled crossover trial (n=14).⁵⁵ The mean change of Rodnan skin score in the placebo arm was an increase of 0.8, while the mean change in the treatment group was decrease by 5.4. A significant difference was observed in the mean change of the Rodnan skin score between placebo and treatment arms ($p<0.001$) and 10 patients showed mild to moderate improvement in Rodnan skin score.

Aminobenzoate Potassium

In a 48-week prospective, double-blind randomized study the efficacy of the antifibrotic agent aminobenzoate potassium was compared to placebo for the treatment of skin manifestations of scleroderma.⁵⁶ Skin mobility and thickening scores were assessed. Of 146 patients in the study, only 52% completed the study. No clinical or statistically significant differences were seen between the placebo and treatment groups for the skin mobility and thickening score changes.

Urokinase

Urokinase is produced by endothelial cells and seems to play a role in endothelial cell migration and revascularization but its exact mechanism of action in this study is not clear. A 4-month placebo-controlled randomized trial of urokinase therapy in 36 patients was conducted with measurements of ultrasonography of the skin.⁵⁷

Ultrasound was used as a noninvasive technique to study the skin and subcutis with both transverse and longitudinal scans (nonblinded assessment). Ultrasound measurement showed diminished echogenicity of the epidermis and dermis and a noticeable improvement in skin thickness.

Colchicine

In addition to its anti-inflammatory activity, colchicine has the ability to interfere with synthesis of collagen by depolymerizing microtubules and reducing fibroblast proliferation. One uncontrolled study evaluated colchicine in 19 patients with scleroderma with a follow-up period ranging from 19 to 57 months.⁵⁸ The average dosage used was 0.6 mg twice daily, and there was improvement noted in skin elasticity; skin score was not measured. Overall, colchicine was well tolerated and the most common adverse event was diarrhea.

Relaxin

Relaxin is a protein primarily secreted by the ovary and placenta, which has tissue remodeling activity. Recombinant human relaxin is thought to reduce synthesis of dermal fibroblast collagen as well as to degrade existing collagen.⁵⁹ To assess the safety and efficacy of recombinant human relaxin in a double-blind placebo-controlled trial, 68 patients were randomized to receive treatment with 25 or 100 µg/kg of human relaxin versus placebo for 24 weeks.⁶⁰ Modified Rodnan skin score was measured. Patients receiving 25 µg/kg/day relaxin had reduction in mean skin score from 27.5 at screening to 18.8 after 24 weeks; patients receiving 100 µg/kg/day of relaxin had reduction in mean skin score from 26.3 at screening to 24.1 after 24 weeks. Patients receiving 25 µg/kg/day of human relaxin had significantly lower skin scores compared to those receiving placebo, but patients receiving 100 µg/kg/day did not show any difference from placebo. The authors suggested that possibly a higher dose of relaxin fails to stimulate collagenase secretion. Adverse events included anemia, site irritation, local infection, and pain at the injection site.

Recently human relaxin was evaluated in a larger, double-blind, placebo-controlled trial (n=195).⁶¹ Placebo was compared with 10 µg/kg/day and 25 µg/kg/day for 24 weeks in patients with stable, moderate-to-severe diffuse SSc. In both treatment groups, the modified Rodnan skin score did not decrease significantly as compared to placebo. Relaxin was associated with serious renal adverse events and hypertension, although most of these events occurred after abruptly stopping infusion. We conducted a meta-analysis of these two randomized trials, which indicates that relaxin is more effective than placebo in reducing the MRSS by 0.668 (0.393, 0.944) using a fixed effects model. However, this small a change in MRSS is not of clinical significance.

Interferon- α

Interferon- α (IFN- α) has been shown to inhibit collagen synthesis and fibroblast proliferation *in vitro*.⁶² The efficacy of this agent was examined in the treatment of diffuse cutaneous SSc for patients with early skin involvement, in a randomized double-blind placebo-controlled study.⁶³ Thirty-five patients received injections of either IFN- α or placebo for 12 months. There was a greater improvement in Rodnan skin score in the placebo group after 12 months. Skin biopsies did not demonstrate a significant decrease in collagen synthesis in the treatment groups. The authors concluded that this agent does not effectively treat cutaneous manifestations of SSc and may be potentially deleterious.

Interferon- γ

Interferon-gamma (IFN- γ) treatment for systemic sclerosis was investigated in a randomized-controlled trial in 44 patients with mean duration of skin sclerosis for 10.8 years.⁶⁴ Patients received recombinant IFN- γ treatment 3 times weekly for 12 months. Skin involvement was measured with a modified Rodnan skin score of 15 sites. While the skin scores tended to improve in the treatment groups, they did not improve significantly in the overall analysis of the treatment or control group. There was a high frequency of mild and moderate influenza-like adverse events in the treatment group.

Recombinant Human Antibody CAT-192

A recombinant human antibody (CAT-192) which neutralizes transforming growth factor β 1 (TGF β 1) was evaluated in the treatment of diffuse cutaneous SSc.⁶⁵ Forty-five patients were assigned to receive placebo or three different dosages of CAT-192. The Rodnan skin thickness score was assessed. The Rodnan skin score improved in all groups but there was no significant evidence for a treatment effect of CAT-192. Additionally, there were more adverse events, including serious adverse events, in patients treated with CAT-192. Authors concluded that CAT-192 did not show efficacy in doses up to 10 mg/kg. Authors also noted that effective prevention of fibrosis, based on animal models, requires that multiple isoforms of TGF β be blocked (not just one isoform), which may potentially explain why CAT-192 did not show evidence of efficacy in the trial.

Imatinib

Imatinib mesylate is a tyrosine kinase inhibitor which interferes with the signaling of TGF- β as well as other kinases that might be involved in the fibrotic response, blocking extracellular matrix synthesis both *in vitro* and in

mouse models.⁶⁶ Imatinib mesylate was used in a 24-year-old patient with diffuse systemic sclerosis of 7 years duration which was severe and progressive.⁶⁷ Within 6 weeks after initiating imatinib treatment at 400 mg/day orally, the patient's skin score decreased from 44 to 33 along with improvement in flexion contractures. Furthermore, at 3 and 6 months the patient's modified skin score was further reduced to 28. Overall, the treatment was well tolerated and no adverse effects were noted.

In another report, two patients with early diffuse cutaneous SSc experienced a reduction in skin sclerosis following therapy with imatinib mesylate.⁶⁸ One patient was treated with 3 months of oral imatinib 100 mg daily and the other with 6 months of oral imatinib at 200 mg daily. Both patients experienced improvement in skin tightening and the modified Rodnan skin score improved in patients 1 and 2 from 36 to 21 and 20 respectively. Immunohistochemical analyses of skin biopsy specimens showed a reduction in phosphorylated platelet-derived growth factor receptor and Abl (both tyrosine kinases thought to play a role in fibrosis) with imatinib therapy. Furthermore, an imatinib-responsive signature specific for diffuse cutaneous SSc was identified ($p<10^{-8}$).

VASODILATORS

Iloprost

Recently, differing dosages of iloprost were compared for the treatment of skin thickening in SSc.⁶⁹ Iloprost is a synthetic analogue of prostacyclin PGI₂ that dilates both systemic and pulmonary arterial vascular beds. Patients were randomized to either high or low-dose intravenous iloprost treatment for 21 days. There was no significant difference between low-dose and high-dose iloprost in reduction of skin score. One year following therapy, the modified Rodnan skin score was unchanged in both groups.

Cyclosporine A and iloprost were compared to iloprost alone in a study of 20 patients for 12 months.⁷⁰ A significant improvement in skin score was noted ($p=0.008$) only in the group receiving both low-dose cyclosporine A and iloprost. In this trial, scores were assessed using plicometry by measuring the plica of each skin area. Additionally, there was a significant reduction of interleukin-6 serum concentration in this group, suggesting that interleukin-6 may play a role in the skin improvement noted.

OTHER THERAPIES

Dipyridamole

In a randomized, double-blind controlled study of patients with early scleroderma (n=28) patients received dipyridamole and aspirin versus placebo for 1-2 years.⁷¹ Clinical

skin induration scores showed no significant improvement in either treatment or placebo groups.

Ketanserin

In a randomized double-blind study (n=24), ketanserin, a specific S2-serotonergic receptor antagonist, was compared to placebo in a 6-month trial.⁷² Ketanserin failed to produce an improvement in clinical signs and symptoms compared to placebo, including modified Rodnan skin score. In another randomized study (n=27) patients were treated with ketanserin for 6 months.⁷³ No significant difference was observed between the two groups with regard to skin changes and more patients in the ketanserin group experienced dysphagia.

Stanozolol

Stanozolol is an anabolic steroid with low virilizing potential, which can enhance impaired fibrinolytic activity. This was tested in a double-blind, randomized placebo-controlled trial of 24 patients.⁷⁴ Measurement of skin disease with modified Rodnan skin score showed reduction in the treatment group, but was not significant ($p=0.37$). Rodnan skin score was unchanged in the placebo group. Magnitude of differences in Rodnan skin score not stated.

Glyceryl Trinitrate

Glyceryl trinitrate was used in a trial of 10 patients with sclerodermatosus skin change in a placebo-controlled trial for 4 weeks.⁷⁵ The topical medication was applied to the forearm only and skin elasticity was measured with the Cutech Extensometer. The application of topical glyceryl trinitrate had no effect on skin elasticity.

Dexamethasone

In a randomized double-blind study (n=35) patients received intravenous dexamethasone pulse therapy or placebo, with pulse therapy repeated once monthly for 6 months.⁷⁶ Rodnan skin score demonstrated significant improvement in the treatment group, decreasing from $28.5 +/ - 12.2$ to $25.8 +/ - 12.8$. In the placebo group, total skin score increased from $30.6 +/ - 13.2$ to $34.7 +/ - 10$. Authors concluded that intravenous pulse dexamethasone may be useful in the treatment of diffuse systemic sclerosis; difference between the two groups not stated. Adverse effects were limited to increase in upper respiratory infections.

Paraffin Bath

In 17 patients with SSc, one hand was treated with daily paraffin bath and hand exercise while the other was treated

only with exercise, functioning as a control.⁷⁷ Pain, stiffness, and skin elasticity were assessed by self-rating using a visual analogue scale. Skin thickness was determined by palpation using the modified Rodnan skin score (nonblinded). Assessments were made at three sites using the index finger, dorsum of hand and the forearm with a maximum score of 9 points. Perceived stiffness and skin elasticity improved significantly in the hand treated with paraffin baths for 6 months. Differences in skin thickness were not analyzed.

PVAC

PVAC (psoriasis vaccine) derived from deglycolipidated *Mycobacterium vaccae* was evaluated in a double-blind, randomized placebo-controlled trial using intradermal injections in patients with diffuse SSc for 24 weeks.⁷⁸ The primary efficacy endpoint was change in modified Rodnan skin score, which improved by 20.6% in the 15 µg PVAC arm but worsened by 16.7% in the 50 µg PVAC arm. Use of PVAC injections was well tolerated with no serious adverse events.

Factor XIII

The efficacy and tolerability of Factor XIII treatment was compared to placebo in a double-blind randomized cross-over trial of 25 scleroderma patients.⁷⁹ Patients received intravenous Factor XIII or placebo for 3 weeks. Clinical assessments made by physicians and patients indicated that treatment with Factor XIII improved cutaneous SSc significantly better compared to placebo (specific endpoint was vague) and this was supported by significant improvement in a function index used to assess the degree of motor disability.

Minocycline

Eleven patients with early scleroderma were treated with minocycline at 100 mg daily for 4 weeks followed by 200 mg daily for 11 months. Four of the patients experienced complete resolution of skin involvement.⁸⁰ A larger study evaluated minocycline in an open-label multicenter trial (n=31) to determine if minocycline therapy improved skin thickness by at least 30% (which was considered a level of improvement unlikely to occur because of the natural history of the disease).⁸¹ Patients with early diffuse SSc of at least 5 years duration were treated with oral minocycline for 1 year, and the primary measured endpoint was modified Rodnan skin score. Thirty-one patients were included for analysis and there was no statistically significant difference in skin score change between minocycline treated patients and subjects reported from the D-penicillamine trial, used as comparitors. Comparison of the modified skin score in the minocycline-treated patients and previously reported D-penicillamine trial, when adjusted for disease duration,

showed no difference and no treatment effect. The authors concluded that the change seen in the modified Rodnan skin score was similar to what may be expected because of the natural disease course and minocycline is not an effective therapy for SSc.

THERAPIES FOR DIGITAL ISCHEMIC ULCERS (TABLE 35.2)

Digital ulcers, a prominent vascular complication occurring in up to half of patients with limited or diffuse SSc, are extremely painful cutaneous lesions, which can lead to significant disability.⁸² The pathogenesis of these ulcers is multifactorial, and progressive tissue ischemia and endothelial cell injury are thought to play a critical role.⁸³ Furthermore, there may be increased production of vasoconstrictors, decreased production of vasodilating compounds such as nitric oxide, intraluminal thrombosis and vasospasm secondary to Raynaud's phenomenon which lead to decreased tissue oxygenation in the pathogenesis of digital ulcers.⁸⁴

In a randomized, double-blind trial of 84 patients, 2% dimethyl sulfoxide (DMSO), 70% DMSO and normal saline were compared for the topical treatment of digital ulcers associated with SSc.⁸⁵ Among all three groups, no significant differences were found in the number of open ulcers, surface area of ulcers, infection rates of ulcers or patient pain assessments. Improvement in any patient

could not be attributed to a specific therapy and more than 25% of patients in the 70% DMSO group withdrew because of significant skin reactions.

Quinapril was evaluated in a double-blind, placebo-controlled study of 210 patients with either limited systemic sclerosis or with Raynaud phenomenon and the presence of SSc-specific antibodies.⁸⁶ Treatment was for 2-3 years. Quinapril did not affect the number of new digital ulcers, nor did it affect Raynaud's severity or other vascular manifestations of SSc. Adverse affects occurred in one-fifth of the patients, with dry cough being the most frequent side effect.

In a double-blind placebo-controlled study of 11 patients with digital ischemic ulcerations, patients received either intravenous iloprost or saline infusions on 5 consecutive days.⁸⁷ Complete healing of all cutaneous ulcers was observed 10 weeks after treatment in 6 of 7 patients receiving iloprost versus none in the placebo group ($p=0.015$). Adverse effects such as nausea, vomiting, and headache were limited to the period of drug infusion and one patient withdrew because of chest pain. The authors concluded that iloprost might be useful for treating digital ulcers associated with SSc.

More recently, different dosages of iloprost were compared in the treatment of ulcer healing. Patients were randomized 1:1 to receive either 2 ng/kg/min or low-dose (0.5 ng/kg/min) iloprost for 3 weeks. Patients had 70% reduction of digital ulcers following either regimen. The

TABLE 35-2—Therapies for Digital Ulcers

Therapy	Outcome Measurement	Efficacy	Level of Evidence	Significant Changes	Reference
2% DMSO and 70% DMSO	Number of open ulcers Surface area of ulcers	0	1b	No significant differences found between treatment groups and placebo group	85
Quinapril	Reduction of new digital ulcers	0	1b	No significant differences found between treatment group and placebo group	86
Intravenous iloprost	Healing of cutaneous ulcers	++	1b	Significant decrease between iloprost and placebo groups	87
High-dose and low-dose iloprost	Reduction in digital ulcers	++	2b	No significant difference between treatment groups; 70% reduction in digital ulcers using either regimen	69
Teprotinil	Change in diameter of largest baseline ulcer	++	4	4/5 patients completing study experienced resolution of ulcer	88
Bosentan	Number of new digital ulcers	++	1b	Significant reduction in number of ulcers in bosentan group	89
Atorvastatin	Number and severity of digital ulcers	+	1b	Significant difference between atorvastatin and placebo groups; digital ulcer severity improved significantly in statin group	90
Local stem cell implantation	Vascular symptoms and ulcer healing	+	4	Ulcer healing and decreased pain	91

DMSO, dimethyl sulfoxide.

What We Know

- Design and interpretation of clinical trials for scleroderma is currently hampered by: lack of endpoints that are valid measures of disease activity; lack of validated diagnostic and entry criteria to study patients with very early disease; and lack of understanding of disease pathogenesis.
- Scleroderma skin disease does not tend to respond well to conventional doses of traditional immunosuppressants.
- High-dose immunosuppression followed by stem cell rescue is a promising therapy that appears to have dramatic efficacy for cutaneous sclerosis.
- Endothelin receptor antagonists are effective at preventing digital ulcerations in scleroderma.
- Prostacyclin analogues and phosphodiesterase-5 inhibitors are promising agents for the treatment of digital ulcerations but need to be tested in prospective, placebo-controlled clinical trials.

authors concluded that low-dose iloprost is just as effective as high-dose iloprost in the treatment of digital ulcers.

Treprostinil is a prostacyclin analogue approved in the United States for pulmonary arterial hypertension treatment. In a single-center, open-label study, treprostinil was further evaluated for the treatment of digital ulcers.⁸⁸ Patients with digital ulcerations secondary to systemic sclerosis received treprostinil infusion for 12 weeks up to a maximum rate of 15 ng/kg/min. The primary endpoint was change in diameter of a selected target lesion (the largest baseline ulcer). Twelve patients were enrolled but seven withdrew because of severe injection site pain, and two patients experienced gangrene of previously ischemic digits, which required amputation. Four of five patients that completed the study achieved primary endpoint, with complete resolution of target lesions by 12 weeks with no recurrence. Furthermore, the average diameter of digital ulcerations decreased for digital tip lesions and lesions overlying the joints. No patients developed new digital ulcerations during treprostinil therapy.

Treatment with the endothelin receptor antagonist bosentan was investigated for the treatment of digital ulcers in patients with SSc.⁸⁹ In a double-blind, placebo-controlled study (n=122) the number of new digital ulcers developing during a 16 week period was studied. Patients receiving bosentan for 16 weeks had a 48% reduction in the number of new ulcers during the treatment period and this difference was statistically significant ($p=0.0083$). In this study, fewer digital ulcers developed in patients treated with bosentan as compared to placebo group, but the p-value is not stated. The reduction in the number of new ulcers was most significant in patients who had ulcers at baseline and in those with diffuse SSc. There was no difference between the treatment groups in the healing of existing ulcers. In the treatment group, 14% of patients experienced elevation of serum transaminases to >three-fold the upper limit of normal, which is comparable to previous studies with bosentan.

Statins are thought to affect endothelial function and potentially slow vascular injury. Atorvastatin was studied in a randomized, double-blinded, placebo-controlled trial (n=84) of patients with Raynaud phenomenon and digital

ulcers.⁹⁰ The treatment group received 40 mg daily of atorvastatin for 4 months. The overall number of digital ulcers was significantly reduced in the statin group (1.6 new ulcers per patient in the treatment group as compared to 2.5 in placebo). Digital ulcer severity also improved significantly in the statin group.

Local stem cell implantation was studied in two SSc patients with nonhealing digital ulcers.⁹¹ Local injections of CD34+ cells from the peripheral blood and bone marrow were used for skin ulcers in the hands in each patient, respectively. The CD34+ cells from bone marrow and peripheral blood showed a rapid beneficial effect on vascular symptoms leading to ulcer healing and decreased pain. The efficacy was associated with restoration of endothelial function and increasing microcirculatory blood flow.

CONCLUSION

In the treatment of cutaneous SSc, many agents have been evaluated and failed, likely because the pathogenesis of scleroderma remains poorly understood. In addition, it is unclear how plastic many of the changes are in patients with well-developed disease. Unfortunately, once patients are diagnosed and thought suitable for clinical trials, many of the changes caused by fibrosis and vasculopathy may be irreversible. It is possible that many of the therapies reviewed here would be effective if applied in patients with very early disease—at this time diagnostic criteria do not exist to identify those patients. Thus, the future of therapy for this disease may indeed focus on prevention of progression, and will require both validation of novel diagnostic criteria for early disease as well as markers of skin activity that predict subsequent fibrosis.

Treatment of Vitiligo

36

Ahmad Reza Hossani-Madani, M.D., M.S., and Rebat M. Halder, M.D.

INTRODUCTION

Vitiligo is a disorder of the pigmentary system, where individuals acquire sharply demarcated, depigmented macules in a localized or generalized distribution. These macules appear “milky white” as compared to the surrounding normally pigmented skin. The consensus definition proposed by the Vitiligo European Task Force (VETF) is as follows: “vitiligo vulgaris/NSV (nonsegmental vitiligo) is an acquired chronic pigmentation disorder characterized by white patches, often symmetrical, which usually increases in size with time, corresponding to a substantial loss of functioning epidermal and sometimes hair follicle melanocytes.”¹ This has sometimes been mistaken as leprosy and syphilis.

EPIDEMIOLOGY

This clinical entity occurs worldwide with an overall prevalence of 0.5-1%, and incidence ranges from 0.1 to >8.8%.² The highest incidence of vitiligo has been reported from India, followed by Mexico and Japan.² There does not seem to be a sex predilection and 70-80% of patients usually present before the age of 30.³ There is a positive family history of vitiligo in approximately 20-30% of patients, with data supporting a non-Mendelian, multifactorial, polygenic inheritance pattern.⁴

HISTORICAL BACKGROUND

Descriptions of white skin spots or patches have existed in ancient literature, dating back to at least 1500 BCE. Descriptions of these white spots have been interpreted as, but not limited to, leprosy and vitiligo. The origin of the word vitiligo is debated. Some suggest that the condition resembled the white glistening of the skin of calves (*vituli*), while others believed that it might be from the Latin word for calf, *vitellus*. Still, some believe that the word is derived from the Latin word *vitium*, meaning blemish. The term vitiligo is thought to have first appeared in the first century A.D., by Celsus, in his work *De Medicina*. In the text, translated from the Latin, Celsus writes:

Vitiligo also, though not dangerous in itself, is still ugly and is due to a bad habit of body. There are three species. It is called alphas when it is white in colour, generally rather rough, and not continuous, so that it looks as if drops of some sort had been sprinkled about. Sometimes also, it spreads still more widely with certain gaps. That called melas differs from it in being of a black colour and like a shadow; otherwise it is similar. Leuce is somewhat like alphas, but is whiter and extends deeper; there are hairs on it, white, and like down. All these spread, but more quickly in some people than in others. The alphas and melas come and go at various seasons; the leuce, once established, is not easily got rid of. The two former are not difficult to treat, the latter is scarcely ever cured, for even if the discoloration is mitigated, the colour of health does not right altogether.⁵

Interestingly, Celsus, as mentioned above divided vitiligo into three different subtypes: alphas, melas, and leuce; with none of them fully fitting the clinical definition of present day vitiligo.

PATHOGENESIS

Although the exact cause of vitiligo is not known, researchers have proposed a number of hypotheses to explain the characteristics of the disease. We will briefly review the most common theories.

Genetic Theory

Vitiligo patients are noted to have positive family histories in 6.25-30% of cases.⁶

Additionally, there have been some studies to suggest associations with HLA markers and vitiligo in different ethnic populations. Therefore, a genetic basis for vitiligo has been suggested.

Autoimmune Theory

Because there is complete absence of melanocytes in vitiligo macules, it has been proposed that there is immune destruction of these cells. Additionally, association of vitiligo with other autoimmune diseases has supported the

autoimmune nature. Dr. Lerner mentions in his 1959 paper on vitiligo, "there is evidence that the incidence of vitiligo is increased in hyperthyroidism, pernicious anemia, and Addison's disease. Patients with alopecia areata also are predisposed to development of vitiligo."³ Other evidence includes demonstration of autoantibodies in the sera against tyrosinase and tyrosinase-related proteins 1 and 2 (TRP-1 and TRP-2), T cell infiltrates in marginal skin, and abnormalities in peripheral mononuclear cells.⁶

Neural Theory

The neural theory was propounded by Lerner in his 1959 paper on vitiligo.³ He bases the hypothesis on four main clinical observations: (1) vitiligo has a segmental variant that presents unilaterally and is restricted to one portion of the body (seemingly along a dermatome), (2) vitiligo anecdotally occurs after a stressful event, (3) one patient with transverse myelitis, with paralysis from the waist down, developed vitiligo above the area of cord damage, not below and (4) he found autonomic dysfunction in patches of vitiligo. The theory suggests that nerve endings near melanocytes release a cytotoxic substance that destroys the melanocytes. Other evidence in support of this theory are the abnormalities of nerve growth factor and neuropeptides in nerve endings from perilesional skin.⁶

Self-destruction Theory

This theory suggests that abnormal accumulation of intermediaries of melanogenesis lead to death of melanocytes. This has been supported by the findings that: (1) derivatives of hydroquinone are capable of producing chemical leukoderma, and (2) abnormal pterin homeostasis may lead to elevated H₂O₂, decreased catalase activity, and increased pterin byproducts, causing melanocyte death.⁶

Growth Factor Defect Theory

This theory suggests that growth and maturation capabilities of melanocytes derived from vitiligo, may be defective. This may partially be reversed by the addition of growth factors.⁷

Convergence Theory

This theory suggests that the cause of vitiligo is multi-factorial and may represent a combination of the above-mentioned theories.⁸

CLASSIFICATION

Vitiligo has been classified a number of different ways, but a commonly used form is the following:

1. Localized
 - a. Focal – one or more macules in one area
 - b. Segmental – zosteriform or quasidermatomal pattern
 - c. Mucosal – only mucous membranes
2. Generalized
 - a. Acrofacial – hands/feet and face
 - b. Vulgaris – symmetrically scattered macules over entire body
 - c. Mixed (acrofacial, vulgaris, segmental)
3. Universal (>80% depigmentation)

TREATMENT

A literature search was done between July and November 2009 to identify randomized-controlled trials involving treatment for vitiligo. The studies of Whitton⁹, Gawkroger¹⁰, Njoo⁶, Forschner¹¹, and Falabella⁴ were extremely helpful in identifying papers for review. We took >75% repigmentation as the relevant outcomes for the papers. However, this was not possible in all cases because of the lack of statistical evidence.

Nonsurgical Repigmentation Therapies

Topical Treatments

WHAT IS THE EFFICACY OF TOPICAL STEROIDS VERSUS CONTROL FOR REPIGMENTATION IN VITILIGO?

One meta-analysis and one study was located that used topical steroids in a RCT, that of Kandil, in 1974.¹²

In the meta-analysis, the pooled odds ratio versus placebo for class 3 corticosteroids was 14.32 (95% CI, 2.45-83.72). Topical class 3 and 4 corticosteroids had the highest mean success rates for localized vitiligo (56%; 95% CI, 50-62% and 55%; 95% CI, 49-61%). Atrophy was the most common adverse effect for local corticosteroid therapy.⁶

In the second study, Kandil¹² randomized 19 patients to receive either 0.1% betamethasone valerate in 50% isopropyl alcohol or placebo (unmedicated base) twice daily on the left or right side of their bodies, for 4 months.

Both patients and investigators were blinded to treatment. Response was graded as repigmentation or cure versus no repigmentation. Two patients were lost to follow-up. Seventeen patients completed the trial. Fifteen of 17 lesions had repigmentation or cure in the treatment group, while 0/17 lesions had repigmentation.

After 4 months, six of 17 (35.3%) patients (9 patches) achieved >90% repigmentation, three patients received 25-90% repigmentation, and six patients were beginning repigmentation in the topical steroid group.

ADVERSE EFFECTS

Two patients in the Kandil study were lost to follow-up. Complications in the topical steroid treatment group

included hypertrichosis (2 patients) and a localized acneiform reaction (3 patients).

RECOMMENDATIONS

For localized vitiligo, topical corticosteroids seem to be effective, based on the meta-analysis. However, skin atrophy must be monitored as a potential side effect during treatment. The second study affirms that topical steroids can be somewhat effective in repigmenting vitiliginous skin.

WHAT IS THE EFFICACY OF TOPICAL STEROIDS VERSUS OTHER TREATMENT MODALITIES FOR REPIGMENTATION IN VITILIGO?

Four studies were identified that fit the criteria. Two of the studies, Khalid et al.¹³ and Lepe et al.¹⁴ examine the use of clobetasol in children versus either PUVA or tacrolimus. The other two studies compare betamethasone to either catalase/superoxide dismutase or calcipotriol. We will examine them in that order.

Fifty children under the age of 12 years old were randomly assigned to either treatment with topical 0.05% clobetasol propionate twice daily or topical 8-MOP followed by sunlight exposure (topical PUVA) thrice weekly for 6 months. After every 1.5 months of treatment, topical steroid holidays were given for 2 weeks.

Nine of 22 (40.9%) patients in the steroid group and two of 23 (8.7%) patients in the topical PUVA group achieved >75% repigmentation. Whitton et al. calculated a significantly better repigmentation in the steroid group, as compared to topical PUVA (RR 4.70; 95% CI, 1.14-19.39).⁹

The second clobetasol study, that of Lepe et al.¹⁴ compared 20 symmetrical, vitiliginous lesions after randomization for treatment to topical 0.05% clobetasol propionate or 0.1% tacrolimus twice daily or 2 months.

Treatment was double-blinded and monitored every 2 weeks. Results reveal percent repigmentation of 49.3% versus 41.3% in the clobetasol and tacrolimus groups, respectively. Greater than 75% repigmentation was seen in five of 20 (20%) lesions in both groups, which was not statistically significant.

The third study¹⁵ involved comparison of 0.05% betamethasone to topical catalase/dismutase superoxide in a randomized, double-blind trial. 25 patients, aged 12-74 years old, were randomly divided to the aforementioned treatments on symmetrical vitiligo lesions.

They found that there was no statistical difference in percent repigmentation between the two groups at 4 (5.63% ± 27.9 vs. 3.22% ± 25.8, $P = .758$) and 10 months of therapy (18.5 ± 93.14% vs. 12.4 ± 59%).

The last study is that of Kumaran et al.¹⁶ They randomized 49 patients into three groups: 0.05% betamethasone dipropionate cream (Group I), 0.005% calcipotriol

ointment (Group II), or betamethasone/calcipotriol combination (Group III).

They found that none of the patients, in either group, achieved >75% repigmentation. Time to repigmentation was significantly faster in Group III, as compared to the other two groups (Group I: 9.04 ± 2.0, Group II: 10.18 ± 1.6, Group III: 5.17 ± 2.4, $p < .01$)

ADVERSE EFFECTS

Khalid et al. had two patients experience blistering reactions in the PUVA group. Adverse events in the steroid group were mild atrophy (4 patients), telangiectasia (2 patients), hypertrichosis (1 patient), and acneiform papules (2 patients). Five patients were lost to follow-up.

Lepe et al. had two lesions in the tacrolimus group experience burning. Adverse reactions in the clobetasol group were: atrophy (3 lesions) and telangiectasia (2 patients).

Sanclemente et al. found that one patient had a mild, erythematous, popular rash that self-resolved.

Kumaran et al. found that four patients did not complete 3 months of treatment. Side effects in the steroid group occurred in seven of 15 patients and included lesional atrophy, lesional soreness, lesional dryness, and hypertrichosis. In the calcipotriol group, two of 15 patients side effects, including perilesional hyperpigmentation and irritant reaction. Side effects in the combination group (2/15) included: hypertrichosis and dryness of the skin.

RECOMMENDATIONS

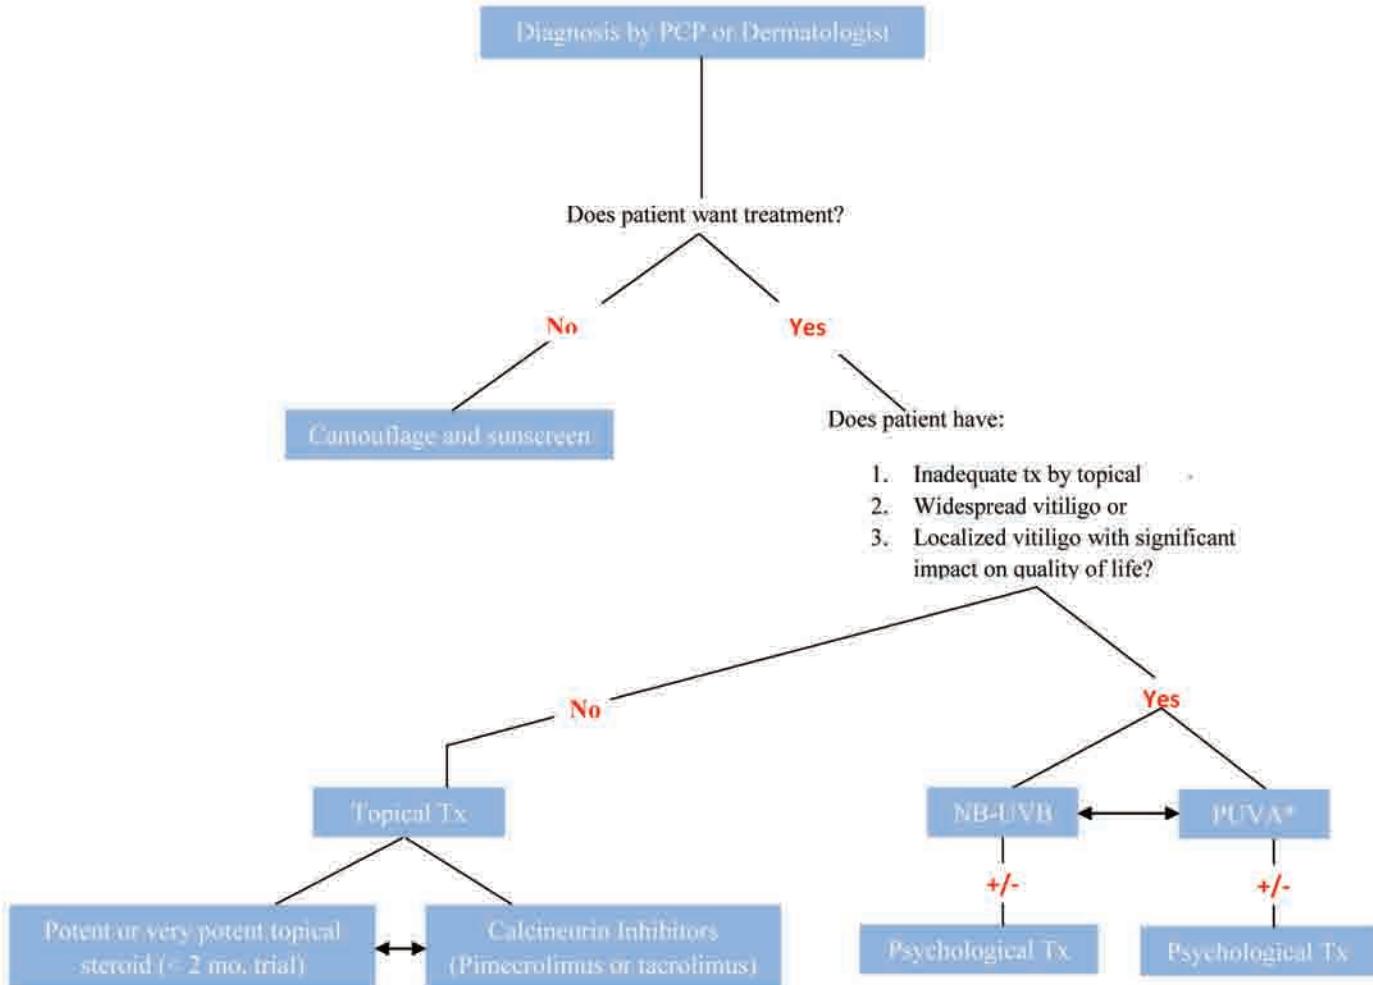

The only treatment that seemed to be inferior to topical steroid was PUVA. These studies reveal that some degree of repigmentation, with improved time to repigmentation may be achieved with topical steroids. However, the side effect profile of steroids tends to make their use more cautious. Steroids have been recommended for first line treatment of localized vitiligo by the meta-analysis of Njoo et al.⁶ However, the calcineurin inhibitors seem to have a safer side effect profile and may be used as alternatives.

WHAT IS THE EFFICACY OF INTRALESIONAL STEROIDS VERSUS CONTROL FOR REPIGMENTATION IN VITILIGO?

One study was identified, employing a randomized, placebo-controlled trial involving injections of 10 mg/mL triamcinolone acetonide suspension or distilled water. Thirty five patients were given weekly treatments for 8 weeks and then followed-up for 4 weeks.¹⁷

Results show that 17/25 (68%) patients in the treatment group and six of 10 (60%) patients in the placebo group achieved a fair to excellent response. Whitton et al. recalculated the statistics to achieve a relative risk (RR) of 0.97 (95% CI, 0.60-1.58), meaning that there was no statistical difference between treatment and placebo groups.⁹

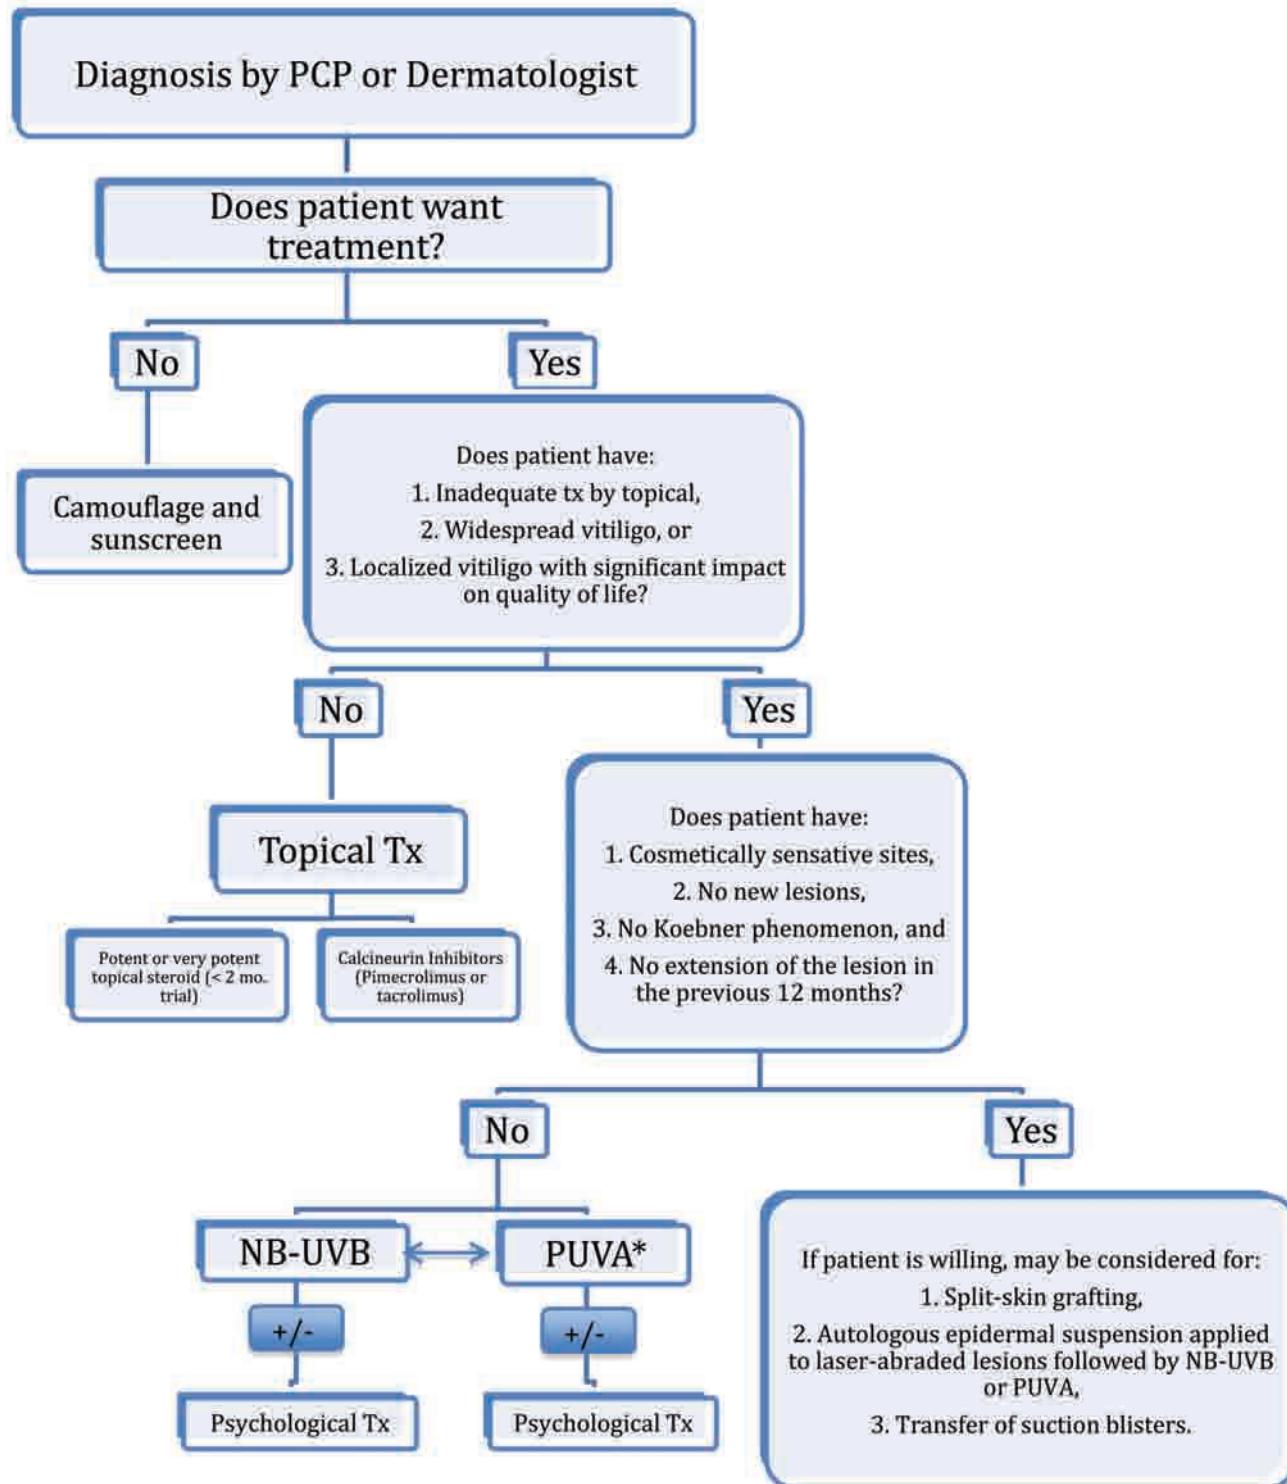

Vitiligo Treatment Algorithm in Children

* relative contraindication for those < 10 years old

FIGURE 36-1 Treatment algorithm for children adapted from Gawkroger DJ, Ormerod AD, Shaw L, et al. Guideline for the diagnosis and management of vitiligo. *Br J Dermatol* 2008;159:1051–76.

Vitiligo Treatment Algorithm in Adults

*Absolute contraindications: systemic lupus erythematosus, previous melanoma, dermatomyositis, xeroderma pigmentosum.

Relative contraindications: Pregnancy, previous non-melanoma skin cancer, current pre-malignant skin condition, cataracts (oral psoralen only)

FIGURE 36-2 Treatment algorithm for adults adapted from Gawkrodger DJ, Ormerod AD, Shaw L, et al. Guideline for the diagnosis and management of vitiligo. *Br J Dermatol* 2008;159:1051–76.

ADVERSE EFFECTS

In the treatment group, adverse effects were as follows: atrophy (8 patients), telangiectasia (2 patients), infection (1 patient), and intradermal hemorrhage (1 patient). The placebo group remained free of adverse effects.

RECOMMENDATION

Based on this one study, a case cannot be made for the use of intralesional steroids.

WHAT IS THE EFFICACY OF CALCINEURIN INHIBITORS VERSUS CONTROL FOR REPIGMENTATION IN VITILIGO?

Two RCTs were identified: One that looked at pimecrolimus and one that looked at different dosings of tacrolimus.

The first is that of Dawid et al.¹⁸ who examined the efficacy of 1% pimecrolimus cream versus placebo. They randomized 20 patients in a left-right manner, to receive treatment twice daily for 6 months. Outcomes measured were size of target lesion and repigmentation at 6 months. Both investigators and patients were blinded to treatment.

They found that 1% pimecrolimus resulted in no significant change in mean target lesion size. Additionally, patients in both groups did not achieve pigmentation >25%. At 6 months, three of 14 in the pimecrolimus groups and two of 14 in vehicle group had 1-25% repigmentation.

The second study¹⁹ looked at 0.1% tacrolimus, evaluating the efficacy of once or twice daily dosing, as opposed to a control lesion, for 6 months. Seventeen patients with generalized vitiligo were randomized for treatment. Fifteen patients with 40 target lesions completed the study. They found that only two lesions (13%) showed >75% repigmentation. In addition, analysis revealed a significantly better treatment outcome for twice-daily tacrolimus than for the untreated control ($P = 0.016$). Only one patient had 26-50% repigmentation in the control group.

ADVERSE EFFECTS

In the first study, four patients did not complete the study because of personal reasons (1 patient), presumed lack of efficacy (2 patients), and lost to follow-up (1 patient). No adverse effects were noted.

The second study lost two patients to follow-up, with reasons unexplained. No mention of adverse effects was made.

RECOMMENDATIONS

From these studies, it seems that topical calcineurin inhibitors may induce pigmentary responses, but not great enough to achieve >75% repigmentation. They may be tried because of favorable side effect profile.

Phototherapy

WHAT IS THE EFFICACY OF NARROWBAND UVB MONOTHERAPY VERSUS CONTROL IN VITILIGO?

Despite the presence of a good number of studies involving the use of UVB, only one study was found comparing narrowband UV-B (NB-UV-B) to control. In the study by Hamzavi and his group in 2004,²⁰ a prospective, coin-toss randomized, left-right controlled comparison trial was done on 22 vitiligo patients. Inclusion criteria included symmetric involvement, >5% total body surface area involvement, >18 years old, no significant medical problems, no treatment with a photosensitizing agent, and no topical or systemic treatment for 2 weeks prior to start of the therapy or during treatment. The side of the body exposed to NB-UV-B was randomly chosen, with the contralateral body half covered with a UV proof gown ("no light exposure"). If the face was included, it was treated completely. Therapy commenced thrice weekly for 6 months or 60 cumulative treatments, whichever came first. They measured body surface area vitiligo involvement, monthly, using their own quantitative tool, the Vitiligo Area Scoring Index (VASI). Additionally, total body photography was done monthly for validation of the VASI. They found that the extent of repigmentation in the NB-UV-B was 42.9% (95% CI, 26.7%-59%) versus 3.3% (95% CI, -19.3%-30.0%) on the untreated side ($P<.001$). They found the legs, trunk, and arms more likely to pigment than the feet and hands.

A meta-analysis of the literature by Njoo et al. in 1999⁶ revealed NB-UV-B therapy to be the safest and most effective therapy (63% success rate, 95% CI, 50-76%) for generalized vitiligo (>2% depigmentation) over a 6-24 month course.

ADVERSE EVENTS

According to Hamzavi et al.²⁰ hyperpigmentation of newly repigmented skin occurred, in addition to mild phototoxic effects. Hyperpigmentation resolved within the 6-month period for all patients in which it occurred. One patient dropped out of the study because of hyperpigmentation. However, the authors state that "twenty-two patients were recruited and treated from July 2000 to February 2001, and all were included in the analysis," creating confusion as to whether the dropped out patient's data was used.

RECOMMENDATIONS

There is a paucity of data from randomized clinical trials to be able to make firm statements in regards to clinical practice. However, the meta-analysis, by Njoo et al. points to the fact that NB-UV-B, as monotherapy, is the safest and least harmful treatment in generalized vitiligo.

WHAT IS THE EFFICACY OF PUVA SOL VERSUS CONTROL FOR REPIGMENTATION IN VITILIGO?

In the evaluation of research involving oral or topical psoralens with subsequent exposure to sunlight, three studies were found that were randomized-controlled clinical trials. The first study, by Pathak et al.²¹ in the 1980s, began as a double-blind, randomized-controlled trial with placebo, but had the placebo group terminated after 9-12 months of treatment for ethical reasons. They initially began with 566 East Indian patients, but had 366 patients complete the study and undergo analysis after 2 years. The patients were divided into 9 treatment groups with varying oral doses of the following compounds plus sunlight exposure: 8-methoxypсорален (8-MOP), 4,5,8-trimethylpsoralen (TMP), psoralen, or placebo. The groups were divided as follows: (1) 0.3 mg/kg 8-MOP, (2) 0.6 mg/kg 8-MOP, (3) 0.8 mg/kg TMP, (4) 1.8 mg/kg TMP, (5) 3.6 mg/kg TMP, (6) 0.3 mg/kg 8-MOP + 0.6 mg/kg TMP, (7) 0.6 mg/kg psoralen, (8) 1.2 mg/kg psoralen, and (9) placebo.

Patients were exposed to the sun, 2 hours after oral ingestion of the drug or placebo, for 45-60 minutes in gradually increasing doses between 11 a.m. and 2 p.m. thrice weekly. Patients were photographed approximately every 6 months during the 2-year treatment period. Repigmentation was measured as the outcome, with overall repigmentation expressed as a percentage of body surface area. The body was divided into different regions for analysis, including the face, head and neck, trunk, arms and legs, lips, hands, feet, palms and soles. Overall, the greatest pigmentation was achieved by the combination of 8-MOP and TMP at 38%, followed by the lower 0.3 mg/kg 8-MOP dose at 31%, and then the higher 0.6 mg/kg 8-MOP dose at 25%. The face, followed by the head and neck, showed the greatest response to treatment and the hands, feet, palms, and soles showed the worse responses, respectively. Almost half of the total number of patients in the 8-MOP/TMP combination and low dose 8-MOP groups achieved full repigmentation of the face, and 60% of the two groups achieved 75-100% repigmentation of the head and neck. Lastly, they found that the 8-MOP/TMP combination group had a statistically significant 19 fold greater rate of successful repigmentation (defined as 75-95% repigmentation response) as compared to placebo (RR 19.20; 95% CI 1.21-304.5). However, this must be viewed with caution for two reasons: (1) we previously mentioned that the placebo group did not complete the study, (2) the confidence intervals for the combination group, as compared to placebo, is wide.

A second study, by Maldonado et al,²² was published in the Spanish literature in 1975. This study employed a randomized, placebo-controlled design, on 50 children, lasting 8 months. Children were given oral trimethylpsoralen in doses ranging from 10-30 mg/day and then exposed either to a sun lamp or to sunlight. Those exposed to the

sunlamp received the TMP 3 hours before exposure, while those randomized to receive sunlight took one dose of TMP after breakfast and the other after lunch. Children randomized to the placebo group received their doses in a fashion similar to the treatment group. Exposure ranged from 3-30 minutes daily until erythema appeared. Patient pigmentary improvement was graded as slight, marked, or clinically cured. They found that the children in the TMP + sunlight/sunlamp group were two times more likely to achieve improvement than those in the placebo + sunlight/sunlamp group (RR 2.29; 95% CI 1.14-4.58).

The third study is the randomized, controlled trial of Farah et al.²³ published in 1965. They enrolled 88 patients and randomly divided them into four groups: (1) oral psoralen + sunlight, (2) topical psoralen + sunlight, (3) oral 20 mg methoxypсорален/8-12 mg triamcinolone daily + sunlight, (4) no treatment or dihydroxyacetone for cosmetic effects. Patients in the treatment groups were exposed to sunlight at midday, 2 hours after ingestion or directly after topical application of the treatment. Thirty-four of 61 patients in the treatments groups were followed up, with the fate of those who were lost to follow-up being unexplained. The number of patients who finished the study in the nontreatment/dihydroxyacetone group was not disclosed. Outcomes were graded as "good" or "none," with "good" meaning >50% repigmentation in the vitiliginous patches. A "good" response to treatment was found as follows: two of nine in the oral psoralen group, two of 10 in the topical psoralen group, 14/15 in the oral methoxypсорален/triamcinolone group, and none in the non-treatment group. The response in the combination group took 3-4 weeks to become evident, with some continuing treatment for 7 months. This study did not employ rigorous statistical analysis and details of patient demographics are lacking.

Lastly, the meta-analysis by Njoo et al.⁶ demonstrated odds ratios for oral 8-MOP, TMP, and psoralen individually, plus sunlight versus placebo as 23.37 (95% CI, 1.33-409.93), 3.75 (95% CI, 1.24-11.29), and 19.87 (95% CI, 2.37-166.32) respectively. This meta-analysis included the results from the above three studies of Pathak et al. Maldonado et al. and Farah et al.

ADVERSE REACTIONS

Forty-nine percent of all patients, in the Pathak et al. study reported side effects. Side effects included: nausea, pruritus, dizziness, headaches, eye discomfort, and gastrointestinal symptoms. The group reporting the highest number of side effects was the combination 8-MOP/TMP group.

Maldonado et al. had three children in the placebo group withdraw from the study.

Lastly, the study of Farah et al. does not make mention of adverse reactions or reasons for withdrawal from the study. The author writes that "the results are recognized as preliminary and do not include prolonged follow-ups."

RECOMMENDATIONS

From the above studies, it can be said that PUVA may be effective in repigmentation, but its results and side effects are difficult to control. Therefore, NB-UVB, or PUVA is preferred over PUVA.

WHAT IS THE EFFICACY OF ORAL OR TOPICAL PUVA VERSUS CONTROL FOR REPIGMENTATION IN VITILIGO?

Unfortunately, there are no identified randomized clinical trials comparing oral or topical PUVA with controls. However, the meta-analysis of Njoo et al.⁶ describes a success rate of 51% (95% CI, 46-56%) for oral methoxsalen and UV-A in generalized vitiligo.

ADVERSE REACTIONS

Njoo et al. state that oral methoxsalen and UV-A resulted in the highest rates of adverse effects, including: (1) nausea and vomiting in 29% (95% CI, 24-35%), and (2) phototoxic reactions in 25% (95% CI, 20-30%).⁶

RECOMMENDATIONS

Randomized, clinical trials involving oral or topical PUVA versus placebo for the treatment of vitiligo are lacking in the literature. However, if we examine the meta-analysis of Njoo et al.⁶ we may say that oral PUVA is the third most effective treatment in generalized vitiligo, following narrowband UV-B and broadband UV-B.⁶ However, there are greater side effects with PUVA treatment as compared to all other treatments.

WHAT IS THE EFFICACY OF NARROWBAND UV-B VERSUS ORAL PUVA FOR REPIGMENTATION IN VITILIGO?

Although there are a number of studies comparing narrowband UV-B to oral PUVA, including those of Westerhoff et al. Bhatnagar et al. and el-Mofty et al. they do not fit the criteria for randomized-controlled trials. The only study found to be a RCT was that of Yones et al. published in 2007.²⁴

Fifty-six patients were recruited and randomly divided into two treatment groups: (1) 25 mg/m² 8-MOP or 50 mg/m² 5-MOP (if the patient had nausea with 8-MOP) + UVA, or (2) placebo + NB-UVB. Both observers and patients were blinded to treatment and the patients received therapy twice weekly.

NB-UVB was started at a dose of 0.1 J/cm² and PUVA at 0.5 J/cm². Patients had body surface area (BSA) involved with vitiligo assessed at commencement and after every 16 sessions, using a Wood's lamp and photography. Participants also completed Dermatology Life Quality Index (DLQI) and visual analog scale (VAS) questionnaires

during the assessments. Outcomes measured were the change in BSA affected by vitiligo and the color match of the repigmented skin compared with unaffected skin after 48 treatments, at the end of therapy, and 1 year after the end of therapy.

Twenty-five patients in each group were included in the final analysis. The median number of treatments in the PUVA group was 47, compared to 97 in the NB-UVB group ($z = 2.1; p = 0.3$). In regards to BSA repigmentation, they looked at improvement at the end of treatment and after 48 treatments (for those who completed that many treatments). At the end of treatment, they found that 16/25 (64%) of patients in the NB-UVB group versus 9/25 (36%) in the PUVA group showed greater than 50% improvement in BSA repigmentation. Although the NB-UVB group tended to produce greater repigmentation than the PUVA group, this trend lacked significance ($p = .06$). After 48 treatments, there was a statistically significant increased efficacy for greater than 50% BSA repigmentation in the NB-UVB (11/21, 53%) versus the PUVA group (3/13, 23%) ($z = 2.3; p = .007$). If we were to take successful repigmentation to mean >75%, as done in the Cochrane review by Whitton et al. we find that at the end of treatment, five of 25 (20%) showed successful repigmentation in the PUVA group and eight of 25 (32%) in the NB-UVB group. In those completing 48 treatments, we find 0/13 (0%) in the PUVA group and one of 21 (5%) in the NB-UVB group with >75% repigmentation. Lastly, repigmentation color match was excellent in all of those in the NB-UVB group, but only in 11 patients (44%) in the PUVA group. ($\chi^2_1 = 19, P < .001$). At the end of the 1 year follow-up, the color match of all patients in NB-UVB group remained excellent, but was excellent in only 14/23 patients (61%) of the PUVA group (NB-UVB vs. PUVA: $\chi^2_1 = 12, P < .001$).

ADVERSE REACTIONS

Firstly, of the 56 patients that were initially recruited (28 in each group), three patients from each group did not commence treatment, for unknown reasons. Secondly, of the 25 patients in the PUVA group, eight patients (32%) had to be switched from 8-MOP to 5-MOP because of nausea. Thirdly, erythematous reactions were classified as Grade 1, just perceptible, or Grade 2, easily perceptible but causing no symptoms or only mild discomfort. The median number of erythema episodes was 9 in the PUVA group and 2 in the NB-UVB group ($z = 3.7, P < .001$). Seven of eight Grade 2 erythema reactions overall were in the PUVA group, with one patient in the PUVA group discontinuing treatment because of adverse effects, as compared to none in the NB-UVB group. Lastly, although the authors did not consider a hyperpigmentary repigmentation to PUVA an adverse effect, they found that 12 patients in the PUVA group had repigmentation that was noticeably darker than unaffected skin.

RECOMMENDATIONS

This study is the first RCT to effectively demonstrate that NB-UVB is superior to PUVA in terms of side effects, efficacy of repigmentation, color match of repigmentation, and efficacy 1 year post-treatment. However, their >75% repigmentation efficacy rates seem lower than previously published data (NB-UVB: 63% success rate, 95% CI, 50-76%; oral methoxsalen + UVA: (51% success rate, 95% CI, 46-56%) for either modality individually.⁶ However, the authors add that NB-UVB is more favorable than PUVA because of no need for oral medication, lack of need for eye protection post-treatment, it may be used in pregnancy, is not contraindicated in hepatic impairment, or for those on warfarin or phenytoin, and has less potential for development of skin cancer.

WHAT IS THE EFFICACY OF THE EXCIMER LASER (308 NM) VERSUS PLACEBO FOR REPIGMENTATION IN VITILIGO?

There is only one RCT, to our knowledge, that compared the 308 nm excimer laser with control lesions. The study of Passeron et al.²⁵ compared topical 0.1% tacrolimus + 308 nm excimer laser with 308 nm excimer laser monotherapy.²³ However, as part of the excimer laser monotherapy, the investigators compared symmetrical, untreated, control lesions on the opposite side.

In the study, 14 patients, age 12-63 years old, had 4 to 10 target lesions chosen (2-5 vitiliginous macules treated by the combination either therapy or laser monotherapy and 2-5 untreated vitiliginous macules on the opposite side). The treatment applied to each target lesion was randomly selected by drawing lots and treated twice weekly, for a maximum of 24 sessions. Repigmentation was graded on a 0-5 scale as follows: 0 – no repigmentation, 1 – 1-24% repigmentation, 2 – 25-49% repigmentation, 3 – 50-74% repigmentation, 4 – 75-99% repigmentation and 5 – total repigmentation. Efficacy was evaluated by two blinded, independent physicians.

They found that no repigmentation occurred in the untreated, control areas, while 17/20 lesions (85%) in the excimer only group showed repigmentation. However, only four of 20 (20%) lesions showed greater than 75% repigmentation in the excimer only group, which was not statistically significant compared with untreated lesions ($P = .15$). The authors state that the lack of statistical significance may be attributed to small sample size.

ADVERSE EVENTS

All patients experienced moderate to severe erythema at least once, and four lesions (2 in excimer alone group) had localized bullous eruptions.

RECOMMENDATIONS

The excimer laser is a relatively newer treatment, used since 2001 for the treatment of vitiligo. From this study, it seems that the excimer laser is effective in causing repigmentation. However, the extent of repigmentation may not be cosmetically adequate. It may be that repigmentation will increase with the number of treatments. It has the advantage of selectively targeting vitiliginous lesions, sparing unaffected skin. More studies are needed to adequately identify its role in vitiligo therapy.

WHAT IS THE EFFICACY OF NB-UVB VERSUS 308 NM MONOCHROMATIC EXCIMER LIGHT FOR REPIGMENTATION IN VITILIGO?

One RCT was identified, by Casacci et al.²⁶ that compared the 308 nm monochromatic excimer light (MEL) with NB-UVB.²⁴ They conducted the study in two centers, one in Italy, the other in France. A left-right randomized, investigator-blinded trial was undertaken with 21 vitiligo patients. Patients ranged from 16-58 years old, with a median age of 38 years old, and varied from skin types II-IV. Corresponding vitiliginous lesions on opposite sides of the body were randomized to receive either NB-UVB or the 308 nm MEL.

Treatment started at 70% of the minimal erythema dose (MED), determined prior to study commencement, and comprised of twice-weekly treatment for 6 months. Treatment was evaluated via clinical examination and photography at baseline and twice monthly. Repigmentation was graded from 0-4 with the score divided as follows: 0-no repigmentation, 1-poor repigmentation ($\leq 25\%$), 2-moderate repigmentation (26-50%), 3-good repigmentation (51-75%), 4-excellent repigmentation (76-100%). Five patients did not complete the study, leaving 16 patients that were included in the results. Lesions with >75% repigmentation included 6/16 (37.5%) in the 308 nm MEL group and 1/16 (6%) in the NB-UVB group. Bilateral areas chosen for treatment included 7 elbows, 4 knees, 2 backs, 1 neck, 1 axillae, and 1 lower limb.

The mean repigmentation score was significantly higher for the 308 nm MEL compared with NB-UVB (2.68 ± 1.35 vs. 2.12 ± 1.02 , $P = .04$). There was no statistically significant difference in treatment time required to achieve follicular repigmentation; however, there was a significant difference for peripheral repigmentation (308 nm MEL: 22.46 ± 8.25 , NB-UVB: 27.63 ± 9.37 ; $P = .0066$). The cumulative UV dose was also significantly lower in the 308 nm MEL group as compared to the NB-UVB group (38.97 ± 4.83 J/cm² vs. 59.43 ± 15.35 J/cm²; $P < .0001$).

ADVERSE EFFECTS

The authors state that symptomatic erythema occurred in nine of 16 (56.2%) patients during the first 12 treatments.

However, they do not state within which groups the erythema occurred. They do state that the side effects were similar between the groups. Five patients did not complete the study, with noncompliance given as the most common reason. No patients experienced blistering reactions.

RECOMMENDATIONS

The 308 nm MEL has at least similar efficacy as NB-UVB in the treatment of localized vitiligo lesions, in this study. There seems to be a faster time to peripheral repigmentation, with lower cumulative UV doses with the 308 nm MEL. Additionally, for localized vitiligo, there is the advantage of avoiding treatment of unaffected skin.

WHAT IS THE EFFICACY OF NB-UVB VERSUS NB-UVB COMBINATION THERAPIES FOR REPIGMENTATION IN VITILIGO?

NB-UVB VERSUS NB-UVB + ORAL ANTIOXIDANTS

Three RCTs were identified that compared conventional NB-UVB to NB-UVB combination therapy with oral antioxidants. The study of Dell'Anna et al.²⁷ combined NB-UVB with an oral antioxidant pool (AP) (α -lipoic acid, vitamins C and E, polyunsaturated fatty acids, and cysteine monohydrate), while that of Middelkamp-Hup et al.²⁸ combined NB-UVB with oral polypodium leucotomos extract, and Elgoweini et al.²⁹ combined NB-UVB with oral vitamin E. We will examine the studies in the above order.

Dell'Anna et al. employed a randomized, double-blind, placebo-controlled, multicenter trial, dividing 35 patients with generalized vitiligo into NB-UVB + placebo or NB-UVB + AP (50 mg α -lipoic acid, 50 mg vitamins C, 20 mg vitamin E, 12% polyunsaturated fatty acids, 50 mg cysteine monohydrate) groups. Patient age ranged from 24–61 years old, with a mean of 39.9 years. Patients began taking 2 tablets of the oral supplements daily 2 months before commencement of NB-UVB therapy, and continued for 6 months during concurrent phototherapy. NB-UVB was administered twice weekly, with a starting dose of 70% of the MED (of unaffected skin).

Two blinded investigators assessed the participants for size and number of lesions at a screening visit before therapy, after 2 months of placebo or AP but before commencement of NB-UVB, and at the end of 6 months of concurrent treatment. Patients were photographed and repigmentation was graded on a scale of 0–3: 0-absent, 1-moderate (< 50%), 2-good (51–75%), 3-excellent (>75%) for each lesion. Additionally, blood was drawn during the assessments and analyzed for peripheral blood mononuclear cell (PMBC) redox status. Twenty-eight of the 35 patients completed therapy with full compliance and were included in analysis.

The investigators found that eight of 17 (47%) of the patients in the NB-UVB + AP group, compared with 2/11

(18%) in the NB-UVB + placebo group, developed >75% repigmentation ($p <.05$). Best responses were noted on the face, neck, and proximal limbs. The average number of treatments to achieve >50% repigmentation was 18 in NB-UVB + AP group compared to 23 in the NB-UVB + placebo group. In terms of redox status, they found that both catalase activity was significantly higher (164 ± 43 U/mg protein vs 139 ± 31 U/mg protein, $p <.05$) and reactive oxygen species (ROS) significantly decreased (60% from baseline, $p <.02$) in the AP group, as compared to the placebo group, at the end of therapy.

The second study, that of Middelkamp-Hup et al. was undertaken to investigate the antioxidative and immunomodulatory effects of the plant extract, *polypodium leucotomos*, on vitiligo. Fifty patients, aged 22–65, with vitiligo vulgaris were randomly assigned to receive 250 mg of oral *P. leucotomos* or placebo three times daily, combined with NB-UVB twice weekly for 25–26 weeks.

Both investigators and patients were blinded to treatment group. Assessment of repigmentation was done via clinical examination and photography at the beginning and end of the study. Patients, additionally, underwent vitiligo severity grading by the investigators and self-assessment, completed a survey on the effect of treatment on quality of life, and had blood drawn for cytokine analysis. One patient was lost to follow-up in the placebo group.

The study revealed that there was no significant difference in the treatment, compared with the placebo group, in percentage of repigmentation obtained at the end of the study. The mean cumulative dose was similar for both the treatment and placebo groups (49 J/cm^2 vs 52 J/cm^2). However, if the intention to treat analysis was abandoned and calculations were done for those who attended >80% of the phototherapy sessions, we find that the treatment group had statistically greater repigmentation than placebo in the head and neck area (50%; 95% CI 36–64 vs 19%; 95% CI 7–31; $P <.002$). Secondly, there was no significant difference was found in the change in quality of life between groups during their assessment. Lastly, no clear trends were observed in the detected cytokines in blood samples, with numbers too small to make conclusions.

The last study is that of Elgoweini et al. where 24 patients, aged 19–50 years, with stable vitiligo were divided randomly into two treatment groups. Group A included patients treated with NB-UVB + oral vitamin E (400 IU alpha-tocopherol) daily, starting 2 weeks prior to NB-UVB therapy (12 patients). Group B included patients treated with NB-UVB as monotherapy (12 patients). Both groups had NB-UVB therapy administered 3 times per week for 6 months.

Improvement was recorded at the beginning and end of treatment, by two independent observers, depending on the extent of repigmentation in the existing lesions. This was graded as none (0%), mild (1%–25%), moderate (26%–50%), marked (51%–75%), and excellent (>75%). Response

to the treatment was also evaluated by digital photography. Blood samples were drawn for analysis of lipid peroxidation (malondialdehyde [MDA]) and reduced glutathione (GSH). Three of 12 patients in the NB-UVB group and one of 12 patients in the NB-UVB + oral vitamin E group did not complete the study.

The investigators state that marked to excellent repigmentation (51-100%) of the vitiliginous lesions was noted in eight of 11 (72.7%) patients in group A and in five of 9 (55.6%) patients in group B. However, there is no statistical analysis of repigmentation percentages for significance. Additionally, the exact numbers of patients achieving >75% repigmentation are not clearly stated in the paper. They, further, claim that number of treatments needed to achieve 50% repigmentation was significantly less in Group A (16 treatments) compared with Group B (20 treatments), and Group A patients experienced less mild erythema (70%) compared to Group B (85%). Again, calculations of *p* values were not shown for these numbers. Lastly, a significant reduction in plasma malondialdehyde, a marker of lipid peroxidation, was found in Group A compared to Group B (*P* <.001).

ADVERSE EFFECTS

Dell'Anna et al. had seven of 35 (20%) patients drop out of the study. Reasons cited, according to the authors, were unrelated to therapy and included: fever, physical trauma, and job changes. They also stated that of those individuals who completed the study, adverse effects were minimal, with no patient requiring suspension or discontinuation of therapy. However, they did not elucidate the nature of the minimal effects.

Middelkamp-Hup et al. had one of 50 patients drop out of the study on the last visit for unknown reasons. Of the 49/50 that completed the study, 10/25 in the *P. leucotomos* group and five of 24 in the placebo group experienced transient itching. Additionally, five of 25 in the *P. leucotomos* group and three of 24 in the placebo group experienced dryness of the skin. Lastly, four of 25 in the *P. leucotomos* group and five of 24 in the placebo group experienced mild gastrointestinal complaints secondary to capsule intake.

Elgoweini et al. had one of 12 patients in the NB-UVB + oral vitamin E group and three of 12 patients in the NB-UVB group discontinue therapy. The authors stated that reasons for discontinuation were unrelated to treatment. Mild erythema was experienced by 70% of those in the NB-UVB + vitamin E group and 85% of those in the NB-UVB group.

RECOMMENDATIONS

From these three studies, it may be concluded that the evidence to support oral antioxidants as an effective adjunct to NB-UVB in the treatment of vitiligo is weak at

present, because of small patient numbers and employment of different antioxidants. It seems that the best responses were found in the facial region in all three studies. Effectiveness seemed to vary, based on the study, with the number of patients with greater than 75% repigmentation not being clearly described in one study, (Elgoweini et al.). Each study looked at different antioxidants or combinations of antioxidants, making comparison difficult. Further studies with a standardized repigmentation grading system are in order to further clarify the role of antioxidants in treatment.

NB-UVB VERSUS NB-UVB + TOPICAL

VITAMIN D₃ ANALOGUE

There are two identified RCT in the literature employing vitamin D₃ analogues: (1) NB-UVB + topical calcipotriol (Arca et al.)³⁰ and (2) NB-UVB + topical tacalcitol (Leone et al.)³¹ published in 2006.

The study of Arca et al.²⁸ enrolled 40 stable, nonsegmental vitiligo patients into two randomly assigned NB-UVB groups: (1) NB-UVB monotherapy (24 patients), and (2) NB-UVB + 0.05% topical calcipotriol twice daily (13 patients). NB-UVB was given three times weekly for 30 treatment sessions. Those in the topical calcipotriol group applied ointment after phototherapy. There was no placebo ointment and no mention was made of investigator or patient blinding.

Treatment was monitored by photography before the beginning and at the end of the treatment. Repigmentation was visually scored as: minimal (0-24%), moderate (24-49%) and marked to complete (50-100%). Thirty-seven of 40 patients completed the study and were included in the analysis.

They found that although both groups had statistically significant reductions in body surface area affected by vitiligo (NB-UVB: $27.21 \pm 10.41\%$ to $16.25 \pm 8.54\%$, *p* <.001; NB-UVB + calcipotriol: $23.35 \pm 6.5\%$ to $13.23 \pm 7.05\%$, *p* <.001) comparison of the reduction in repigmentation rates between the two groups showed no statistically significant difference (*P* > .05). The repigmentation was 50-100% for 10/24 (41.67%) patients in the NB-UVB group and 6/13 patients in the NB-UVB + calcipotriol group. This study did not employ >75% repigmentation as a clinical endpoint, and thus did not provide a breakdown of patients in that manner.

The second study randomly assigned 32 subjects, aged 18-54, with generalized vitiligo and symmetrical lesions to treatment with either NB-UVB or NB-UVB plus 4 µg/g tacalcitol applied daily. A left-right randomization was employed, with investigator blinding. Sixty four lesions were selected with locations on the face (12 pairs), axillae (10 pairs), elbows (5 pairs), knees (3 pairs) and forearms (2 pairs). NB-UVB therapy consisted of twice-weekly treatments for up to 6 months, starting with 70% of MED.

One investigator assessed repigmentation at the beginning and at the end of treatment, with photographs taken every 4 weeks. Repigmentation was scored 0-3 as follows: 0-none, 1-moderate (<50%), 2-good (50-80%), 3-excellent (>80%). Patients were also classified as “good responders,” “responders,” and “nonresponders.” However, the definition of the groups is not given in the paper.

The study showed that lesions treated with combination therapy showed significantly higher repigmentation scores than those with NB-UVB alone ($p<.0005$) at the end of the study. 16/32 (50%) lesions in the combination group versus 0/32 (0%) were scored as >80% pigmentation (score 3) at the end of 6 months of treatment. Lastly, those lesions in the combination group classified as “good responders,” (23 lesions) showed quicker onset of repigmentation compared with those in the NB-UVB group classified as “good responders” (23 lesions) (55 ± 25 days vs 130 ± 39 days).

ADVERSE EFFECTS

Arca et al. lost three of 40 patients (0.075%) in their study: one in NB-UVB group and two in the NB-UVB + calcipotriol group. The patients left for personal reasons. Individuals who completed the study experienced mild, transient itching or erythema as a side effect.

Leone et al. had no patients lost to follow-up. They state that the combination treatment was generally well tolerated, with side effects limited to mild erythema and itching. Of the 12 subjects treated on the face with combination treatment, most experienced mild irritation and desquamation following ointment application.

RECOMMENDATIONS

The top two studies present conflicting information with similar treatments. Arca et al. found no significant difference between treatment groups, while Leone et al. found the differences significant at all points during the study. The difference may be attributed to the first study examining repigmentation in the entire body, as opposed to the second study examining repigmentation in single lesions. No recommendations can be made based on the data.

NB-UVB VERSUS NB-UVB + TOPICAL TACROLIMUS

One randomized, placebo-controlled, double-blind trial was identified that compared NB-UVB with NB-UVB plus 0.1% tacrolimus ointment. This was done by Mehrabi and Pandya and published in 2006.³²

They recruited nine patients and randomly assigned paired vitiligo patches to either placebo (petrolatum) or treatment with 0.1% tacrolimus ointment twice daily, followed by NB-UVB three times weekly for 12 weeks. The starting dose was determined to be 70% of the minimal erythema dose for a patient with type 1 skin.

Blinded investigators examined the patients at 4-week intervals with concomitant photography of the target lesions. An image computer program was used to calculate the surface area affected by vitiligo in the target areas. Eight of the 9 patients completed the study.

They found that both sides had improved repigmentation overall. However, there was no statistically significant difference between the two groups (NB-UVB + placebo: 41.28% improvement versus NB-UVB, + tacrolimus: 49.24% improvement).

ADVERSE EFFECTS

One patient was withdrawn from the study at week 7 because she had missed nine of 20 NB-UVB treatments. The authors stated that common adverse effects reported by the 9 patients included redness (78%) and itching (89%). Less frequent complaints included non-specific blistering (44%) and a burning sensation (44%). Slight vesicle formation was noted on examination of two patients, resulting in withholding of 1 light treatment each and in the reduction of the next treatment dose by 10%.

RECOMMENDATIONS

This study did not show any benefit from tacrolimus in addition to NB-UVB. However, no definite recommendations can be made based on the results of this one study.

NB-UVB VERSUS NB-UVB + TOPICAL PSEUDOCATALASE

One randomized, double-blind, placebo-controlled trial was identified that investigated the utility of twice daily pseudocatalase cream in conjunction with NB-UVB versus NB-UVB plus placebo for 24 weeks. et al.³³

Thirty-nine patients were initially recruited and divided into treatment and placebo groups on an intention to treat (ITT) and per-protocol population (PPP) basis. Seven patients withdrew prior to commencement of the study. Patients applied either placebo or pseudocatalase to the entire body and received NB-UVB 10-30 minutes after application, three times weekly.

Patients were assessed during four visits: (1) initial screening, (2) extent of vitiligo assessed and photography of the hands and face done, (3) 12 weeks (photographs taken), (4) 24 weeks (photographs taken). Hand/face repigmentation analysis was done via digital photography and investigator assessment, while the whole body was only assessed by the investigator (without pictures). Fourteen patients in the treatment group and 18 patients in the placebo group commenced the study. Twelve of 14 patients in the treatment group and 13/18 patients in the placebo group completed the 24-week trial.

The analysis showed that there was no statistically significant difference between treatment groups on digital photography of the face and hands. There was a significant difference from baseline to the end of treatment, within groups, for the pseudocatalase group on the left and right face ($P = .0001$ and $P = .005$, respectively) and placebo group ($P = .003$ and $P = .01$)

ADVERSE EFFECTS

Seven patients withdrew prior to commencement of the study, with reasons cited as refusal to cooperate, screen failure, and going overseas. Another seven patients withdrew after commencement of the study: two in the treatment group and five in the placebo group. Reasons cited for withdrawal after commencement were, refusal to cooperate, personal reasons, and one adverse reaction (anxiety). The most common treatment-related adverse events were: pruritus, increased sweating, and thermal burns secondary to radiation therapy.

RECOMMENDATIONS

This study made use of pseudocatalase cream as an adjunct treatment. Assessment of efficacy; however, was mainly examined on the hands and face. Perhaps future studies should quantify repigmentation on the entire body. From this one study, a role for pseudocatalase, in addition to NB-UVB, has not been established.

NB-UVB VERSUS NB-UVB + VITAMIN B12/FOLIC ACID

The study of Tjioe et al.³⁴ explored the utility of vitamin B12 and folic acid as adjunctive treatments to NB-UVB. Twenty-seven patients, 20–68 years old, were randomized to receive NB-UVB or NB-UVB plus 1000- μ g vitamin B12/5 mg folic acid twice daily. Patients were given phototherapy 3 times a week, starting at 0.10 J/cm² and increasing by 0.30 J/cm², for 1 year. Assessment of repigmentation was accomplished by visual scoring monthly, and with before and after photographs. No placebo capsules were used during the study and there is no mention of investigator blinding.

They found that although NB-UVB was effective in repigmentation, there was no statistical difference between the two patient groups ($p \geq .175$). They further found that >90% repigmentation was found on the face, neck and throat, lower arm, chest, back and lower legs, while less than 25% repigmentation was seen on the hands, wrists, feet and ankles.

ADVERSE EFFECTS

Transient erythema was observed in all patients occasionally, although mild.

RECOMMENDATIONS

This study does not give repigmentation statistics in a written form, comparing the two groups. In addition, this study lacked a placebo control and investigator blinding was unclear. Based on this one study, clear recommendations cannot be made for use of vitamin B12/folic acid combinations in the treatment of vitiligo.

Surgical Repigmentation Therapies

Autologous Transplantation Techniques

WHAT IS THE EFFICACY OF NONCULTURED, AUTOLOGOUS EPIDERMAL CELL SUSPENSION TRANSPLANTS VERSUS PLACEBO FOR REPIGMENTATION IN VITILIGO?

A literature review revealed three RCT and one meta-analysis, to our knowledge, involving the use of noncultured, autologous epidermal cell suspension transplants for the treatment of vitiligo. We will examine these reports from oldest to most recent.

The first study if the meta-analysis by Njoo et Al.,⁶ published in 1999. They did a systematic review of autologous transplantation methods for the treatment of vitiligo. Their review does not make any mention of noncultured, autologous epidermal cell suspension transplants, but does mention that no conclusion can be made as to the efficacy of culturing techniques because of the small number of patient's studies.

The second study is that of Van Geel et al. published in 2004,³⁵ which was a prospective, randomized, double-blind, placebo-controlled, study on patients with generalized, and mostly stable vitiligo. They recruited 28 patients, aged 15–65 years old, with paired, symmetrically distributed lesions (33 pairs total) and randomly assigned them into two groups, after epidermal ablation (using pulsed CO₂ laser): (1) cellular suspension (melanocyte medium + hyaluronic acid + epidermal cells) and NB-UVB or PUVA or (2) placebo (melanocyte medium + hyaluronic acid) and NB-UVB or PUVA. Donor skin specimens for the cellular suspension were derived from the gluteal region. Lesions <4 cm² were treated in whole, while those >4 cm² had only a part of the lesion marked for treatment. For the first 2 weeks postprocedure, an occlusive dressing was placed and changed weekly. Treatment with either NB-UVB or PUVA, twice weekly, was commenced after the 3rd week, to stimulate melanocyte proliferation.

Efficacy of treatment was evaluated by percentage of repigmentation in the tested lesions. This was done by tracing the contours of the lesions and entering them into a computer for digital image analysis on the day of treatment and 3, 6, and 12 months after treatment. Repigmentation pattern was also noted at 1 and 3 months after treatment.

This study revealed that there was a statistically significant difference between groups at all time points. The

treatment group had >70% repigmentation of the treated area in 77% of the lesions 1 year after treatment. The placebo group did not have any lesions with >70% repigmentation at any time point. Lastly, the repigmentation pattern was diffuse (not perifollicular or peripheral) in 94% of responding lesions.

The third study is that of Tegta et al.³⁶ published in 2006, which compares two different dilutions of epidermal suspensions, containing differing numbers of melanocytes, over a 3-month period. They divided 22 patients, ranging from 10-54 years old, randomly into two groups: (1) suspension prepared from graft one-third size of recipient area (Group A), and (2) suspension prepared from graft 1/5 size of recipient area (Group B). Total melanocyte count of the suspensions was accomplished via a hemocytometer (Group A: 231.60 ± 27.03 melanocytes/mm²; Group B: 154.90 ± 27.65 melanocytes/mm²). The recipient site was prepared by blister formation, via suction, UVA, or liquid nitrogen spray, or a dermabrader if no blistering was used. Cellular suspensions were injected into blisters created at the lesions.

Assessment of the patients was carried out at 2, 4, 8, and 12 weeks. Efficacy was determined by degree of repigmentation, graded as no response, minimal (<25%), mild (26-50%), moderate (51-75%), and marked (>75%). Investigator/patient blinding was unclear. Twenty patients, 10 from each group, completed the study.

Differences in repigmentation, between the two groups, were found to be statistically significant at the end of the 3 months ($P < .05$). 5/10 (50%) patients in Group A and 0/10 (0%) of patients in Group B showed >75% repigmentation. Time to initial repigmentation was not statistically significant between the groups (Group A: 2.63 ± 5 vs. Group B: 3.00 ± 5).

The last study, that of Back et al.³⁷ published in 2009, was a randomized, placebo-controlled, study evaluating the use of a noncultured keratinocyte/melanocyte cosuspension in generalized vitiligo. They randomized 13 patients, aged 18-77 years old, into two groups: (1) melanocyte/karatinocyte cosuspension in Dulbecco's Modified Eagle's Medium (DMEM)/2% autologous serum, or (2) Dulbecco's Modified Eagle's Medium (DMEM)/2% autologous serum alone. The cell numbers were verified with a hemacytometer and the solutions were injected subcutaneously, after diamond-tipped burr dermabrasion.

Two outcomes were measured: (1) time to re-epithelialization (starting 3 days after procedure until complete healing), and (2) repigmentation of prepared areas (3, 6, 9, and 12 weeks and 6, 9, and 12 months thereafter). Both were assessed by a blinded investigator. Re-epithelialization was done visually, as was repigmentation. Repigmentation was also measured by a tristimulus colorimeter.

They found that there was no statistical difference in time to re-epithelialization between the two groups (median = 7 days in both groups, $P = .76$). Additionally, they found that five of 13 areas achieved normal pigmentation at

one time point, in the treatment arm, and two of 13 areas in the placebo group. However, of the 10/13 patients that followed-up at 12 months, 84% of the treated areas versus 100% of the placebo group displayed no pigmentation.

ADVERSE EFFECTS

Van Geel et al. had one patient in which there was doubt as to the original location of the test lesion, leading to exclusion from analysis and a second patient who left the country and was lost to follow-up. Erythema was seen in all lesions during the first 2 weeks, and gradually faded. Five patients experienced hyperpigmentation in the lesion, which gradually faded over 6 months. No scars were observed. They make mention of one patient with the Koebner phenomenon after treatment, but make no mention as to whether there was donor site involvement.

Tegta et al. had one patient lost to follow-up after developing a bacterial infection at the recipient site, two days after grafting. The patient was given systemic antibiotic treatment. Additionally, one patient had initial hypopigmentation in the donor area.

Back et al. had two areas develop slight infection, treated with topicals. They also had one subject develop severe hyperpigmentation at the donor site, persisting until the 1-year follow-up. Ten subjects suffered from a new leukodermic lesion at the donor site at the 1-year follow-up.

RECOMMENDATIONS

Two of the above-mentioned studies, Van Geel et al. and Tegna et al. provide evidence in favor of successful repigmentation with autologous cellular suspensions. The study of Back et al. provides evidence to the contrary. The difference in success may be the number of melanocytes transplanted. Tegna et al. had success with an average dilution of 231.60 ± 27.03 melanocytes/mm², and they recommended dilutions of 210-250 melanocytes/mm² for successful repigmentation. However, their study lacked a placebo group, but was added for interest. Van Geel's group also added either NB-UVB or PUVA to enhance melanocyte stimulation. Therefore, success is most likely operator dependent. Side effects of treatment include Koebnerization at the donor site, which was most evident in the study by Back et al. and infection at recipient or donor sites.

WHAT IS THE EFFICACY OF PUNCH GRAFTING FOR REPIGMENTATION IN VITILIGO?

One meta-analysis and two RCTs were identified that involved punch-grafting: one comparing punch-grafting plus topical corticosteroids versus punch-grafting plus PUVA, and the second comparing punch-grafting plus PUVA sol versus split-thickness skin grafting (STSG) plus PUVA sol. We will begin with the first study.

The meta-analysis of Njoo et al.⁶ shows punch-grafting to have the highest rate of adverse effects, including: donor site scar formation (40%, 95% CI, 34-47%) and recipient site cobblestoning (27%, 95% CI, 21-33%). However, it was shown to be a cheap and easy surgical method of repigmentation.

The second study, by Barman et al.³⁸ randomly divided 50 patients into two punch-graft groups, those who received PUVA twice weekly (group 1) and those who received topical 0.1% fluocinolone acetonide daily (group 2). Both adjuncts commenced 4 weeks post punch-grafting.

Treatment was monitored monthly for 6 months by photography and measurement of pigment spread. A total of 42 patients, 17 in group 1 and 25 in group 2, completed 6 months of therapy.

They found no statistical difference in pigment spread between the PUVA and topical steroid groups (mean at 6 months: 6.38 vs. 6.94, $P = 0.19$).

The third study is that of Khandpur et al.³⁹ which compared punch-grafting to STSG. Sixty-four patients were randomized into two groups: (1) punch-grafting plus PUVAsol or (2) STSG plus PUVAsol. They both started oral PUVAsol therapy (0.6 mg/kg/day, followed by sun exposure 2 hours later) after 2 weeks, on alternate days.

Assessment of treatment was done monthly for 3 months. Photography and visual repigmentation assessment were done at 3 months.

They found that 15/34 (44.1%) patients in the punch-graft group and 25/30 (83.3%) patients in the STSG group had >75% repigmentation after 3 months, which was statistically significant ($p < .001$). However, there is an internal discrepancy in the data of the paper which makes comparative analysis between study groups difficult.

ADVERSE EFFECTS

For Barman et al. six patients were lost to follow-up and two were excluded because of vitiligo reactivation. In group 1 (punch-graft + PUVA), seven patients experienced nausea and vomiting, six had cobblestoning, four had erythema and depigmentation of the graft, one patient had a pyogenic infection, and one had perilesional hypopigmentation, itching, scaling, and thickening of the skin. In group 2 (punch-grafting + topical steroid), five patients had polka-dot appearance, four had cobblestoning and atrophy of grafted area, three had graft depigmentation, and one had infection, perilesional hypopigmentation, and erythema.

Khandpur et al. had 81 punch-graft rejections (12.57%), cobblestoning (13/34, 38.23%), variegated appearance (7/34, 20.58%), and superficial scarring at the donor site in all cases in group 1. Group 2 patients experienced achromic fissuring (4/30; 13.3%), four graft contractures in three patients (2.61%), and rejection of seven grafts (4.57%) in one case; tire-pattern appearance in two patients (6.6%); milia formation in four (13.3%); and depigmentation of the grafts in 2 (6.6%) cases. Superficial and hypertrophic

scarring also occurred at the donor site, in all and three patients respectively.

RECOMMENDATIONS

Both of the above studies are comparing different treatment modalities. Blinding for these procedures may not be done for technical reasons. Punch grafting has not been compared to placebo in a RCT, to the best of our knowledge. PUVA or topical steroids do not seem statistically different effects, as adjuncts to punch grafting. In addition, STSG seems to be a better option, than punch grafting in terms of cosmetic appearance (prevention of cobblestoning), using fewer grafts, and enabling coverage of larger areas, as stated by the Khandpur et al. These few studies do not allow firm recommendations to be made for clinical practice.

WHAT IS THE EFFICACY OF SPLIT-THICKNESS SKIN GRAFTING VERSUS SUCTION BLISTERING FOR REPIGMENTATION IN VITILIGO?

The meta-analysis of Njoo et Al.,⁶ make mention of both of these surgical modalities. There was also one RCT identified, that examined STSG versus suction blistering.

Njoo et al.⁶ state that the highest mean success rates were achieved with STSG (87%; 95% CI, 82-91%) and epidermal blister grafting (87%; 95% CI 83-90%).

The study of Ozdemir et al.⁴⁰ randomly divided 20 patients, aged 10-49 years old, into two groups: those treated with STSG and those treated with suction blistering. STSG were taken from the gluteal area.

Two of three investigators were blinded to treatment. They followed the patients every 2 weeks for 3 months to assess repigmentation and adverse effects.

They found that repigmentation rates were 25-65% in the suction blister technique and 90% in the STSG technique ($P < .001$) after 3 months. However, they make no mention as to the percentage of repigmentation.

ADVERSE EFFECTS

Ozdemir et Al.,³⁸ found that the donor sites experienced Koebner phenomenon, hypopigmentation, hyperpigmentation, scarring, and infection. The recipient sites experienced milia, pigment loss, papule development, peripheral hypopigmentation, scarring, and infection.

RECOMMENDATIONS

The study results were difficult to interpret and the derivation of the repigmentation rates is not clear. They make no mention of percent repigmentation in the areas grafted. The side effects noted above warrant caution in using these surgical therapies, without full patient consent. Additional studies will be necessary to improve on existing techniques.

What We Know

- Topical Treatments: We know from RCTs that topical steroids are more effective than placebo; however, their effects are not statistically different from catalase/dismutase superoxide, tacrolimus, or calcipotriol. Steroids do seem to be more effective than PUVA. For localized vitiligo, topical corticosteroids seem to be effective, based on the meta-analysis. However, skin atrophy must be monitored as a potential side effect during treatment.
- Phototherapy: We can conclude that NB-UVB performs better than PUVA in terms of efficacy and side effect profile. Various adjuncts have been used with NB-UVB with varying results. The excimer laser may

- be as effective as NB-UVB, with the advantage of sparing unaffected skin.
- Surgical Treatments: Split-skin grafting seems to provide cosmetically acceptable results, while punch grafting tends to yield suboptimal cosmesis. Autologous cellular suspension transplants may be effective in repigmentation. All of the surgical techniques are operator dependent and vary from study to study. More studies are needed.
- There has been an increase in the number of RCTs seen in the literature in the field of vitiligo. However, standardization of definitions and assessment of treatment are needed to allow for ease of study comparison, in the future.

Treatment of Hirsutism (Medical Interventions)

37

John Thomas O'Malley, M.D., Ph.D., and Najwa Somani, M.D., F.R.C.P.C.

INTRODUCTION

Hirsutism is a disorder in women in which there is excessive growth of terminal (coarse, medullated) hair within androgen-dependent areas such as the chin, upper lip, chest, breasts, abdomen, back, and anterior thighs. Hirsutism should be differentiated from hypertrichosis because the underlying etiologies and medical implications of these disorders are different. Hypertrichosis is an androgen-independent increase in hair growth that occurs in a generalized, nonsexual distribution. Hypertrichosis is most often caused by drug ingestion, although there are many other causes; while the causes of hirsutism are most often the result of increased quantity or activity of male sex hormones, or androgens, in the blood of afflicted female patients.

Women with hirsutism carry a significantly higher risk of developing psychological disorders.¹ In addition, hirsute women perceive themselves to be in poorer health than nonhirsute women, and there are fewer in employment despite having similar educational backgrounds.¹⁻³ In some women, the negative psychosocial implications are further compounded by additional cosmetically disturbing findings of androgen excess such as androgenetic (patterned) alopecia, acanthosis nigricans and acne. Dermatologists and, in recent years, nonphysician run cosmetic clinics are consulted to treat excess and unwanted hair. Given that the etiologies underlying hirsutism can be associated with medically important conditions such as infertility, insulin resistance, and diabetes, cardiovascular disease and endometrial carcinoma, appropriate medical evaluation of patients is essential.^{4,5}

EPIDEMIOLOGY

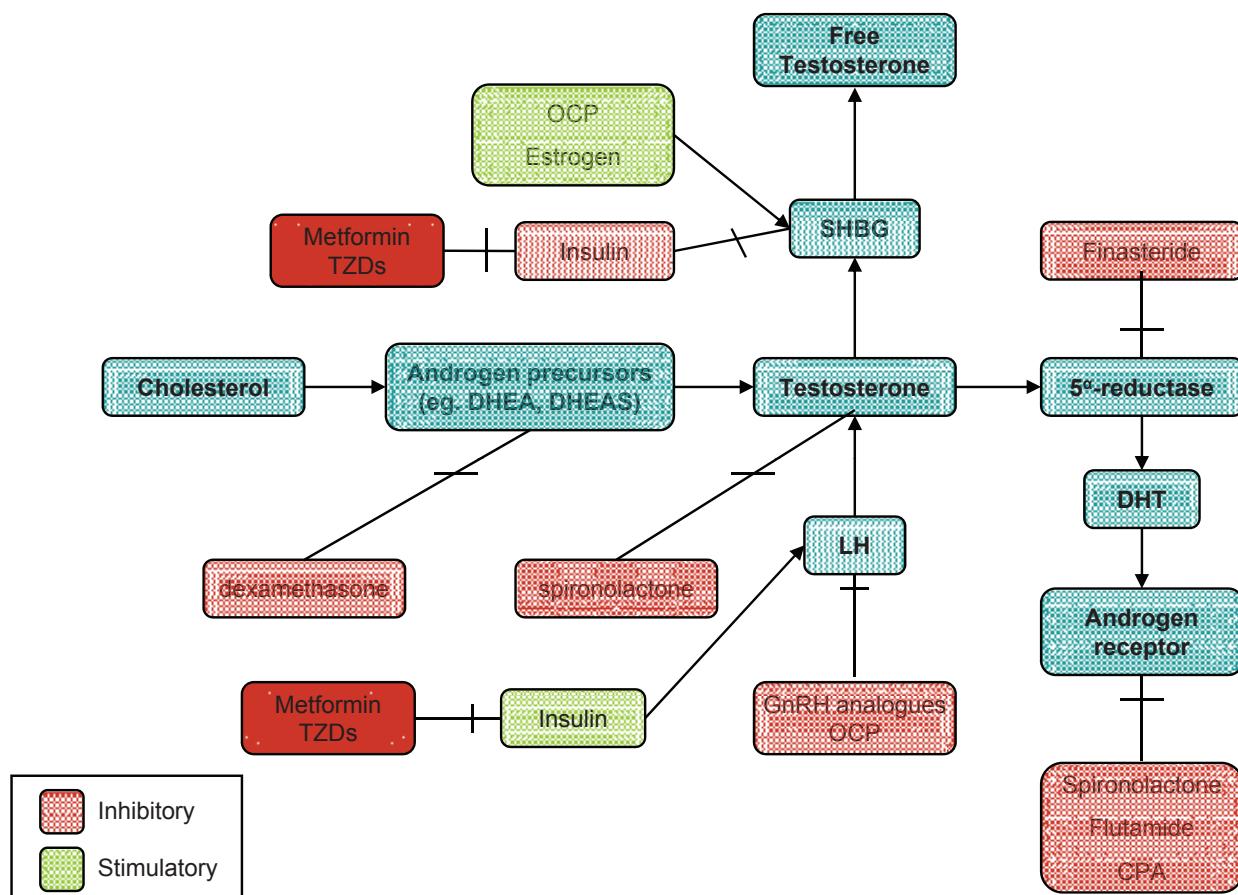

Hirsutism affects approximately 5-10% of reproductive age women.⁵⁻⁷ A 1993 marketing research survey of 25,000 women estimated that 41 million women in the United States had unwanted facial hair and that 22 million removed facial hair as frequently as once per week. (<http://sec.edgar-online.com/skinmedica-inc/s-1a-securities-registration-statement/2005/07/08/Section4.aspx>).

ETIOLOGY/DIAGNOSIS

Hirsutism, in the vast majority of cases, is a cutaneous manifestation of an underlying hormonal imbalance where androgens are in excess. It is also affected by increased sensitivity to androgens in the hair follicles, and the sebaceous glands around the hair follicles (target organ dysfunction).⁸ To be active in the skin, free (biologically active) testosterone (i.e., testosterone that is unbound to sex hormone binding globulin (SHBG)) must be converted to dihydrotestosterone (DHT) by the enzyme 5 α -reductase (Figure 37-1). Androgen sensitivity is partly determined by 5 α -reductase activity in the skin. Approximately 80% of women who exhibit increased serum androgens, namely testosterone, androstenedione and dehydroepiandrosterone-sulfate (DHEAS), manifest hirsutism.⁹ The most common cause of hirsutism is polycystic ovarian syndrome (PCOS) accounting for greater than 70% of cases.^{9,10} The next most common etiology is "idiopathic" hirsutism, which occurs in approximately 23% of hirsute patients who have regular menstrual cycles and do not have a detectable androgen excess by conventional testing.¹⁰ Other less common causes of androgen excess, resulting in hirsutism include nonclassic congenital adrenal hyperplasia (21-OH deficiency), the hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) syndrome, various endocrinopathies, androgen-secreting tumors, and androgenic drug intake.⁴

Briefly, diagnosis of hirsutism requires a thorough history and physical examination, with particular emphasis on the pattern and onset of hirsutism, menstrual irregularity, weight gain, and use of androgenic medications. The goals of evaluation are three-fold:

1. To determine the underlying etiology for the hirsutism (PCOS, endocrinopathies, androgenic medications, etc.).
2. To assess the amount, severity, and distribution of hirsutism as a baseline measure from which to benchmark response to therapy or progression.
3. To identify those patients at risk for associated medical problems (insulin resistance, cardiovascular disease, infertility, etc.).

Mechanism of action of the class of medications used to treat hirsutism

Drug	Mechanism of action
Oral contraceptive pills	1. Suppresses leutinizing hormone & ovarian androgen production 2. Increases sex hormone binding globulin
Antiandrogens	
Flutamide	Competitive inhibition of the androgen receptor
Finasteride	Inhibits 5α reductase
Spironolactone	1. Aldosterone antagonist 2. Competitive inhibition of the androgen receptor
Insulin sensitizers	
Metformin	Activates AMP-activated protein kinase thereby inhibiting hepatic gluconeogenesis
Thiazolidinediones	Bind peroxisome proliferator-activated receptors which decreases insulin resistance by sensitizing tissues to the action of insulin
Glucocorticoids	Suppresses adrenal androgens
Gonadotropin releasing hormone agonists	Suppresses ovarian steroidogenesis by decreasing levels of LH and FSH
Eflornithine topical cream	Inhibits ornithine decarboxylase and polyamine synthesis which is necessary for hair growth

FIGURE 37-1 Schematic of androgen biosynthesis and mechanisms of action of drugs used to treat hirsutism.

DHT-dihydrotestosterone, OCP-oral contraceptive pills, SHBG-sex hormone binding globulin, DHEA dehydroepiandrosteronesulphate, LH-luteinizing hormone, CPA-cyproterone acetate, TZDs-thiazolidinediones

The current standard for clinically grading hirsutism is by using the classic or modified Ferriman-Gallwey (FG) scale.¹¹ A score of 8 to 15 is compatible with mild hirsutism.^{12,13} Initial laboratory investigations may include total or free testosterone, DHEAS and 17-hydroxyprogesterone with further laboratory work-up and investigations guided by history and physical examination findings. There is some debate as to whether women with mild hirsutism (FG 8-15) require laboratory work-up. However, it is generally accepted that testing should be performed in all women with moderate to severe hirsutism (FG>15) or with hirsutism that is associated with menstrual irregularity, infertility, central obesity, rapid onset, acanthosis nigricans or clitoromegaly.¹⁴ Additional tests that could be considered based on clinical suspicion include a transvaginal ultrasound, CT/MRI of the abdomen and pelvis (for tumors), cranial MRI (for pituitary adenoma), prolactin, and dihydrotestosterone level, among other tests.

SEARCH METHODOLOGY

A MEDLINE search was performed between February and March 2010 using the search terms “hirsutism” and “treatment” to identify meta-analyses and randomized-controlled trials (RCT) that compared treatment options for hirsutism. Endocrinology and Obstetrics and Gynecology clinical groups’ guidelines and relevant bibliographies were also reviewed (Table 37-1).

TREATMENT OVERVIEW OF HIRSUTISM

Treatments used to manage hirsutism can be divided into two major categories: physical methods and pharmaceutical methods. Physical methods can be further broken down into temporary and permanent methods of hair removal. Temporary methods include shaving, waxing, plucking, and chemical depilatory agents. Bleaching can also be included in this category, although it is not truly a method of hair removal but only serves to lighten the hair.

Permanent methods of hair removal include photoepilation (laser treatment) and electrolysis.

Pharmaceutical management of hair removal can either be topical or systemic. Systemic treatments focus mainly on regulating androgen excess or peripheral androgen receptor function and, in women with PCOS or related syndromes with hyperinsulinemia, regulating insulin sensitivity. Common systemic treatments include oral contraceptive pills (OCPs), antiandrogens (spironolactone, flutamide, finasteride, and high dose cyproterone acetate [CPA]), insulin sensitizers (metformin and thiazolidinediones), gonadotropin-releasing agonists (e.g., nafarelin and leuprolide), and glucocorticoids (e.g., dexamethasone). Topical treatment includes eflornithine 13.9% cream, an ornithine decarboxylase inhibitor, and finasteride 0.25% cream (Table 37-2). Evidence from meta-analyses or, when they are unavailable, randomized-controlled trials comparing these different treatment modalities will be briefly described and discussed in the context of hair reduction in patients afflicted with hirsutism.

RESEARCH QUESTIONS AND ANSWERS

What is the comparative efficacy of OCPs versus placebo?

Oral contraceptive pills contain ethinyl estradiol (EE), a synthetic estrogen, in combination with a progestin. Estrogens increase hepatic production of SHBG, thereby reducing free testosterone concentration (the biologically active form of testosterone) (Figure 37-1). Most synthetic progestins are chemical derivatives of testosterone (known as 19-nortestosterone derivatives).¹⁵ First and second generation progestins consisting of norethindrone and progestins such as norethindrone acetate and ethynodiol diacetate that metabolize to norethindrone, and levonorgestrel and norgestrel have varying degrees of androgenic activity (Figure 37-2). Newer third generation progestins such as desogestrel and norgestimate possess minimal

TABLE 37-2—Adverse Effects of OCPs

Drug	Reported Doses	Main Adverse Effects		Pregnancy category
		Common	Serious	
Oral contraceptive pills (OCPs)	—	Gastrointestinal upset, breast tenderness, headache, cyclical weight gain, mood swings, lipid abnormalities (\downarrow HDL; \uparrow LDL)	Depression, VTE, myocardial infarction, stroke, pulmonary embolism	—
Spirostanolactone	50-200 mg/d	Irregular menses, breast tenderness, headaches, gastrointestinal upset, lethargy	Hyperkalemia Rare: hepatocellular toxicity, vasculitis, agranulocytosis	D
Finasteride	2.5-7.5 mg/d	Decreased libido, weakness, postural hypotension, dizziness	Rare severe myopathy, hypersensitivity reaction	X
Flutamide	125-500 mg/d	Galactorrhea, decreased libido, hot flashes, gastrointestinal upset, liver enzyme elevation, anemia, peripheral edema	hepatic failure, hypersensitivity, interstitial pneumonitis, leucopenia, thrombocytopenia	X
Metformin	1.5-1.7 g/d	Gastrointestinal upset, weakness, headache, decreased vitamin B12 levels, metallic taste	Lactic acidosis, pneumonitis, leukocytoclastic vasculitis	B
Thiazolidinediones	—	Edema, hypertension, headache, hypoglycemia, diarrhea	Increased risk of cardiovascular events, anemia, exacerbation of heart failure, fractures, arthralgias	C
Dexamethasone	0.5 mg qhs	Weight gain, hypokalemia, decreased bone density, immune suppression, depression	HPA axis suppression, fractures	C
Leuprorelin	3.75 mg IM monthly	Edema, headache, pain, depression, menopausal symptoms (hot flashes, decreased libido, vaginitis), gastrointestinal upset, weakness	Increases cardiovascular disease risk, gastrointestinal hemorrhage, leucopenia, renal failure	X
Eflornithine cream	BID, at least 8 hrs apart	Acne, pseudofolliculitis barbae, skin irritation, headache	Pancytopenia (systemic use)	C

DHT-dihydrotestosterone; OCP-oral contraceptive pills; SHBG-sex hormone binding globulin; DHEA dehydroepiandrosteronesulphate; LH-luteinizing hormone; CPA-cyproterone acetate; TZDs-thiazolidinediones

androgenic properties, but may carry a higher risk of blood clots (Table 37-2). Cyproterone acetate (CPA) (available worldwide except in the US) and drospirenone function as androgen receptor antagonists but typically do not increase androgenicity because they are structurally unrelated to testosterone. CPA (2 mg) combined with EE (0.035 mg) is marketed as Diane-35® (Berlex, Inc.) in Canada and Dianette in the UK. The drug is Health Canada approved for treatment of androgen-sensitive skin conditions including hirsutism (<http://www.bayer.ca/files/DIANE-35-PM-ENG-02OCT2008-123244.pdf>). While it is not indicated as an OCP, it provides effective birth control and will be included under the umbrella of the OCP designation. OCPs suppress luteinizing hormone (LH) and increase SHBG, thereby reducing concentrations of bioavailable testosterone (Figure 37-1). They also reduce adrenal androgen secretion and block androgens from binding to their receptor.¹⁴ Therefore, OCPs reduce hirsutism by reducing the concentration of bioavailable androgens and inhibit androgens from mediating their biologic effects in the skin.

Two clinical trials have evaluated the efficacy of OCPs versus placebo or no treatment in hirsute women. The first of these, a placebo controlled trial, analyzed 20 women with PCOS who took 2 mg CPA+ EE 35 mcg.^{16A} (Saeed R, Akram J, Changezi HU, Saeed M. Treatment of hirsutism in polycystic ovarian syndrome with Diane, 50 mcg ethynodiol diacetate and 2 mg cyproterone acetate. Specialist (1993) 9:109–112) cited in: 16) While there was no objective assessment of hirsutism, there was a significant subjective improvement in hair growth, although the confidence limits were large (odds ratio (OR) 45; 95% confidence interval (CI) 2.01, 1006.8). (Saeed R, Akram J, Changezi HU, Saeed M. Treatment of hirsutism in polycystic ovarian syndrome with Diane, 50 mcg ethynodiol diacetate and 2 mg cyproterone acetate. Specialist (1993) 9:109–112) cited in: 16)¹⁶ The second clinical trial examined 45 women with either idiopathic hirsutism or PCOS and evaluated the effectiveness of 150 mcg desogestrel+ EE 30 or 50 mcg (16 patients) versus 2 mg CPA+EE 35 mcg (10 patients) versus no treatment (19 patients) over 2 years.¹⁷ At the end

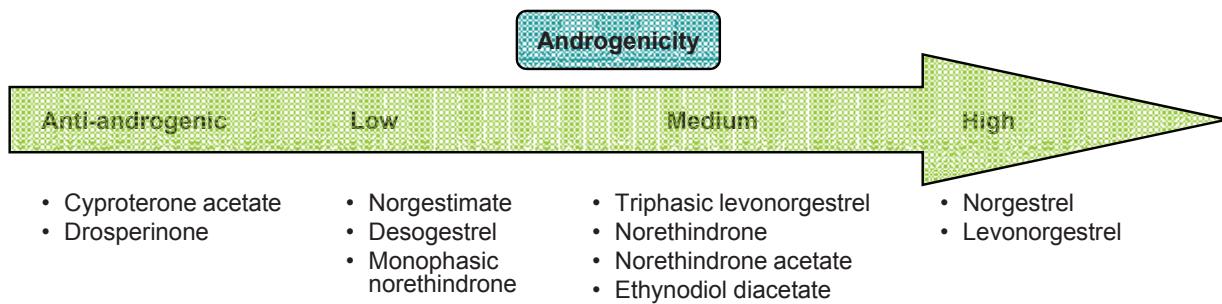

FIGURE 37-2 Schematic of androgenicity of various progestins.

of the two years, FG hirsutism scores were significantly reduced (-7.1 ± 0.6 ; $p<0.01$) in the women treated with OCPs.¹⁷ In a combined analysis of these two trials, pooled odds ratio demonstrated that there was a greater reduction in FG hirsutism scores with OCP therapy compared to placebo or no therapy (weighted mean difference (WMD) -8.0 , 95% CI, -11.0 to -4.5).¹⁴

Drosperinone (DRSP) is a novel 4th generation progestin derived from 17 α -spironolactone. It possesses antiandrogenic and antimineralcorticoid activity similar to that of spironolactone.^{18,19} Four studies enrolling between 18 to 52 women with PCOS or mixed etiology hirsutism found a decline in FG scores with 3 mg DRSP+EE 30 mcg (Yasmin®, Bayer HealthCare Pharmaceuticals) treatment over 6 to 12 months of treatment (Table 37-3).¹⁸⁻²¹ All studies lacked a control group, thereby making it difficult to accurately assess the clinical relevance of the findings. In all of the studies, testosterone levels improved significantly and there was a dramatic rise in SHBG. There were no significant adverse events and the drug was well tolerated. A positive overall profile of action with respect to body weight and blood pressure was observed and was attributed to drosperinone's anti-mineralocorticoid activity.²¹

A comparative randomized study between DRSP+EE and CPA+EE combinations in 91 women found equivalent efficacies between the two OCPs (Table 37-3).²²

Based on these limited studies, monotherapy with OCPs reduces hirsutism in women afflicted with PCOS or idiopathic hirsutism compared to placebo. The studies reviewed used either OCPs with an antiandrogenic progestin, or a third generation progestin with minimal androgenic properties. Aside from one head- to-head study of DRSP+EE and CPA+EE, there are no other head-to-head comparisons of other classes of progestins. Recent clinical guidelines recommend the use of OCPs as a first line treatment of hirsutism in women who do not wish to conceive.¹⁴

Although widely prescribed and typically well tolerated, OCPs do have several adverse effects (Table 37-2). Among these is the concern for venous thromboembolism (VTE), which is elevated with all OCPs, as a class but may be higher with certain types of progestins. A Danish national cohort study that included 10.4 million woman years of observation, found that the risk for VTE in women who took combined OCPs decreased with longer duration of use and with decreasing dosage of estrogen. For the same dose of estrogen and duration of use, OCPs containing

TABLE 37-3—Uncontrolled Clinical Trials of DRSP/EE

Study	Sample	Treatment duration	Result
Drosperinone + ethinyl estradiol alone (no control group)			
Pehlivanov <i>et al.</i> 2007 (19)	20 ♀ with PCOS	6 cycles	23% drop in FG score. Mean difference in FG score compared to baseline: -2.55 (95% CI -4.59 to -0.50 ; $p=0.0159$)
Guido <i>et al.</i> 2004 (21)	18 ♀ with PCOS	12 cycles	16% drop in FG score. (16.20 ± 5.81 at baseline; 13.53 ± 4.96 at 12 months ($p<0.01$))
Gregoriou <i>et al.</i> 2008 (20)	52 ♀	12 months	FG score reduced to 51.8% of baseline
Batukan <i>et al.</i> 2006 (18)	50 ♀ with mod-severe hirsutism	12 months	Mean FG score declined by 78%
Drosperinone + ethinyl estradiol versus Cyproterone acetate + ethinyl estradiol			
Batukan <i>et al.</i> 2007 (22)	91 ♀ (48 DRSP/43 CPA)	12 months	No significant difference between groups in % reduction of total FG score (0.80 (0-0.42) vs 0.81 (0-0.75)) respectively ($p=0.6$)

FG=Ferriman-Gallwey score; DRSP=drosperinone; CPA=cyproterone acetate; PCOS=polycystic ovarian syndrome

cyproterone, desogestrel, gestodene, or drospirenone were associated with a higher risk of VTE (approximately 2-fold higher risk) than pills containing levonorgestrel (LNG).²³ This finding was refuted by a more recent study, which confirmed the elevated risk of VTE with OCPs as a class, but found no significant elevation of risk among those using DRSP + EE versus other low-dose COCs (including LNG + EE (crude OR for DRSP + EE versus low-dose LNG/EE was 1.0 (95% CI 0.6-1.6), and the adjusted OR was 1.0 (95% CI 0.6-1.8). Practically speaking, even with a 2-fold higher risk with some OCPs, the overall risk remains low since the absolute risk of VTE with any use of combined OCPs is less than one in 1000 woman years.²³ Where OCP therapy is contemplated, women should be evaluated for risk factors for VTE which includes a personal or family history of VTE, increased body mass index, and smoking.

What We Know

- OCP therapy is associated with a significant reduction in hirsutism scores compared to placebo or no treatment. Recent guidelines recommend OCPs as the first line therapy for hirsutism, given the teratogenic potential for antiandrogens
- OCPs should be chosen with a progestin component of low androgenicity or with antiandrogenic effects.
- Desogestrel, CPA, and DRSP containing OCPs are the best studied.

What is the comparative efficacy of antiandrogens versus placebo?

Spironolactone

Spironolactone is an aldosterone antagonist with structural similarity to progestins. The drug is a competitive inhibitor of the androgen receptor and also inhibits androgen biosynthesis and increases androgen metabolism (Figure 37-1).²⁴ There are two RCTs that have compared spironolactone to placebo for the treatment of hirsutism. One RCT by McClellan et al. compared 38 women to "idiopathic" hirsutism (baseline FG score not reported) taking spironolactone 100 mg daily (n=19) to women taking a placebo (n=19).²⁵ After 9 months, the women taking spironolactone demonstrated a trend towards subjective improvement, but this did not achieve statistical significance. The objective outcome measure (change in hair shaft diameter of a sample of hair taken from the thigh), was not significantly improved by spironolactone. Furthermore, only 58% (11/19) of patients completed the treatment arm. A more recent meta-analysis utilizing a Hedges' g approach to calculate a standardized mean difference from the aforementioned study, found that this subjective improvement was statistically different between the hirsute women taking spironolactone and the women taking placebo

(standardized mean difference (SMD) -1.1, 95% CI -2.1, -0.05).^{25,26}

A second RCT by Moghetti et al. compared 40 hirsute women taking antiandrogens spironolactone, flutamide, or finasteride to placebo (n=10 in each group) for a period of 6 months.²⁷ Objective outcome measures were reduction in hair shaft diameter and FG score. In the group taking spironolactone versus placebo, there was a significant decrease in hair diameter ($p<0.01$) and in FG score ($p<0.001$). Although the actual study did not provide statistical analysis of patient self-evaluation of clinical outcome, a meta-analysis found significantly improved subjective hirsutism scores compared to the women taking placebo (mean weighted difference in favor of treatment (MWD) -7.2, 95% CI -10.98, -3.42).²⁸ Furthermore, two separate meta-analyses combining these two trials demonstrated a subjective improvement in hair growth in patients taking 100 mg/d spironolactone compared to placebo (OR 7.18, 95% CI 1.96, 26.28).^{25,27,28} (WMD -4.8 (-7.4, -2.2); I²=0%)²⁶ (Figure 37-3) Adverse effects of spironolactone included a dose-dependent association with menstrual irregularity, hyperkalemia and increased diuresis with associated postural hypotension and dizziness (Table 37-2).

The FDA package insert for spironolactone states that spironolactone at dosages several times higher than those used in humans, resulted in mammary tumors in rats (http://www.accessdata.fda.gov/drugsatfda_docs/label/2008). Although no significant causal association with breast cancer have been found in women exposed to spironolactone, it is recommended either to exercise caution or not to give spironolactone to women with a genetic predisposition to breast cancer or other estrogen-dependent malignancies.²⁹ As with all antiandrogens, spironolactone is a teratogen that can cause pseudohermaphroditism in male fetuses. Adequate contraception is therefore a requirement with therapy.

Finasteride

Finasteride is an inhibitor of type II 5a-reductase (Figure 37-1). A meta-analysis of three RCTs analyzing patients with PCOS or idiopathic hirsutism being treated with 5-7.5 mg finasteride exhibited a significant reduction in FG scores after 6 months of treatment compared to placebo (WMD -2.9; 95% CI -5.3, -0.6) (Figure 37-3).^{26,27,30,31} A reduction in dihydrotestosterone level was also seen in finasteride-treated patients. While the aforementioned studies used higher dosages of finasteride, another randomized trial (n=56 hirsute patients with either PCOS or idiopathic hirsutism) demonstrated that dosages of 2.5 mg and 5 mg daily of finasteride resulted in significant reductions in modified FG scores ($p<0.001$), and that there were no significant differences between the two dose groups after 12 months of treatment.³² Although the study lacked a control group, the findings suggest that dosages ranging from 2.5-7.5 mg may be similarly efficacious to treat

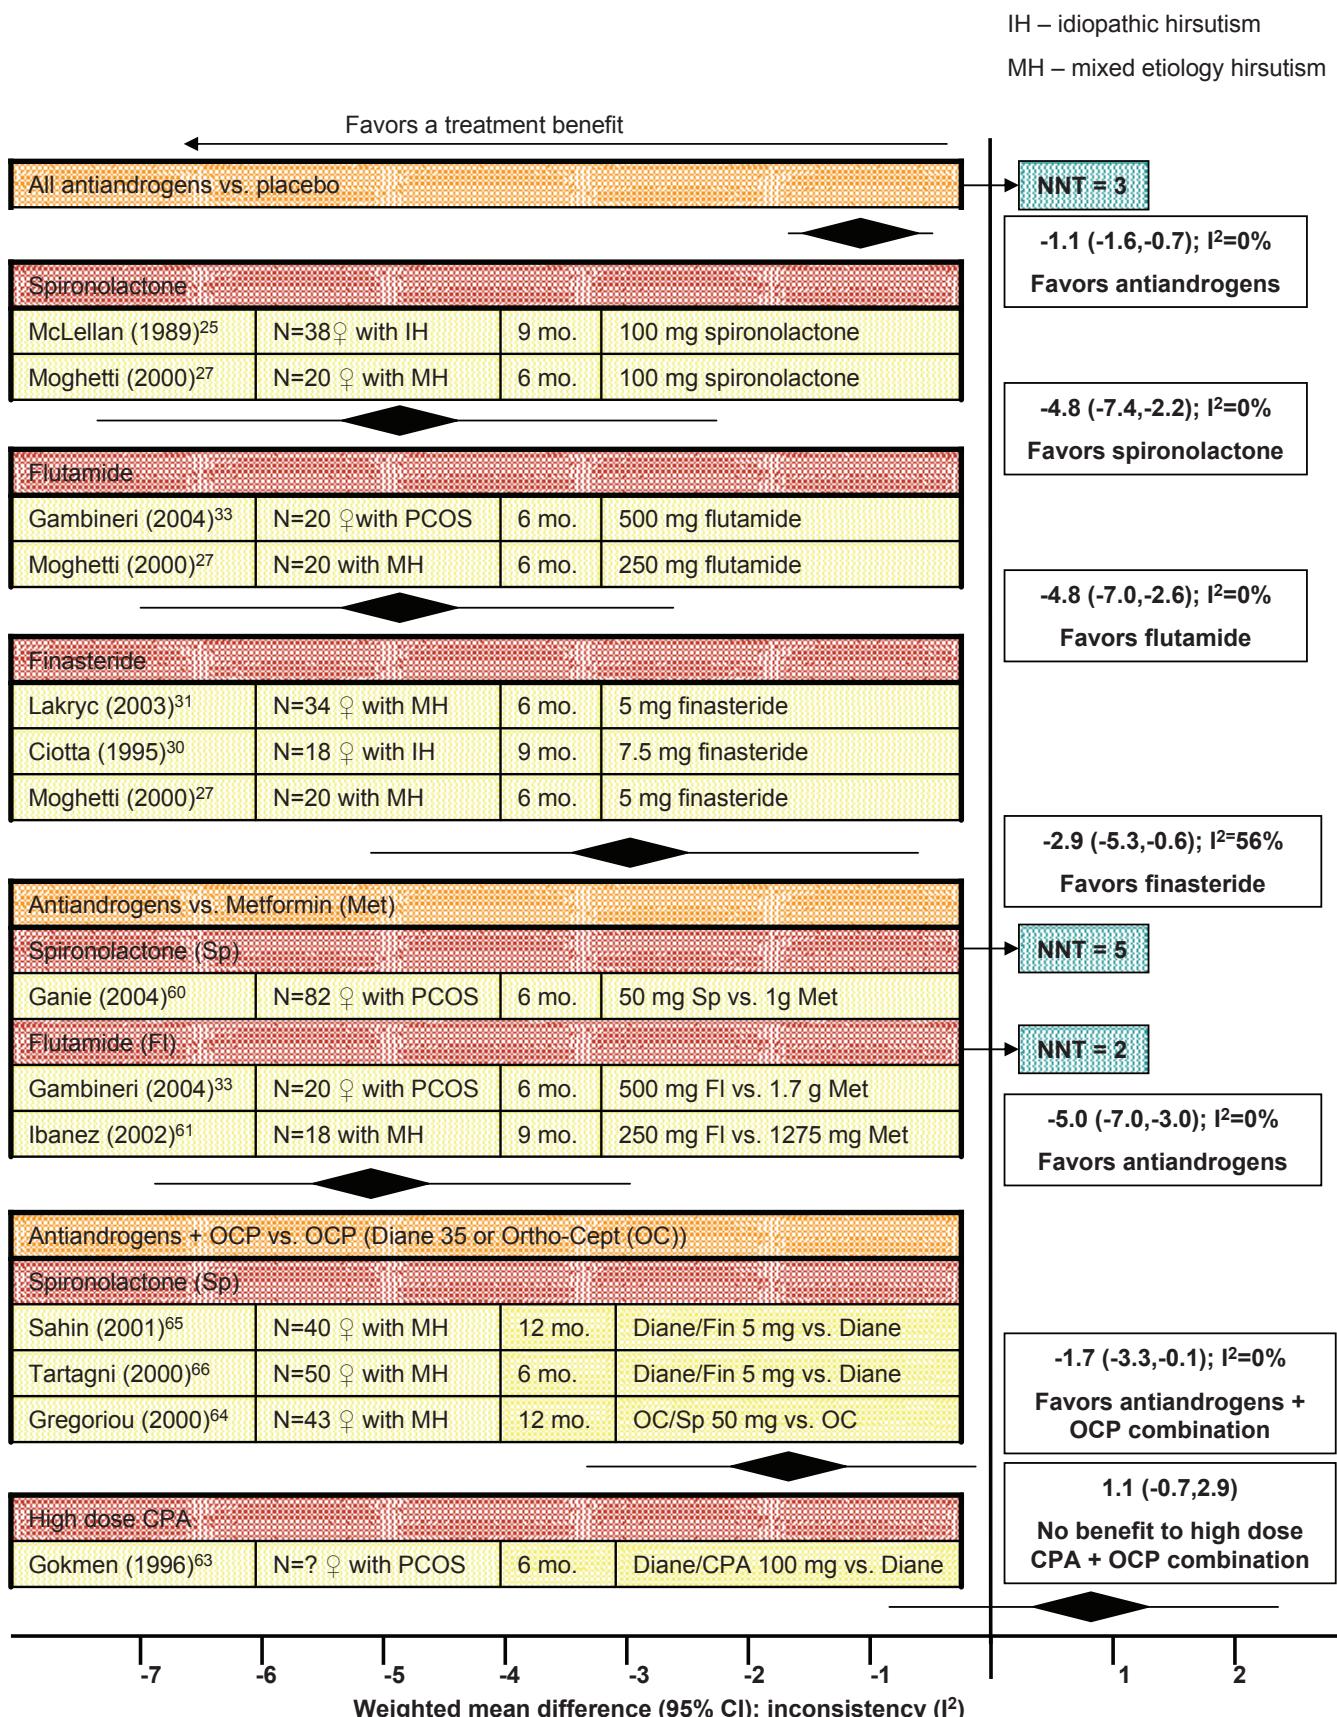

FIGURE 37-3 Summary of antiandrogens for the treatment of hirsutism. (Adapted from Swiglo BA, et al. *J Clin Endocrinol Metab*. 2008;93(4):1153–60.)

DHT-dihydrotestosterone; OCP-oral contraceptive pills; SHBG-sex hormone binding globulin; DHEA dehydroepiandrosteronesulphate; LH-luteinizing hormone; CPA-cyproterone acetate; TZDs-thiazolidinediones

hirsutism. While finasteride was well-tolerated in the trials above, adverse effects can include decreased libido, hypersensitivity, postural hypotension, dizziness, and rarely severe myopathy (Table 37-2). Like other antiandrogens, finasteride is pregnancy category X because of its teratogenic potential to induce pseudohermaphroditism in the male fetus. Therefore, a reliable method of contraception is required in women with child-bearing potential who take this drug.

Flutamide

Flutamide is a pure nonsteroidal antiandrogen that displays a dose-response inhibition of the androgen receptor (Figure 37-1). In general, treatment does not alter serum androgens or other hormone levels. Doses of 250-750 mg/d have shown efficacy in reducing hirsutism. A meta-analysis of two RCT comparing patients taking 250-500 mg flutamide to patients taking a placebo, calculated a significant improvement in hirsutism, in the context of lower FG scores, after 6 months of treatment (WMD -4.8; 95%CI -7.0, -2.6) (Figure 37-3).^{26,27,33} The lower 250 mg dose is preferred because of better patient tolerability and fewer adverse effects. Patient drop-out rates are high in virtually all studies examining flutamide, particularly in those groups receiving >250 mg daily.^{34,35} A RCT examining 125 mg, 250 mg, and 375 mg daily doses of flutamide + OCP (with levonorgestrel) versus placebo + OCP found that all dosages resulted in a significant decline in hirsutism score after 12 months ($p=0.02$), but there were no significant differences among the 3 dosages of flutamide.³⁶ Other small studies lacking a control group have shown efficacy of 62.5 and 125 mg daily doses.^{37,38} Based on the limited evidence provided, low dose flutamide (125 mg daily) may be equally efficacious to higher dose regimens.³⁶ Like other antiandrogens, flutamide is a teratogen and requires concomitant use of contraception in fertile women. The most serious adverse effect of flutamide is fatal and nonfatal hepatotoxicity which is dose dependent and occurs in fewer than 1% of patients (it commonly occurs within the first 3 months of treatment) (Table 37-2).^{39,40} Overall, the clinical utility of flutamide is constrained by this risk of hepatotoxicity.

A more recent comparative study examined 44 unselected hirsute women taking combination of flutamide 125 mg and finasteride 5 mg with patients taking either antiandrogen alone.⁴¹ The study found that combination therapy reduced FG scores to a similar extent as flutamide alone (49% vs. 45% decrease in scores, $p>0.05$). However, combination therapy resulted in significantly greater improvement in hirsutism scores, compared to finasteride alone (49% vs. 32%, $p<0.05$) after 12 months of treatment. Similarly, other randomized-controlled trials comparing finasteride and flutamide directly demonstrate that flutamide is superior to finasteride in reducing hirsutism.^{42,43}

Based on these studies, flutamide alone is as effective as combination therapy (flutamide and finasteride), and is superior to finasteride as a single agent in reducing hirsutism. The limiting factor for flutamide remains the risk of hepatotoxicity.

ANTIANDROGENS AS A CLASS

To answer whether antiandrogens as a class of drugs can ameliorate hirsutism, the above meta-analysis by Swiglo et al. incorporated five RCTs comparing patients taking antiandrogens to patients taking placebo and found that women treated with antiandrogens had significantly lower hirsutism FG scores than the placebo group (sample mean difference (SMD) -3.9; 95% CI -5.4, -2.3) (Figure 39-3).^{25-27,30,31,33} The antiandrogens included in this meta-analysis were spironolactone, finasteride, and flutamide. Subgroup analysis demonstrated negligible differences between the efficacies of the three antiandrogens when compared to each other. Another study not included in this meta-analysis suggested that patients treated with spironolactone maintained lower hirsutism scores for a significantly longer period after cessation of therapy (at least 1 year), as compared to patients taking finasteride.⁴⁴ However, the meta-analysis did not directly address durability of treatment responses. A significant limitation of all studies in the field was a paucity of RCTs reporting patient self-assessment of hirsutism as an outcome measure of treatment efficacy.

The majority of the RCTs from which conclusions were drawn had small sample sizes and methodologic shortcomings (i.e., no blinding). Thus, the overall quality of evidence supporting antiandrogen use for the treatment of hirsutism is low. In conclusion, there is weak but positive evidence demonstrating that antiandrogens as a class improve hirsutism in women with PCOS and idiopathic hirsutism. Based on the meta-analysis, three women would need to be treated for one to notice an improvement in her hirsutism (NNT). Overall, flutamide may be more effective than finasteride, although the meta-analysis did not bear

What We Know

- Antiandrogens are an effective treatment for hirsutism (3 women need to be treated with spironolactone, flutamide or finasteride (NNT) for one to notice an improvement).²⁶
- Treatment with antiandrogens needs to be continued for at least 6 months to see a benefit.
- Flutamide may be more effective than finasteride but its risk of fatal and nonfatal hepatotoxicity limits its clinical utility compared to other antiandrogens.
- Antiandrogens can feminize a male fetus and must be used in conjunction with adequate contraception

out this difference. In addition, spironolactone may result in a longer period of reduced hair growth compared to finasteride although more studies are needed to confirm this conclusion. Ultimately, the decision to select a particular antiandrogen depends upon patient preferences and tolerability.

Are antiandrogens or OCPs more efficacious for the treatment of hirsutism?

A Turkish study compared hirsutism scores in 42 women taking CPA (2 mg)-EE (35 mcg) combination (Diane 35) to patients taking 5 mg/d finasteride over 9 months. (Saeed R, Akram J, Changezi HU, Saeed M. Treatment of hirsutism in polycystic ovarian syndrome with Diane, 50 mcg ethinyl estradiol and 2 mg cyproterone acetate. Specialist (1993) 9:109–112) cited in: 16) While both treatments reduced hirsutism scores compared to baseline scores, there was no significant difference between the finasteride and OCP group (WMD -2.5; 95% CI, -5.4 to 0.4) based on meta-analysis.^{14,45} Another study examining 40 women taking CPA (25 mg/d) and EE (20 mcg/d) to patients taking 5 mg/d finasteride for 9 months also found no significant differences in hirsutism scores between the groups at the end of the study period.⁴⁶ An additional two studies comparing patients taking flutamide 250 mg/d alone with patients taking spironolactone 100mg/d plus Diane-35, concluded that there were similar F-G scores at the end of the study period (6 months and 9 months, respectively).^{47,48} In conclusion, CPA+EE and finasteride at the dosages studied are equally efficacious with regard to ameliorating hirsutism. Also, the addition of spironolactone to Diane-35 did not confer an additional benefit in reducing hirsutism as compared to patients taking flutamide alone. Unfortunately, there were no comparative studies examining OCPs available in the United States and other antiandrogens.

In hirsute patients with PCOS, can monotherapy with insulin sensitizing drugs reduce hirsutism?

Hyperinsulinemia can cause hyperandrogenemia in two ways: (a) insulin can bind to insulin-like growth factor-1 (IGF-1) receptor and, thereby, mimic the action of IGF-1, which augments androgen production by the theca cell in response to LH; (b) insulin decreases SHBG production, resulting in increased levels of circulating free testosterone (Figure 37-1).⁴⁹ Metformin and thiazolidinediones (TZDs) are the two main classes of drugs that have been studied with regard to their effect on hirsutism. Metformin reduces androgen production by inhibiting glucose output, thereby, effectively lowering insulin levels. TZDs, such as pioglitazone and rosiglitazone, sensitize tissues to insulin in the liver, skeletal muscle and adipose tissue.

Metformin

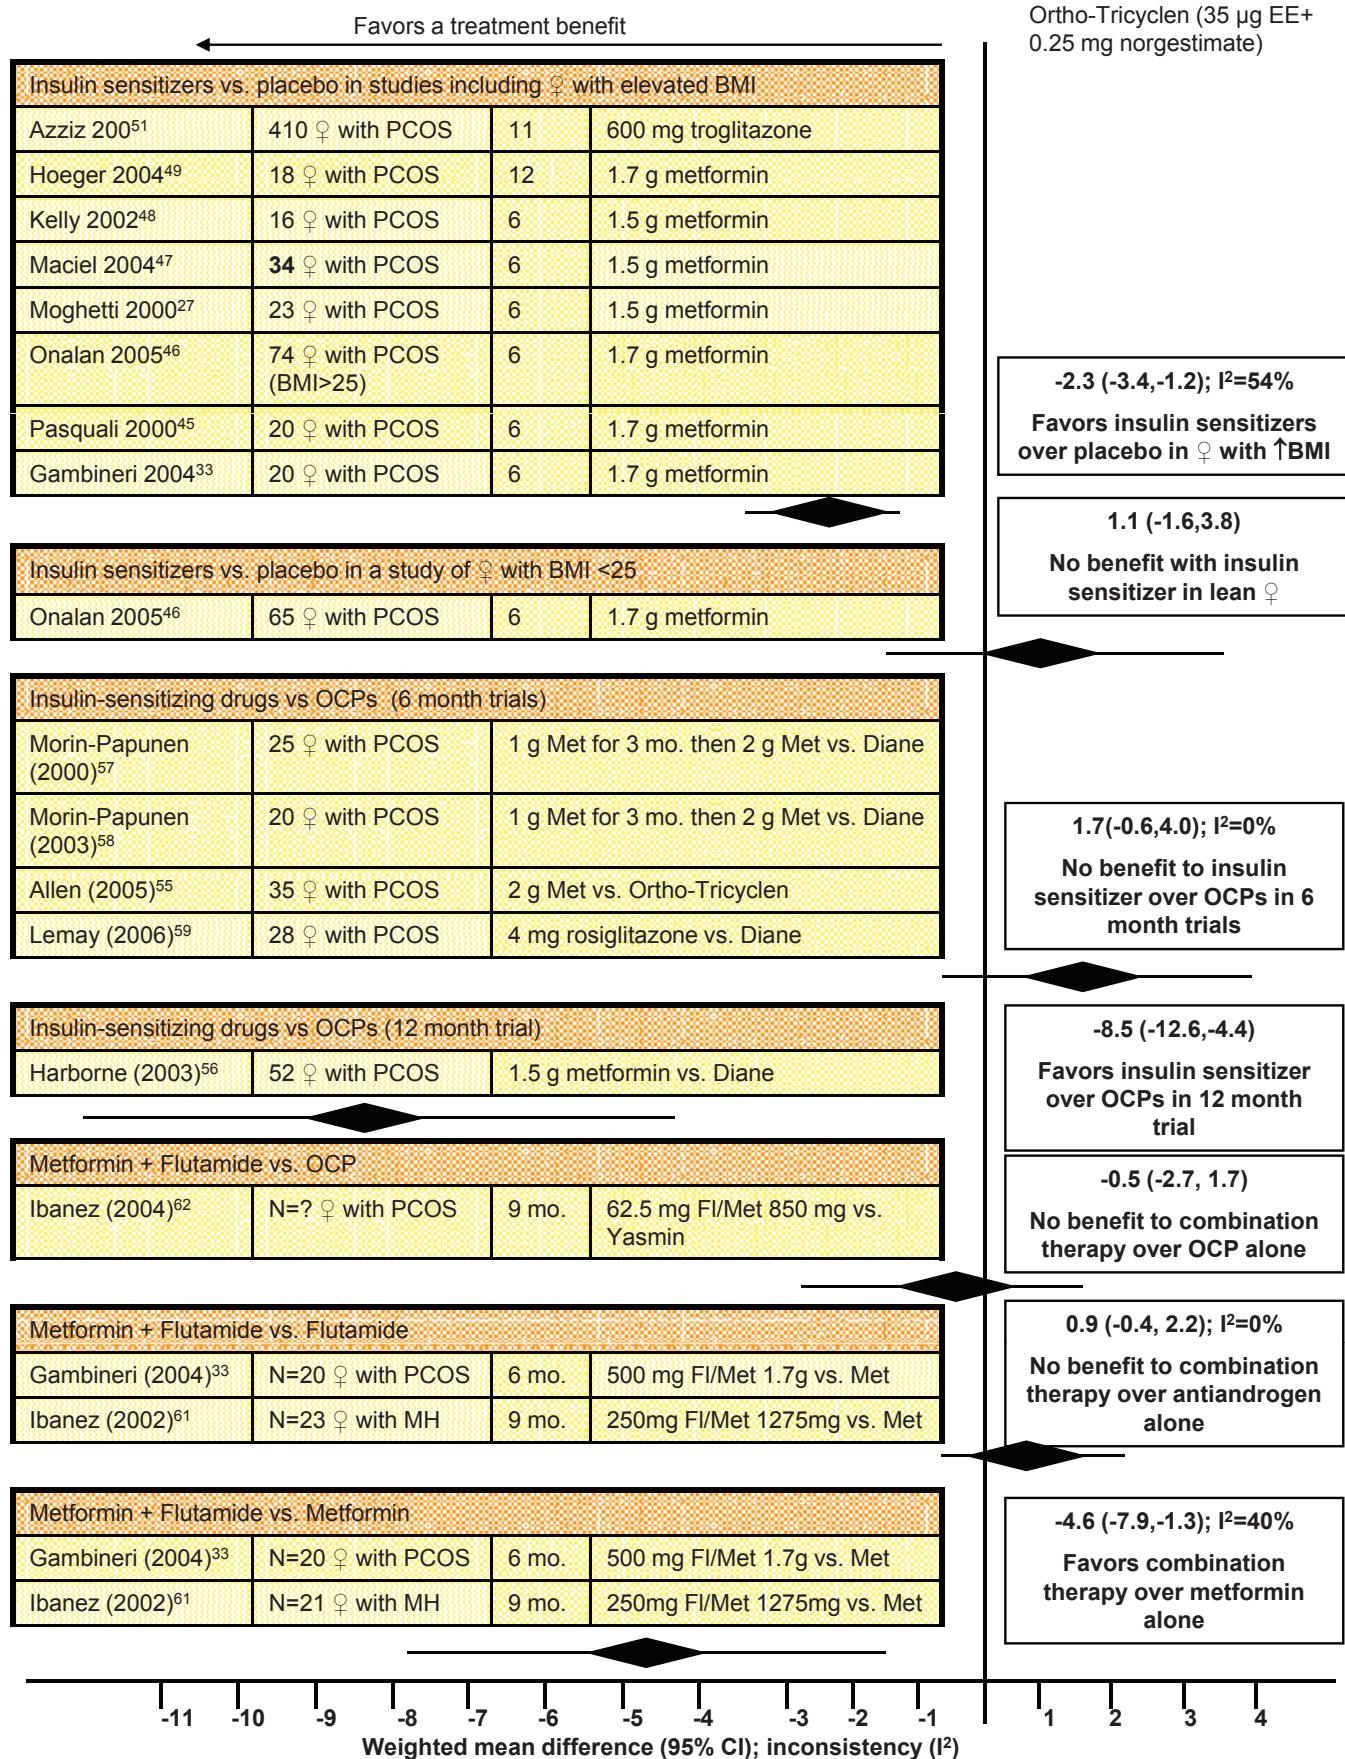

A meta-analysis of all trials examining insulin sensitizers identified seven RCTs that examined the effectiveness of metformin in lowering Ferriman-Gallwey scores of women with PCOS over 6-12 months of treatment compared to placebo (Figure 37-4).^{27,33,50–55} The authors determined the pooled weighted mean difference (WMD) between treatment and control interventions and the associated 95% confidence interval. They also calculated inconsistency (I^2), which describes the quantity of variance across trials not caused by chance, where $I^2 < 25\%$ corresponds to less inconsistency and $I^2 > 75\%$ corresponds to large inconsistency. For the meta-analysis, the authors subdivided one trial (Onalan study) into two separate studies.⁵² In this study, patients were randomized according to BMI (lean vs. obese) and the two subgroups were analyzed separately for a total of “8” studies examining metformin versus placebo. Sample sizes ranged from 16 to 74 women and the dose of metformin used ranged from 1.5-1.7 g/day. Two of the “8” trials showed significantly decreased FG scores in the metformin-treated women compared to placebo;^{52,56} while, the remaining 6 trials showed no difference.^{33,51,53–55} Meta-analysis of all “8” trials together found no significant beneficial effect of metformin on FG scores compared to placebo (WMD –1.4; 95% CI –2.8, 0.1).⁵⁰ The overall quality of the RCTs on which the meta-analysis is based is low to very low. Based on this evidence, metformin does not significantly reduce hirsutism scores when compared to placebo in patients with PCOS.

Obese Versus Lean Patients with PCOS

Interestingly, subgroup analysis of the study that stratified women according to BMI found a significant beneficial effect for metformin compared with placebo in obese women with PCOS (WMD –2.5, 95% CI –3.5, –1.5), but not in their lean counterparts (WMD 1.1; 95% CI –1.6, 3.8) (Figure 37-4).^{50,52} The random effects pooled estimate of all studies that enrolled either overweight or obese women (i.e., $BMI > 2SD$ above 25 kg/m^2) or a mixed population of lean and obese women also showed significant reduction in FG score (–2.3, 95% CI –3.4, –1.2).^{33,50–55} Although there was only one study that analyzed only lean women,⁵² the evidence suggests that reducing hirsutism with insulin-sensitizing drugs may be more efficacious in obese patients. Nevertheless, larger randomized-controlled studies to verify these findings are necessary.

Thiazolidinediones

There was only one RCT examining TZDs versus placebo (Figure 37-4). The study included premenopausal women with PCOS (n=410). Treatment with 600 mg daily of troglitazone (a drug that is no longer available) was better than placebo at lowering FG scores (WMD –2.4; 95% CI –3.8, –1.0).^{50,57} Adverse effects were similar between treatment

**FIGURE 37-4** Summary of antiandrogens for the treatment of hirsutism.

DHT-dihydrotestosterone; OCP-oral contraceptive pills; SHBG-sex hormone binding globulin; DHEA dehydroepiandrosteronesulphate; LH-luteinizing hormone; CPA-cyproterone acetate; TZDs-thiazolidinediones

and control groups with the most common adverse event being elevations of transaminase levels. The safety of TZDs has recently come into question with reports of increased cardiovascular events, heart failure, macular edema, and osteoporotic bone fractures (particularly in post-menopausal women) in otherwise normal women with glucose intolerance.^{58–60} These adverse effects may limit patient acceptability and utility of this class of drugs.

One study compared hirsute patients taking rosiglitazone (4 mg/d) to patients taking metformin (850 mg twice daily) (n=96 pts) for 24 weeks. At the end of the study period, the patients taking rosiglitazone had significantly greater reductions in F-G scores (40% reduction) as compared to the patients taking metformin (19% reduction).⁶¹ While rosiglitazone was well tolerated in the study, the adverse effects of rosiglitazone dampen its therapeutic efficacy.

Insulin Sensitizers as a Class

A meta-analysis of all the placebo-controlled comparisons of insulin-lowering drugs as a class for the treatment of hirsutism shows a small but significant benefit (WMD –1.5; 95% CI –2.8, –0.2).⁵⁰ However, the quality of evidence on which this conclusion is based is low to very low and there was significant inconsistency between trials ($I^2 > 75\%$).⁵⁰

What is the efficacy of insulin-lowering drugs compared to other hirsutism treatments?

Insulin-Lowering Drugs Versus OCPs

A meta-analysis was performed of five trials comparing insulin-lowering drugs (4 RCTs using metformin 1–2 g^{62–65}, 1 RCT using rosiglitazone 4 mg⁶⁶) to OCPs (4 trials used Diane-35 (2 mg CPA + 35 mcg EE)^{63–66} and 1 trial used 35 mg EE + 0.25 mg norgestimate⁶² (Ortho-Tricyclen® Ortho-McNeil-Janssen Pharmaceuticals, Inc.) (Figure 37-4). The trials enrolled between 20–52 women with PCOS and treatment duration varied between 6–12 months. The analysis found no significant difference in hirsutism scores between the treatments (WMD –0.5; 95% CI –5.0, 3.9), but there was large inconsistency across studies ($I^2 = 79\%$).^{50,62,64–66} However, subgroup analysis showed that therapy with metformin for 12 months significantly reduced FG scores compared to patients taking Diane-35 or OCPs for 12 months (WMD –8.5; CI 95% –12.6, –4.4) (Figure 37-4).^{50,63} Whereas for most antiandrogens, treatment benefit is significant at 6 months, a longer duration of therapy may be required to see improved hirsutism scores in patients taking insulin lowering therapy.

Insulin-Lowering Drugs Versus Antiandrogens

A total of three RCTs were identified by Cosma et al. as being suitable for inclusion in their meta-analysis of insulin

sensitizers versus antiandrogens (Figure 37-3).^{33,50,67,68} The trials included 18–82 women with PCOS or mixed etiology of hirsutism. All three trials compared metformin (dose ranges from 1 g to 1.7 g) to either spironolactone 50 mg (1 trial), or flutamide 250 mg, or 500 mg (2 trials). The meta-analysis demonstrated that patients treated with antiandrogens had significantly lower hirsutism scores compared to patients taking metformin (WMD –3.7; 95% CI –6.8, –0.6).^{33,50,67,69} In addition, those patients taking flutamide benefited more (WMD –5.0; 95% CI –7.0, –3.0) (NNT=2) than those patients taking spironolactone (WMD –1.3; 95% CI, –2.6, –0.03) (NNT=5).⁵⁰ Follow-up was 6 to 9 months and because other trials have shown better responses with metformin at 12 months of treatment, the full benefit of metformin may not have been realized in these studies. Nevertheless, based on these studies, hirsute women with PCOS treated with antiandrogens, will have a significantly better treatment response compared to those taking metformin.

Combination Systemic Therapy and their Effects on Hirsutism

Does the addition of antiandrogens to OCPs more significantly benefit hirsutism compared with OCPs alone?

Swiglo et al. performed a meta-analysis on four RCTs of women treated with antiandrogens and OCPs versus OCPs alone (Figure 37-3). The four clinical trials enrolled 20 to 43 women with PCOS, IH, or mixed etiology hirsutism.^{26,70–73} Baseline FG scores were comparable between treatment groups. Antiandrogens studied included 5 mg finasteride (2 trials),^{72,73} 50 mg spironolactone (1 trial),⁷¹ and 100 mg CPA (1 trial).⁷⁰ Three trials used Diane-35 (0.035 mg EE + 2 mg CPA)^{70,72,73} and 1 trial used 0.030 mg EE + 0.150 mg desogestrel (Ortho-Cept® Jannsen-Ortho, Inc.),⁷¹ and treatment ranged from 6–12 months. Meta-analysis of all four trials showed no significant difference between treatment groups (WMD –0.8; 95%CI –2.3, 0.7).^{26,70–73} Subgroup analysis of the antiandrogens, however, did favor treatment with finasteride or spironolactone combined with OCP over OCP alone (WMD –1.7; 95% CI –3.3, –0.1) (NNT=6).^{26,71–73} Based on these studies, combination therapy with spironolactone or finasteride plus an OCP may confer additional benefit over OCPs alone for reducing hirsutism.

Does the addition of metformin enhance an antiandrogen's effect on reducing hirsutism compared to monotherapy with either an antiandrogen, OCP, or metformin alone?

A meta-analysis of two trials compared treatment to 1.275–1.7 g metformin combined with flutamide versus flutamide

alone for 6 and 9 months (flutamide dose 250 – 500 mg) (Figure 37-4). The meta-analysis did not find a significant added benefit from metformin compared to flutamide alone (WMD 0.9; 95% CI –0.4, 2.2).^{26,33,68} Thus, flutamide is sufficient to reduce hirsutism and the addition of metformin confers no additional benefit. It is uncertain whether a longer duration of treatment (i.e., 12 months) or stratification for subjects with elevated BMI would have shown a greater benefit in the metformin add-on group.

Combination therapy of metformin plus flutamide did not show added treatment benefit over OCP alone (WMD –0.5 (–2.7, 1.7) (Figure 37-4).^{26,33,68}

Two trials examining combination therapy of metformin and flutamide versus metformin monotherapy both showed a treatment benefit with combination therapy over metformin alone (WMD of these two studies –4.6 (–7.9, –1.3); I²=40%; NNT=2) (Figure 37-4).^{26,33,68}

In women with hyperandrogenism, do glucocorticoids improve hirsutism?

In the setting of classic CAH caused by 21-hydroxylase deficiency, long-term glucocorticoids suppress adrenal androgens and are effective in managing hirsutism as well as in normalizing ovulatory cycles. In women with NCAH, glucocorticoids at low doses reduce adrenal androgens, but are typically used in reproductive age women to induce ovulation, thereby improving infertility. A minority of hyperandrogenic women, including some with PCOS, who have functional adrenal hyperandrogenism, may also be glucocorticoid sensitive. A few small trials have examined whether glucocorticoids improve hirsutism.

What We Know

- Antiandrogens are more effective than metformin (NNT =2 for flutamide vs. metformin; NNT=5 for spironolactone vs. metformin)²⁶
- The addition of antiandrogens (spironolactone or finasteride) to OCPs is more efficacious than OCPs alone (NNT=6)²⁶
- The addition of an antiandrogen (flutamide) to metformin is more efficacious than treatment with metformin alone (NNT=2)²⁶
- Weak evidence shows limited to no significant beneficial effect of insulin sensitizers (metformin and TZDs) as a class for hirsutism.
- Although pooled studies of metformin show no beneficial effect on hirsutism scores, metformin may be beneficial in reducing hirsutism in overweight and obese patients with PCOS, especially those patients who have taken metformin for at least 12 months.

A trial of 30 women with NCAH comparing hydrocortisone 10 mg bid (n=16), versus CPA 50 mg daily from the 5th to the 25th day of the menstrual cycle, combined with estradiol 3 mg daily over the last 10 days of CPA administration (n=14), found a 54% reduction in FG score after 1 year of treatment in the CPA group, but only a slight decrease (26%) with hydrocortisone treatment. By contrast, androgen levels dropped significantly in the hydrocortisone group but not among subjects taking CPA.⁷⁴ This interesting finding emphasizes the importance of peripheral androgen receptors in the clinical expression of hyperandrogenism. A German study found similar results.

A randomized trial of 25 unselected women with hyperandrogenemia and hirsutism and without demonstrated adrenal hyperandrogenism found no statistically significant difference between groups treated with dexamethasone and spironolactone (n= 15) versus spironolactone (n=10) monotherapy over 6 months.⁷⁵

In women with glucocorticoid-sensitive hyperandrogenic hirsutism not related to NCAH, a controlled trial comparing dexamethasone treatment to spironolactone (n=54 hirsute women randomized to take spironolactone 100 mg/day, dexamethasone 0.37 mg/day, or both dexamethasone and spironolactone), showed a significant decrease in FG scores after 1 year in all groups. The reduction in hirsutism score was greater when spironolactone was included in the treatment regimen compared to dexamethasone alone (p<0.05).⁷⁶ Androgen levels decreased significantly only in the dexamethasone and dexamethasone plus spironolactone-treated groups. Interestingly, dexamethasone provided a prolonged remission of hirsutism at 1 year post-therapy; while hirsutism scores returned to baseline at 1 year after withdrawal of therapy in those who received spironolactone alone.⁷⁶ Although glucocorticoids modestly reduced hirsutism in hyperandrogenic women, the adverse effects, including adrenal atrophy, hypertension, weight gain, striae, and decreased bone mineral density preclude their regular use in hirsute women with the exception of those with classic CAH and those women with NCAH requiring treatment for infertility.

Are GnRH analogs effective in reducing hirsutism in hyperandrogenic women?

Chronic GnRH therapy suppresses LH and to a lesser extent FSH, leading to reduced ovarian androgen production. Since hirsutism is partially caused by functional gonadotropin hyperandrogenism, GnRH therapy should lead to reduced hirsutism scores. Indeed, uncontrolled trials have demonstrated mild reductions in FG scores compared to baseline in hyperandrogenic women treated with a GnRH agonist.^{77,78} In a RCT that compared nafarelin alone, an OCP (EE plus norethindrone) alone or OCP plus nafarelin combination therapy, there was a significant reduction in hair shaft diameter in the patients

TABLE 37-4—Summary of Trials Analyzing Gonadotropin-Releasing Hormone (GnRH) Agonists in the Treatment of Hirsutism

Drug comparison	Dose Range	Follow-up	Summary of studies
<i>GnRH vs. OCPs</i>			
Heiner et al. 1995 (72)	400 µg nararelin vs. 1 mg norethindrone+ 35 µg EE vs. 400 µg nararelin+ 1 mg norethindrone+ 35 µg EE	24 wks	Significant decrease in hair shaft diameter only in the combination therapy group
Carre et al. 1995 (73)	3.75 mg decapeptyl q4 wks × 24 wks vs. 1 mg norethindrone+ 35 µg EE cyclically vs. 3.75 mg decapeptyl q4 wks × 24 wks + 1 mg norethindrone+ 35 µg EE cyclically	24 wks	Similar decreases in FG scores across all treatment groups
<i>GnRH +/- OCPs versus antiandrogens</i>			
Bayhan et al. 2000 (74)	3.75 mg leuprolide vs. 5 mg finasteride	6 mo	The mean % change (+/- SD %) in FG scores: GnRH: 36% (+/- 14%) Finasteride: 14% (+/- 11%)
Carmina et al. 1997 (75)	3.75 mg decapeptyl + 0.625mg EE+ 10 mg medroxyprogesterone acetate vs. CPA 50 mg+ 50 µg EE	1 yr	FG scores decreased in both groups but remained low after 1 year of further follow-up in the patients receiving decapeptyl

taking the OCP plus naftarelin after 24 weeks of treatment compared to the other two treatment arms (Table 37-4).⁷⁹ While the RCT showed a beneficial effect of combination therapy, other trials concluded that GnRH agonists added to OCPs did not further reduce FG scores or hair diameter when compared with OCP alone (Table 37-4).⁸⁰⁻⁸²

A comparative study (n=60 women with idiopathic hirsutism) examined GnRH alone (depot leuprolide 3.75 mg) versus 5 mg finasteride. FG scores were decreased more in women treated with leuprolide compared to women taking finasteride (Table 37-4).⁸³ When comparing high-dose CPA (50 mg) plus ethinyl estradiol with GnRH agonist therapy (Decapeptyl 3.75 mg), there was a similar decrease in mFG scores at 1 year in both groups; however, the reduction in hirsutism was sustained for a longer period of time in the GnRH agonist group, with hair growth remaining significantly decreased 1 year after withdrawal of therapy (Table 37-4).⁸⁴

Based on weak evidence from the above studies, GnRH agonist therapy appears to improve hirsutism compared to placebo, but there is no definitive evidence that add-on therapy to an OCP confers any additional treatment benefit. Furthermore, there does not appear to be

significantly greater efficacy with GnRH therapy compared to antiandrogens, although treatment benefits may be more sustained with GnRH agonists. The clinical utility of GnRH agonists is limited by their expense, the requirement for intramuscular or intranasal administration, and the need for estrogen supplementation to counteract their menopausal side effects such as hot flashes and emotional lability. GnRH agonists can also exacerbate acne and seborrhea and decrease bone mineral density (Table 37-2).

What We Know

- Glucocorticoids only modestly reduces hirsutism, and their side effects preclude their routine use for hirsutism except in the setting of classic CAH, and in those women with NCAH requiring treatment for infertility.
- The addition of glucocorticoids to antiandrogen therapy can prolong the duration of hirsutism remission.
- GnRH agonists may also prolong remission of hirsutism. Side effects and other more efficacious first and second line treatments, limit the use of these agents.

Are there any herbal supplements that can help reduce hirsutism?

Spearmint herbal tea has recently been shown to have antiandrogenic effects.⁸⁵ A trial by Grant randomized 42 women with PCOS to take either spearmint tea or a placebo herbal tea twice daily for 1 month.³¹ At the end of 30 days, androgen levels (free and total testosterone) were significantly reduced ($p<0.05$); however, there was no significant reduction in FG ratings ($p=0.12$). The latter finding was likely caused by the short duration of the study. The study findings are intriguing. Further trials of longer duration and basic studies regarding the mechanisms for spearmint's antiandrogenic effects are warranted.

TOPICAL MEDICAL TREATMENTS

Are topical therapies effective at reducing hirsutism?

Eflornithine 13.9% Cream

Eflornithine is an irreversible inhibitor of ornithine decarboxylase, the rate-limiting enzyme for polyamine synthesis and subsequent hair growth. Eflornithine 13.9% cream, when applied topically, reduces the rate of hair growth. There are two large industry-sponsored trials examining topical eflornithine for hirsutism. According to Wolf et al. (n=596, 395 women treated with eflornithine, 201 women treated with vehicle), eflornithine significantly reduced the growth and appearance of facial hair as compared to placebo after 8 weeks of twice daily application based on physician's global assessment, and this reduction was maintained for the rest of the treatment period of 24 weeks.⁸⁶ After treatment discontinuation, hair growth returned to pretreatment levels by 8 weeks. Adverse effects included pruritus and dry skin. In another trial, eflornithine treatment led to significant improvements in quality of life measures using the ESTEEM instrument to assess the psychological bother of hirsutism.⁸⁷ Furthermore, the ESTEEM instrument showed strong concordance with physicians' assessments using the mFG scale. Based on these studies, eflornithine reduces facial hirsutism in treated areas and has a minor side effect profile (Table 37-2). However, results are temporary and the treatment can be expensive. No studies have been conducted to evaluate safety in pregnant or in breastfeeding women. http://www.vaniqa.com/files/Vaniqa_Prescription_Info.pdf

Finasteride 0.25% Cream

Finasteride is FDA approved for androgenetic alopecia in men. Off-label use of a compounded finasteride cream for

treating hirsutism has been analyzed in one study. Lucas et al. performed a split-face study to examine the effects of a compounded finasteride cream (0.25%) versus placebo applied twice daily for 6 months in 8 unselected women with mixed etiology facial hirsutism or hypertrichosis (one woman) over 6 months. The study drug was compounded by grinding 15 tablets of finasteride (5 mg each) into propylene glycol and Dermabase (Paddock Laboratories, Inc.). Mean hair count decreased with finasteride treatment but not with placebo ($p<0.05$) and hair thickness also significantly decreased ($p<0.01$) on the side of the face treated with finasteride.⁸⁸ Finasteride cream is contraindicated in women who are pregnant or who may become pregnant. There were no significant treatment-related side effects. Although this study demonstrated treatment-related efficacy, the study was of poor quality with some women simultaneously taking an OCP or hormone replacement therapy. It is therefore, difficult to draw definitive conclusions based on such limited evidence. Further study may be worthwhile.

What We Know

- Finasteride topical cream cannot be recommended based on the available evidence.
- Eflornithine cream is a suitable and safe topical treatment option for hirsutism. Safety studies in pregnant women have not been conducted.
- Drinking spearmint tea lowers androgen levels. Studies have been of insufficient duration to adequately evaluate the effects of spearmint tea on hirsutism.

CONCLUSION

Most of the available evidence regarding various treatments for hirsutism including meta-analyses is based on original studies of low or very low quality and therefore, the evidence upon which recommendations are made is weak. Figure 37-5 provides a model for efficacy of systemic treatments for hirsutism based on the available evidence and Figure 37-6 provides treatment algorithms based on the above evidence. There are relatively few placebo-controlled RCTs with large sample sizes that adequately stratify patients according to their underlying etiology, and have methodologies of good quality. There are recognized limitations to clinician-assessed FG scoring, yet few studies actually measure patient-reported hirsutism outcomes and correlate these with FG score. The Endocrine Society's guidelines and commissioned meta-analyses for medical interventions are highly recommended sources for further information and guidance on the topic (Table 37-1).

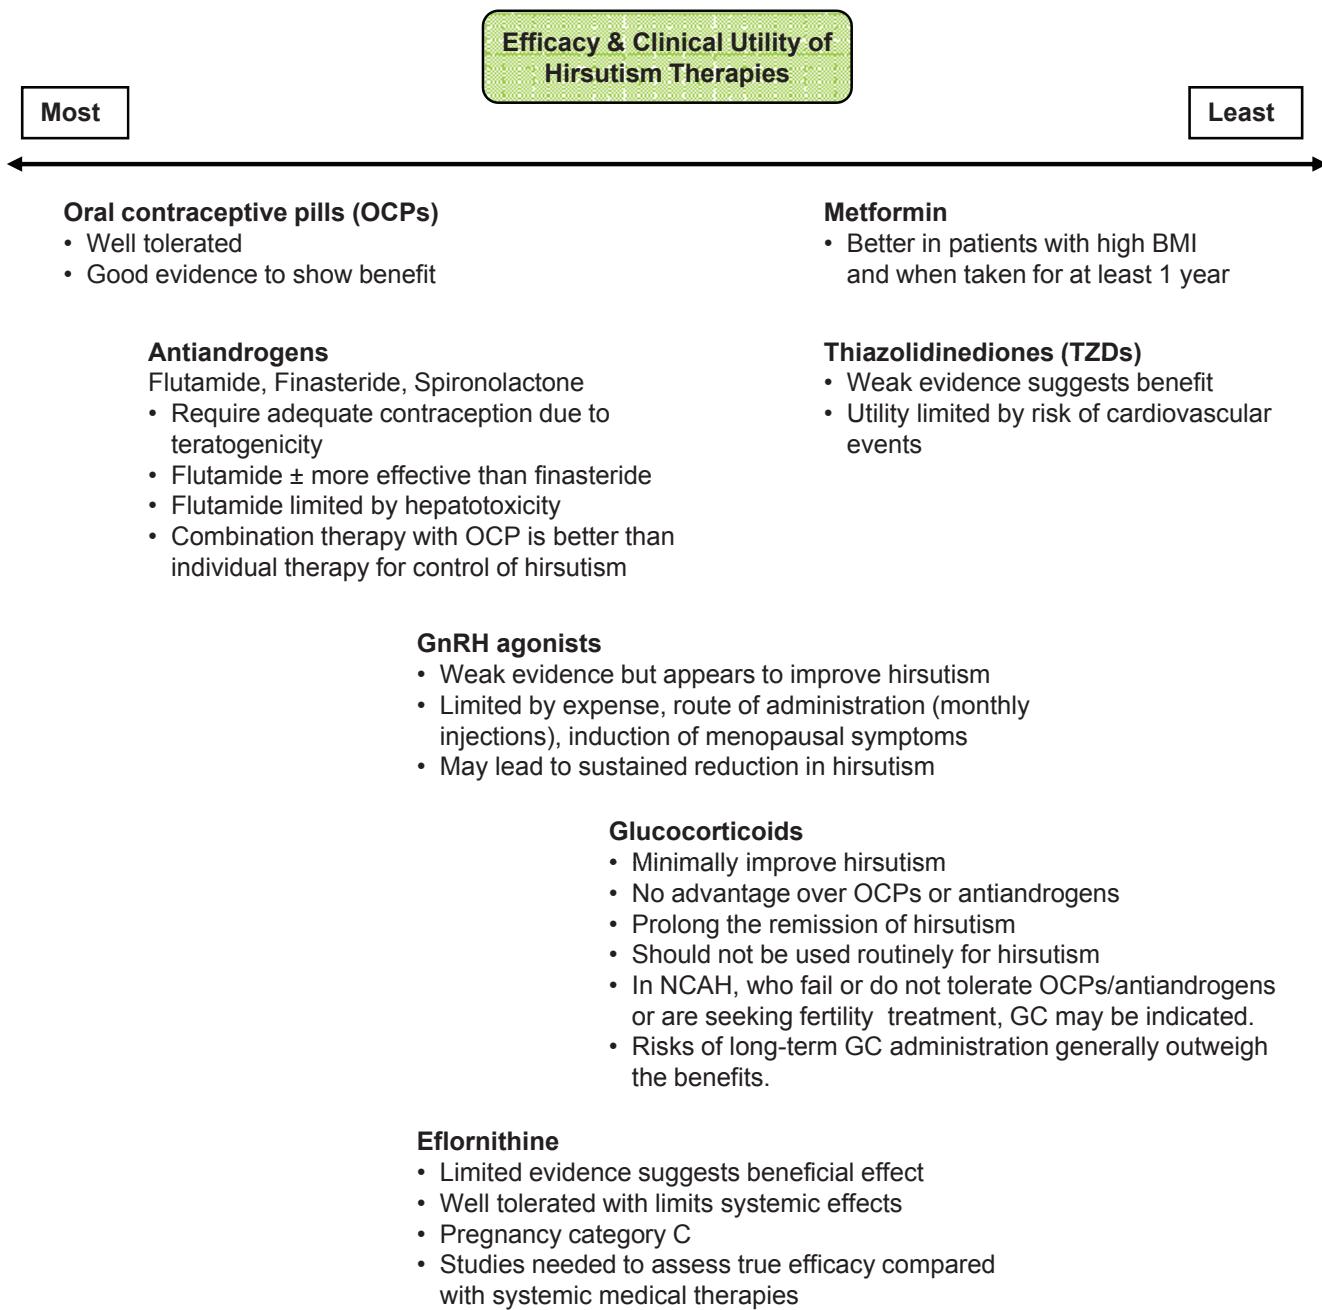

FIGURE 37-5 Evidence-based efficacy models for the systemic treatment of hirsutism.

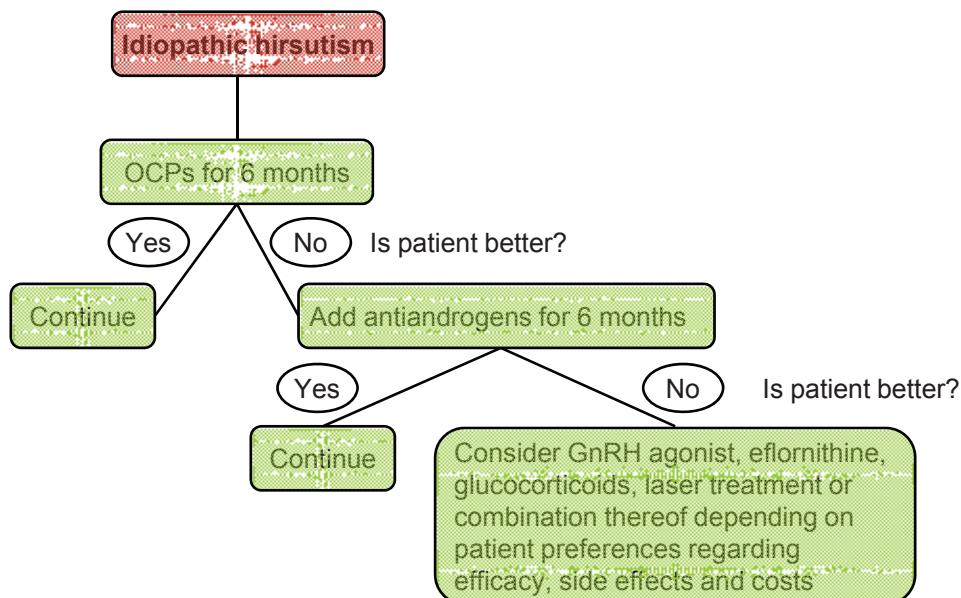

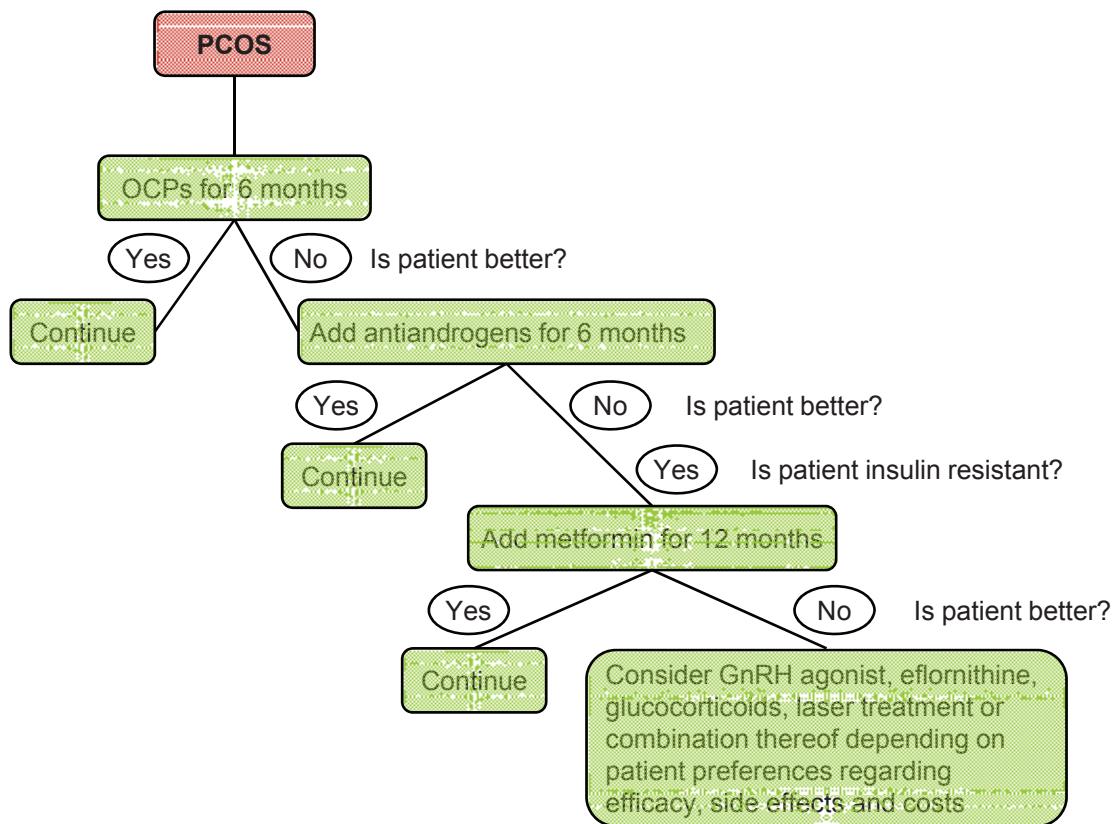

FIGURE 37-6 Evidence-based treatment algorithms for the medical treatment of hirsutism.

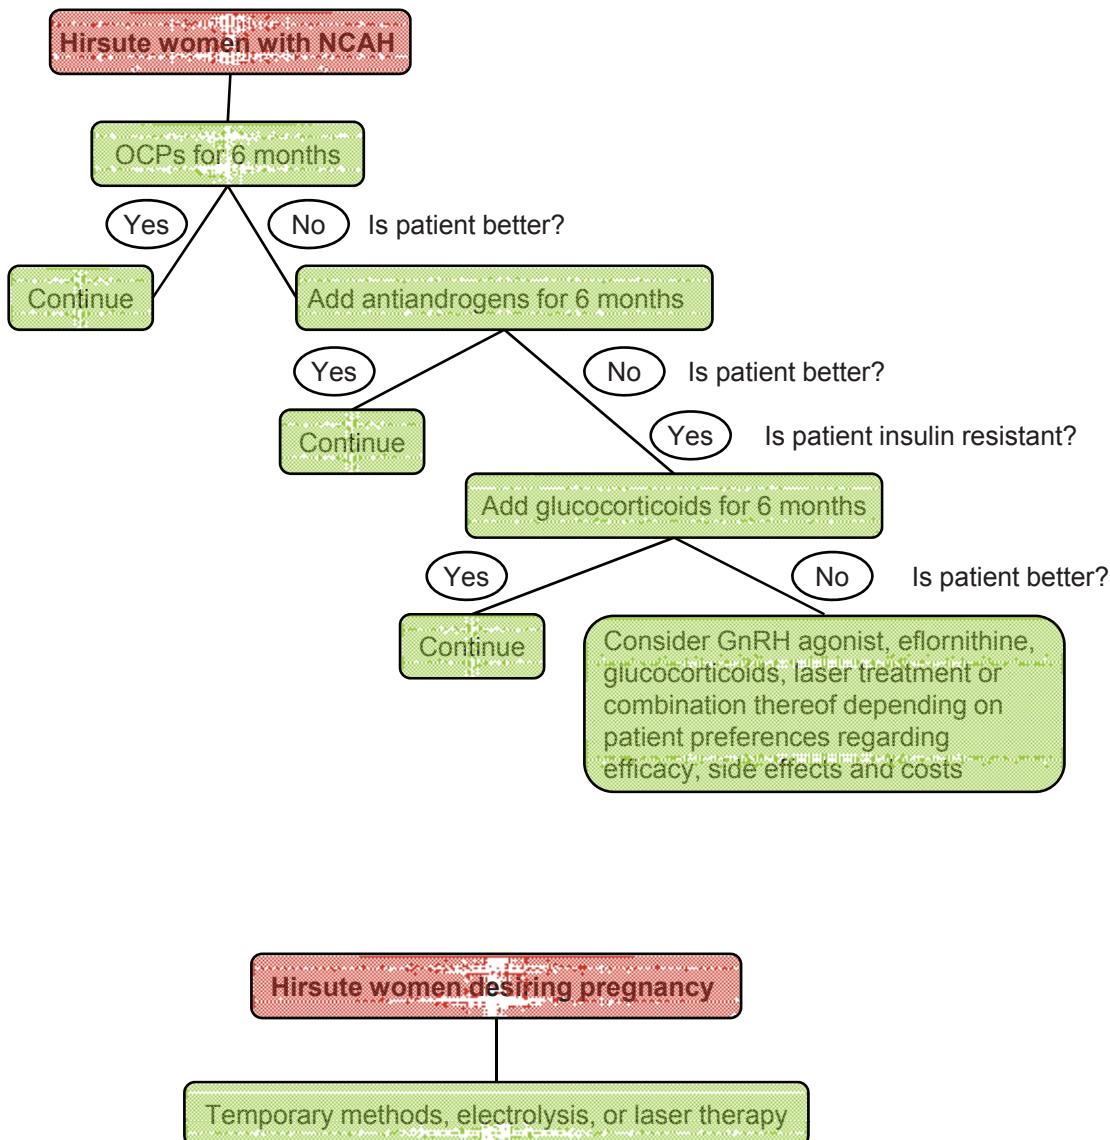

FIGURE 37-6 (Continued)

What We Know

- OCP therapy is associated with a significant reduction in hirsutism scores compared to placebo or no treatment. Recent guidelines recommend OCPs as the first line therapy for hirsutism given the teratogenic potential for antiandrogens
- OCPs should be chosen with a progestin component of low androgenicity or with antiandrogenic effects.
- Desogestrel, CPA, and DRSP containing OCPs are the best studied.
- Antiandrogens are an effective treatment for hirsutism (3 women need to be treated with spironolactone, flutamide or finasteride (NNT) for one to notice an improvement).²⁶
- Treatment with antiandrogens needs to be continued for at least 6 months to see a benefit.
- Flutamide may be more effective than finasteride but its risk of fatal and nonfatal hepatotoxicity limits its clinical utility compared to other antiandrogens.
- Antiandrogens can feminize a male fetus and must be used in conjunction with adequate contraception.
- Antiandrogens are more effective than metformin (NNT = 2 for flutamide vs. metformin; NNT = 5 for spironolactone vs. metformin)²⁶
- The addition of antiandrogens (spironolactone or finasteride) to OCPs is more efficacious than OCPs alone (NNT = 6)²⁶
- The addition of an antiandrogen (flutamide) to metformin is more efficacious than treatment with metformin alone (NNT = 2)²⁶

(Continued)

What We Know (Continued)

- Weak evidence shows limited to no significant beneficial effect of insulin sensitizers (metformin and TZDs) as a class for hirsutism.
- Although pooled studies of metformin show no beneficial effect on hirsutism scores, metformin may be beneficial in reducing hirsutism in overweight and obese patients with PCOS, especially those patients who have taken metformin for at least 12 months.
- Glucocorticoids only modestly reduce hirsutism, and their side effects preclude their routine use for hirsutism except in the setting of classic CAH, and in those women with NCAH requiring treatment for infertility.
- The addition of glucocorticoids to antiandrogen therapy can prolong the duration of hirsutism remission.
- GnRH agonists may also prolong remission of hirsutism. Side effects and other more efficacious first and second line treatments, limit the use of these agents.
- Finasteride topical cream cannot be recommended based on the available evidence.
- Eflornithine cream is a suitable and safe topical treatment option for hirsutism. Safety studies in pregnant women have not been conducted.
- Drinking spearmint tea lowers androgen levels. Studies have been of insufficient duration to adequately evaluate the effects of spearmint tea on hirsutism.

Evidence-Based Procedural Dermatology

38

Murad Alam, M.D., M.S.C.I.

Evidence-based procedural dermatology is finally no longer an oxymoron, but the road has been arduous and hilly terrain yet lies ahead. The inherent difficulties in advancing this field are largely the same ones that plague much of surgical research, regardless of specialty. In addition, there are peculiar obstacles to surgical research that are dermatology-specific. Finally, proceduralists themselves cannot be absolved of all responsibility. We sometimes suffer from reluctance to measure what we believe to be true. While this has been taken by detractors to be indicative of an anti-intellectual bent, the reality is quite the opposite. Surgeons are among the most therapeutically courageous, creative, and methodical dermatologists, but they are sometimes more inclined to invest their energies and intellect in improving procedures than in measuring the results.

DEFINITION OF PROCEDURAL DERMATOLOGY

For the purpose of this discussion, procedural dermatology may be defined to include minor and major invasive and noninvasive procedures performed by dermatologists. In concrete terms, these include several major categories of procedures, including skin cancer surgery and cosmetic procedures. Skin cancer surgery includes treatment of actinic keratoses with cryotherapy and photodynamic therapy; skin nonmelanoma skin cancer with electrodesiccation and curettage, excision, and Mohs; atypical nevi with excision; and melanoma with wide local excision and Mohs. Cosmetic procedures can be subdivided into energy procedures (laser, light, radiofrequency, ultrasound) that typically require large devices; minimally invasive cosmetic procedures (injectables and fillers, superficial peels and microdermabrasion, sclerotherapy); and major cosmetic procedures (ablative resurfacing with laser, peels or dermabrasion; rhytidectomy; blepharoplasty; endovenous laser or radiofrequency surgery, liposuction, large-scale skin reduction). In a nebulous area between cancer surgery and cosmetic procedures lie procedures pertaining to the removal of indefinitely benign but troublesome growths, such as cysts and lipomas.

THE MAKING OF A PROCEDURAL DERMATOLOGIST

To some extent, procedural dermatology has been defined by the availability of advanced training in the field. Apprenticeships with cosmetic surgeons and Mohs surgeons have been a staple of the past half century. Over time, these have coalesced into formal half-year or year-long training experiences.^{1,2} Professional organizations such as the American College of Mohs Surgery (ACMS, formerly ACMMSCO) and the American Academy of Cosmetic Surgery (AACS) have sought to standardize such training by creating clear expectations for training directors and trainees (e.g., fellows). More recently, in the past 5 years, an American Council of Graduate Medical Education (ACGME)-accredited fellowship in Procedural Dermatology has been inaugurated. Development of the guidelines for this fellowship has helped define the scope of advanced procedures in which dermatologists should have technical expertise. At times, a rancorous debate has ensued about which procedures are advanced procedures that so-called dermatologic proceduralists may consider their area of expertise, and which procedures are routine dermatologic procedures that are expertly performed by any dermatologist. Some maintain that no such distinction can be made and that no subset of dermatologists can claim any particular expertise in any particular procedure; procedures belong equally to all dermatologists. The countervailing argument has been that dermatology recognizes other clinically based subspecialties, such as pediatric dermatology and dermatopathology, and procedural dermatology, may have a similar claim when its practitioners have obtained additional training.

In any event, the term “procedural dermatology” is now used to signify both an area of dermatology (the subject of this chapter), and the clinical practice of so-called procedural dermatologists, and confusion can result. In the remainder of this chapter, the term will only be used to refer to the body of knowledge, and no implication will be made that any particular subset of dermatologists is more likely to successfully deliver any of the interventions subsumed in this category.

PROCEDURAL DERMATOLOGY IN THE DERMATOLOGY LITERATURE

Since the advent of the *Journal of Dermatologic Surgery and Oncology* (now *Dermatologic Surgery*) 35 years ago, procedural dermatology has had a friend in the medical literature. As Perry Robins relates it,³ when he founded JDSO, the prevailing view was amazement and a firm belief that he would be unable to fill it with articles of even dismal quality. This did not come to pass. More recently, during the past 10-20 years, there has been an upswing in the willingness of the principal general dermatology journals in the United States (e.g., *Journal of the American Academy of Dermatology*, *Archives of Dermatology*) to consider procedural manuscripts. No doubt, some of this sea change may be ascribed to the leadership of these journals; both Kenneth A. Arndt and June Robinson, collectively editors-in-chief of Archives for the past quarter century, are themselves pioneering proceduralists. There are also several other notable venues for procedural dermatology articles, including the *Journal of Cosmetic and Laser Therapy*, *Lasers in Surgery and Medicine*, and *Lasers in Medical Science*. Some other journals that have had many procedural contributions are the *Journal of Drugs in Dermatology*, *Journal of Dermatological Treatment*, and *Skin Therapy Letter*.

The procedural dermatology literature is evolving. There remains a brisk pipeline of articles pertaining to novel devices, especially laser and energy devices. As each such device is subtly different, and as there are no true generics for devices, trials must be repeatedly performed to establish the settings and parameters for efficacious treatment. The types of devices appearing frequently in the literature vary with the times. For instance 5-10 years ago, there was an abundance of articles about hair removal lasers; then came nonablative radiofrequency tightening devices and fractional resurfacing devices. An increasing number of articles now also address combination cosmetic treatments, such as those combining injectables with energy devices.

However, not all the notable articles of the past decade have been about cosmetic procedures. In the realm of cancer surgery, there has been a flurry of work pertaining to the treatment of skin cancer in transplant patients; the diagnosis and treatment of lentigo maligna and melanoma, including dermoscopy; and better understanding of management of rare tumors, like Merkel cell carcinoma.

MAJOR METHODOLOGIC ISSUES IN PROCEDURAL DERMATOLOGY

Comparative Studies

There are several major technical problems that have historically limited the rigor and hence authoritativeness of the procedural dermatology literature. One of these is the dearth of comparative studies that assess a novel intervention directly against an older procedure with a similar

indication. Thus, a study of a novel fractional laser resurfacing device may compare its benefits to the absence of any alternative treatment, rather than comparing it to an older resurfacing device, or some other resurfacing technique (e.g., medium-depth chemical peel), or even a placebo, such as an emollient. While this process of comparing treatment to no treatment can result in detection of a large effect size (i.e., relative benefit for the treatment arm), this may still not induce a change in clinical management, since the alternative treatment is rarely to do nothing, and the prevailing standard-of-care treatment may be as good as the novel experimental treatment. Moreover, comparisons to lack of treatment do not account for placebo effect. That is, when patients are provided a free procedure, as in the case of many studies, they are prone to see a significant benefit even when little or no benefit objectively exists. This overestimate of efficacy is not a deliberate attempt to deceive, but rather may be an expression of gratitude for the free treatment, a desire to please the investigator, or a form of self-reassurance that the pain and inconvenience of the procedure were worthwhile. Comparing one procedure to another procedure may mitigate the placebo effect. Of course, sometimes this can be infeasible, and it is not always possible to do a sham procedure that looks and feels just like the experimental procedures. To wit, patients who get petrolatum to one area and laser to another will know which side received the “real” treatment, and therefore be subject to a significant beneficial placebo effect on that side versus the other side; similarly, if an ablative laser is used on one side and a nonablative laser on the other, the sensations will be markedly different, as will the appearance of the skin post-treatment.

Power and Sample Size

Another significant methodologic concern is the need for adequate sample size in studies of procedures.⁴ Sample size is intimately related to effect size and power. Intuitively, the bigger the difference expected between the efficacy of two procedures (i.e., the larger the effect size), the fewer subjects will be needed to show this is the case (i.e., the smaller the sample size that will be needed). Power refers to the level of surety that a given real difference will be detected with a particular sample size; if the investigators want to be extremely sure that no difference is missed, they select a high power (e.g., 0.9 rather than 0.8), which will require a correspondingly larger sample size. Primarily, procedural dermatology studies suffer from underpowering. Part of the problem is that many studies are commenced without even attempting a power study; investigators just select a number that *prima facie* appears reasonable to them, or they enroll as many as they can. This many is frequently not enough. When a power study is performed, the projected sample size may not be practical to achieve. It can be onerous to collect a large number of patients at just one site. Moreover, multicenter trials are difficult to

perform, given the incompatibility of sparse funding for clinical research in procedural dermatology and the ever-burgeoning additional costs of cross-center collaborations mandated by health insurance portability and accountability act (HIPAA) requirements and ever-expanding institutional review board (IRB) strictures. However, even when patients are available and costs not prohibitive, it may be challenging to correctly power a study in the absence of prior research with which to estimate effect size. Since clinical research in procedural dermatology is young, often there are no older similar studies on which to base assumptions. This ambiguity may engender overly rosy guesses: when you do not know how many you need, you might as well make it easy for yourself and go with the lower number.

Measurement of Outcomes

A related obstacle is the subjectivity and imprecision of the outcomes to be measured. For instance, in a cardiology study, outcomes such as death or left-ventricular ejection fraction are precisely measurable. In procedural dermatology, on the other hand, outcome measures for cosmetic trials can be such vague constructs as patient satisfaction, or degree of improvement in appearance of photoaging. For cancer reconstruction trials, the outcome may be the attractiveness or imperceptibility of the scar. Indeed, the FDA has been reluctant to grant any device an indication for “skin tightening” in large part because no rigorous definition for this amorphous outcome has been put forth. Procedural dermatology outcomes are often qualitative, ordinal, or categorical, not dichotomous or continuous. This complicates estimation effect size and power, and the overall utility of the trial. To a large extent, obtaining useful information from a procedural dermatology study is contingent on the training and skill level of the blinded raters used to assess the subjective outcome. If they are ill trained, distracted, or imprecise, it may be impossible to detect an effect regardless of the patient number. Similarly, the skill level of the surgeon performing the procedures is a variable that can skew outcomes. If chemical peels are being compared to laser resurfacing for efficacy in treatment of acne scars, it will be important to ensure that all the operating surgeons are equally expert on both procedures, so that the outcomes are a reflection of the difference between modalities and not of the surgeons’ limited skills in one area. Finally, sometimes the real difference being examined in a procedural trial is so small that a subjective measure is unlikely to be able to elucidate it. For instance, even in the best hands, two materials for soft-tissue augmentation may be so similar that patient differences, injection technique, and other factors outweigh any inherent difference between the products. As there are no generic devices, and every maker touts their own iteration as the superior version, many cosmetic surgery trials are designed to compare two devices (e.g., hyaluronic acids, or fractional lasers) that use

the same underlying technology; such trials can be remarkably uninteresting when not much difference is found.

Some investigators have worked hard to improve the quality of outcome assessment. Thus, precise measuring devices, like ultrasound scanners and 3-D animations, have been used to map and compare differences too small for the naked eye to detect. The caveat here is that it is hard to give credence to the output of a measurement device that has not been validated, as it is certainly possible for such a device to generate precise measurements that are neither reproducible nor accurate. A stronger critique is that even if the machine detects a “real” difference, this may not be interesting if no human, even with the best eyesight under optimal conditions can corroborate the change. It seems unreasonable to advocate that a patient obtain a cosmetic procedure that is ostensibly superior when none of their friends, family, or acquaintances will be able to distinguish it from a less expensive, older one. That is not to say that the best measure of a cosmetic or reconstructive procedure is patient self-assessment. Patient assessments are notoriously inaccurate, almost invariably inflated for several reasons: (1) a desire to please the investigator, who may also be their personal physician; (2) an expression of gratitude for a free procedure to reduce the visible signs of aging or restore function; (3) an expectation that the discomfort and inconvenience associated with the intervention would necessarily result in aesthetic improvement; and (4) lack of numeracy and quantitative skills, which exacerbates the tendency to overestimate improvement.

From a philosophical standpoint, the best assessment of the efficacy of a cosmetic procedure remains whether the patient looks better after than before. Practically, the least biased, most valid measure of improvement currently available is probably blinded rater assessment. The quality of the rater is important, and in general, board-certified, experienced dermatologists are more credible than residents and fellows in training, medical students, and other well-intentioned bystanders. Having more than one rater may minimize the disproportionate effect of one rater’s preferences: personal standards of physical attractiveness may play a role in evaluating any cosmetic outcomes, even when no overt bias is present. On the other hand, multiple raters do increase study complexity and cost, and raters may not agree. Statistical tests can be performed to assess the degree of inter-rater agreement. An alternative method that has been accepted by FDA for device clinical trials is “forced agreement.” In this approach, multiple raters score an outcome independently, and then meet to debate and resolve any discrepancies.

A major obstacle to blinded rater evaluation is that the process can undermine the quality of the data being assessed. It is difficult to maintain blinding during live subject examination; additionally, live examination precludes comparing before and after results side-by-side. So photographs are typically used. Nevertheless, even high quality standardized photographs taken from several vantage points have flattened

topography, limited contrast, and artificial hue compared to the original. Three-dimensional representations can be created to overcome these limitations, but these constructs are also a proxy for the real thing, and not as good. Notably, in many procedural studies, single- or rater-blinding is the best that can be managed. This derives from the nature of the underlying procedures, which often preclude patient blinding. One laser may not feel like another, and one excisional technique may take longer, require different equipment, and leave a different scar than another. The obvious solution, sham surgery on the control side, is often infeasible, and requires a very convincing rationale to survive IRB review.

Statistical Methods

A final limitation that pervades many procedural dermatology studies is inadequacy of the statistical section. In some cases, statistics are not necessary. For example, papers that elucidate surgical technique, or those that survey a subset of proceduralists, may only provide descriptive statistics, such as the percentage of a certain procedure associated with complications, or the number of Merkel cell carcinomas treated by a cohort of dermatologists in Indiana in 2008. However, very often, some statistical analysis is desirable. This can be facilitated by enlisting the services of a good biostatistician, who may be available from a local university or an affiliated comprehensive cancer center. Indeed, before even commencing a study, it is very useful to write a complete protocol itemizing exactly what is to be done, the types of data to be collected, and the main outcome measures. At this point, before a single patient is enrolled, the biostatistician can not only provide a power study and sample size estimate, but also confirm that the data will be analyzable to yield information of the type desired by the investigator. If the statistical analysis is post-hoc, the statistician can still explain what can be analyzed. It is often helpful to formulate questions that the investigators would like the study data to answer. The biostatistician can then organize the data in an appropriate manner, apply the necessary statistical tests, and explain the findings. Typically, in procedural dermatology studies that do include statistical analyses, p-values are listed to demonstrate statistical significance or lack thereof. While this can be helpful, it is also valuable to list 95% confidence intervals of the key measures. Confidence intervals are an intuitive way to display the likely range of a given variable, and compare it to other variables.⁵ To wit, let us say that eating beets reduces new actinic keratoses to 3 a month but excision cuts down the rate to 1 per month, $p=.42$. On a cursory read, it is easy to mistake the difference between one and three as clinically significant, or to be baffled as to why the p-value is so high. But if the confidence intervals are listed, and it turns out that the likely true efficacy range of excision is 1 ± 4 (95% CI: -3 to 5), and of beets, 3 ± 2 (1 to 5), it becomes obvious that the overlapping of

the confidence intervals means no persuasive difference has been detected. Confidence intervals are as yet reported infrequently in procedural dermatology trials.

An important distinction rarely tackled is the difference between statistical significance and clinical significance. A study that does not detect a statistically significant difference cannot be said to have found a difference of clinical significance. However, even if a statistically significant difference is revealed, it may not be clinically significant. The subjective nature of many outcome measures in procedural dermatology makes this problem worse. As an example, let us say an ultrasound-tightening device results in 45% improvement of fine wrinkles, but a radiofrequency device provides 55% improvement, with this difference being statistically significant. It remains unclear whether the difference is clinically significant, as it is uncertain to what extent patients value a 10% difference in wrinkles, and to what extent a decrement of 10% is associated with objective harm. A related issue is willingness-to-pay. Willingness-to-pay is a measure of the value in dollars that patients hypothetically ascribe to a given outcome. In our example, we would like to know how much patients are willing to pay for the 10% wrinkle reduction possible with the more efficacious device. A high enough amount may make the radiofrequency procedure desirable even if it is more expensive; but if the patient premium for the incremental 10% benefit is low, patients may prefer to forego a more expensive radiofrequency procedure for a cheaper ultrasound procedure.

Randomized Control Trials, Structured Reviews, and Meta-Analyses

Randomized trials are probably more feasible and hence more common for comparing cosmetic dermatologic interventions. Here, however, there are problems associated with recruitment and loss to follow-up. Cosmetic patients are often not willing to endure the perceived indignity of being in a study, and may be willing to pay full price to avoid this. They want what they want, when they want it, and are at variance with the traditional medical model, in which a compliant patient is beholden to the physician for improving their health. Potential patients may also be reluctant to receive placebo, or worse yet, undergo a split-body randomization, in which part of their skin surface may be improved, but part left unchanged. No one wants to be asymmetrical, especially when the purpose is betterment of appearance, not disease amelioration. Furthermore, when patients do enroll in cosmetic trials, they may be highly susceptible to dropping out. Once the intervention has been received, they have limited incentive to return for follow-up visits to assess treatment efficacy and longevity. Studies that are conservatively designed with an “intention-to-treat” methodology, which includes all randomized patients in the final analysis, may see their results weakened to nonsignificance by this problem. More patients

can be recruited, but this is not easy either, as explained before.

Meta-analyses are studies that combine and re-analyze the data from multiple randomized trials on same question. Structured reviews also evaluate evidence from many similar studies, ideally mostly randomized-controlled trials, but such reviews do not necessarily re-analyze any data. To the extent that there is a dearth of randomized-controlled trials in both skin cancer and cosmetic surgery, there is limited substrate for creating meta-analyses and structured reviews. This means that many important questions cannot be definitively answered, with conflicting low-level evidence forcing every physician to make their own judgments. Clearly, there is a need for more randomized trials. Additionally, it would be helpful if there were some coordination among investigators, such that the most vital questions were studied first, and each in several independent studies. There have been some efforts to unite data collection for procedural dermatology trials across centers; for instance, the Sulzberger Institute of the American Academy of Dermatology has funded the Dermbase project, which creates a web-based interface for prospective multicenter data collection.

TOPIC-RELATED LIMITATIONS

Cosmetic and Laser Surgery

Procedural dermatology is comprised of subfields, and the most notable division is between cosmetic dermatologic procedures and skin cancer surgery. Each of these is associated with specific challenges that complicate the prosecution of high-quality research. Cosmetic dermatology suffers from problems with patient recruitment. Cosmetic patients from one's own practice may be the easiest to recruit for studies since they have a pre-existing relationship, and are likely to follow instructions and return for follow-up visits. However, this same relationship may lead these patients to provide an overly optimistic judgment of the efficacy and tolerability of a procedure. Recruiting cosmetic patients from newspaper advertisements and public postings is fraught, because this results in many patients willing to receive a free cosmetic procedure but unwilling to follow-up, and because myriad screen failures (e.g., patients who come in to be evaluated but do not qualify for the study) can make an underfunded cosmetic study even more financially unsound.

As noted in the preceding section, outcomes of cosmetic procedures are especially difficult to measure in a meaningful way. In part, this is because aging is not classified as a disease. Therefore, it is necessarily difficult to compare the visible signs of aging to those of a "non-disease" benchmark for similarly aged patients of similar stature, gender, and ethnic type. Since patient features cannot be compared to fixed reference points (e.g., as in the assessment of blood pressure), we are limited to comparing preprocedure

features to postprocedure features. Patients continue to age while these procedures and comparisons are performed, thus further complicating the comparison. In fact, cosmetic dermatology studies often have a relatively short follow-up period for this reason: over the long-term, whatever the benefits of the intervention, they are overwhelmed and subsumed by the relentless deterioration of the aging body. Follow-up may also be abbreviated for other reasons: (1) subjects may after a few months choose to receive other noninvestigational cosmetic procedures, which can obscure measurement of the effects of the initial intervention; and (2) some cosmetic procedures intrinsically have a short half-life. Short follow-up periods can be problematic for tightening, filling, and wrinkle reduction procedures in which immediate postoperative edema, which soon remits, can be mistaken for a successful outcome.

In addition, with cosmetic surgery studies, there are problems pertaining to conflict of interest. Cosmetic interventions often require devices, which range in complexity from syringes containing temporary filler pastes, to lasers and energy devices comprised of hundreds of parts. Most of these devices are developed by commercial entities, which in turn enlist dermatologists to study their use. Often the physician leaders in device research derive significant revenue from the manufacturers and distributors of the corresponding devices, so creating a situation in which the investigators may be vulnerable to conscious or unconscious bias to selectively detect high levels of device efficacy. Demands to eliminate such conflicts are unrealistic because virtually all the leaders in cosmetic device research have multiple relationships with industry. Moreover, it is not clear whether an investigator who has a low level of familiarity with a new device, or who has not previously worked to develop and test similar devices, would be able to execute a clinical trial that best utilized the device to attain a given clinical endpoint. Significant background knowledge appears to be a prerequisite for optimally adapting a device for a particular indication. Nonetheless, the charge that the underlying conflicts do sometimes detract from the transparency of the research is a troubling one, and difficult to disprove.

Skin Cancer Surgery

Studies of skin cancer surgery and reconstruction are also associated with specific challenges and limitations. In a common type of cohort study, surgeons describe a number of patients who have undergone a novel procedure, or a procedure at least partially modified from the standard approach. Such studies are always at risk of degenerating into anecdote. Case series or cohorts may be from a single center or refer to procedures performed by a single surgeon, with this structure rendering them susceptible to selection bias and limiting their external validity.⁶ An associated issue is that large series may pull patients from many

years, even decades, and the surgical methods may have evolved or changed over this duration.

Well-controlled cohort studies and randomized control trials have some of the same problems. In all of these, it is quite common to have inadequate methods sections that do not fully describe, in minute detail, the exact surgical approach. Thus, even if the reader is convinced of the efficacy of a surgery, replicating this clever solution may be impossible without contacting the authors for additional information. It may also be difficult to completely account for the idiosyncrasies of specific surgeons, and to generalize to a hypothetical standard surgeon. Well-designed prospective studies do attempt to enroll multiple qualified surgeons, and even to provide consistent training to these, but surgeons are not robots, and all surgeons have strengths, weaknesses, and biases that predate the inception of the study. Not every hand movement can be prescribed, not every scalpel cut can be standardized, and not every surgeon handles tissue equally gently. A study may find a procedure to be of limited benefit not because the procedure is inherently flawed, but because the surgeons who performed it may not have been best suited to making it more successful.

Some limitations of skin cancer research are exogenous to dermatologic surgeons. Thus, randomized-controlled trials to assess novel treatments for nonmelanoma skin cancer are elusive because highly effective, nonexperimental treatments already exist. Indeed, it is unlikely that treatments can be devised that are *more* effective than Mohs surgery, which in some studies has a cure rate of in excess of 99% for primary basal cell carcinoma. Experimental nonmelanoma skin cancer treatments may have benefits in terms of patient convenience or cost savings. However, these benefits are much harder to elucidate in a well-designed study; convenience is a fungible concept, and aggregate cost includes indirect costs, such as “shoe leather” costs associated with repeated patient appointments, daycare costs, and the like, which are hard to gauge precisely. Novel cancer treatments may be most useful for rare or aggressive skin cancers, which are less amenable to standard therapy. However, the very rarity of these cases makes a randomized control trial difficult to perform.

FUNDING SOURCES

Funding for procedural dermatology studies is sparse, sporadic, and unpredictable. Nonmelanoma skin cancer, and even early, primary melanoma, does not elicit much enthusiasm from federal funding agencies. In the absence of significant nonmelanoma skin cancer-associated mortality, procedural dermatologists are forced to highlight the associated quality-of-life impact,^{7,8} which is not considered as persuasive by nondermatologists. Appropriate metrics have not been developed to sum the aggregate quality-of-life decrement among literally tens of millions of nonmelanoma skin cancer patients in the United States.

So-called “utility” measures, which can compare quality of life across disparate disease states, remain controversial. As a consequence, funding for nonmelanoma skin cancer research has been very limited. Veterans Administrations grants, Dermatology Foundation grants, and modest local funding has supported the preponderance of clinical research in this area. Research on topical prophylactic medications, such as imiquimod, has been bankrolled by manufacturers, but as discussed before, this can hardly be considered an unbiased approach.

In the realm of cosmetic procedural dermatology, the situation is even grimmer. Apart from research underwritten by device manufacturers, there is little clinical research of any sort in this area because of the lack of other funding sources. Dermatology Foundation career development grants on the science of human appearance are welcome, but data from these projects cannot be leveraged to obtain federal funds, which are not at all forthcoming in this area. Minute professional association grants, like those from the American Society for Dermatologic Surgery and the American Society for Laser Medicine and Surgery, can initiate interesting routes of inquiry, but not sustain them. Paradoxically, the extremely high level of safety associated with cosmetic dermatologic procedures has reduced the urgency to study these. The one moderately well-studied cosmetic procedure is liposuction, which has elicited this special attention because of a misunderstanding on the part of regulators and the general public regarding the risks of tumescent liposuction versus liposuction under general anesthesia; that is, tumescent liposuction is exceedingly safe, but we in dermatology have had to substantiate this in the face of unsupported misinformation. However, the safety of other cosmetic procedures should not diminish our interest in studying them. Efficacy, longevity of effect, convenience, level of discomfort, cost, and other similar parameters can be used to distinguish between high quality and less successful cosmetic procedures. In this vibrant, ever-changing area, such research can also help ensure that successive devices are better, and not merely different.

ADVANCES IN EVIDENCE-BASED PROCEDURAL DERMATOLOGY

It is easy to lose the forest for the trees. While there is much in procedural dermatology that could be better, during the past several decades, the field has made enormous advances. Virtually all cosmetic laser devices and most fillers and injectables were developed and refined by procedural dermatologists. In the skin cancer realm, proceduralists have drastically reduced with Mohs the recurrence rates associated with nonmelanoma skin cancer; they also perform more facial reconstruction than all other medical specialties combined. For the most vulnerable patients, such as organ transplant recipients, procedural dermatologists have clarified optimal diagnosis and treatment regimens.⁹ Perhaps most notable among the

achievements that can be ascribed to procedural dermatology is the conclusive determination that complex cancer and cosmetic surgeries can be safely performed under local anesthesia.¹⁰ The body of knowledge now clarifying this beyond a shadow of a doubt is truly immense. Indeed, even invasive procedures such as liposuction can be performed *more* safely under local anesthetic in an office setting than under general anesthesia in a traditional operating room.

Journals that publish procedural dermatology articles have helped to improve the quality of research in this area. For instance, *Dermatologic Surgery*, historically the principal repository for the procedural dermatology literature, has de-emphasized anecdotal "how I do it" type articles in favor of articles that attempt to describe the utility of a procedure in more systematic manner. Peer review has become more stringent as the number of procedural dermatologists has grown, and the specialty has become large enough to field numerous experts in various sub-fields and topic areas. The quality of some research in procedural dermatology has risen to the point where it has found a home in the well-regarded general medical literature, including journals such as *Cancer* and *JAMA*. The breaching of this glass ceiling is a source of encouragement to young investigators.

In the future, such young investigators may help transform this field. Historically, in academic procedural dermatology, a single procedural dermatologist or dermatologic surgeon was responsible for performing surgery, teaching residents, administering staff, and occasionally writing a paper or two. Over the past 10 years, many university dermatology departments have acquired two or more dermatologic surgeons. As the number at some centers moves to three and more, it becomes possible for one or more surgeons to be freed of many routine clinical and teaching responsibilities so that they may devote more time to research. This research can be internally funded, by a tax on surgery section revenues, or by external grants, which may be easier for an applicant to garner if 70-80% of effort is protected for research. Based on this model, notable efforts to perform population-based research have been

undertaken at Kaiser Permanente in California, and at the Mayo Clinic in Rochester. Various centers, the University of Michigan being the most prominent, have been successful at creating an incubator for academic procedural dermatologists with a research focus. A number of procedural dermatologists have now acquired advanced training in clinical epidemiology and health services research; for perhaps the first time, young trainees are deliberating embarking on this path early in their careers, hoping to become the research pioneers of tomorrow.

Treatment of Unwanted Hair (Nonmedical Interventions)

Sailesh Konda, M.D., and Tina S. Alster, M.D.

INTRODUCTION

Patients seeking treatment for unwanted hair has become one of the most common reasons for dermatologic consultation. The causes of hirsutism and hypertrichosis are numerous, including heritable factors, endocrine disorders, and exogenous drug therapy.¹ Increased hair density in men and women may be localized or generalized. Patient concerns related to hair removal treatment include clinical efficacy, safety, expense, convenience, associated pain, and other short- and long-term side effects.

ANATOMY OF THE HAIR FOLLICLE AND HAIR GROWTH

The hair follicle can be divided into four distinct regions—bulb, suprabulbar zone, isthmus, and infundibulum. The actively growing portion of the hair is the matrix, which along with the dermal papilla, comprises the hair bulb. Matrix cells rapidly divide, migrate upward, and are confined to the lowermost portion of the follicle. The isthmus of the follicle is the short portion located between the point of attachment of the arrector pili muscle and the entrance of the sebaceous gland duct. The infundibulum lies above the entry of the sebaceous duct to the hair follicle orifice and merges with the epidermis.

Actively growing (anagen) hairs are characterized by a hair matrix surrounding a dermal papilla with well-developed inner and outer root sheaths. On the scalp, a typical anagen follicle produces a hair shaft for approximately 2 to 3 years—giving rise to longer hair. The shorter hairs found in other body locations have correspondingly shorter anagen periods. Dying or regressing (catagen) hairs are identified by markedly thickened vitreous layers and fibrous root sheaths surrounding an epithelial column, above which the presumptive club forms. The catagen stage of the hair cycle lasts for only a few weeks and ends as the hair enters into a “resting” (telogen) stage. A telogen hair has a fully keratinized club, which is surrounded by an epithelial sac. Below this lies the secondary hair germ and condensed dermal papilla.² New anagen hair growth is initiated by cells that reside in the bulge region—the protuberance of cells that serves as a point of attachment for the

TABLE 39-1—Hair Growth by Body Location

Body location	% Anagen hair	Telogen stage
Beard	70	10 weeks
Upper lip	65	6 weeks
Axillae	30	3 months
Arms	20	18 weeks
Legs/Thighs	20	24 weeks

arrector pili muscle.³ During the 3 months of telogen, the bulge lies near the secondary hair germ.

The majority of hair follicles (80–85%) on the scalp are in the anagen phase and the remaining follicles are either in the catagen (2%) or telogen (10–15%) phase. On other areas of the body, anagen hairs may account for only 20–50% of the total number of hairs present. Telogen may last for a couple months on the face and for many months on the upper arms and legs⁴ (Table 39-1).

Anagen hairs vary in size from the large terminal hairs found in the beard and on the scalp to fine vellus hairs covering most of the glabrous skin. Vellus and terminal hairs go through all stages of the follicular life cycle, but the length of anagen is much shorter in vellus hairs. Although vellus hairs cover most of the human body, terminal hairs are of more interest to both the clinician and patient as their presence is more noticeable in hirsute conditions².

TEMPORARY METHODS OF HAIR REMOVAL

Bleaching

Bleaching lightens the color of the external hair shaft to make it less noticeable without physically removing the hair follicle. This method is best used for the treatment of excess pigmented hair on the face or arms of fair skinned patients. The contrast of yellow bleached hair against the skin of darkly pigmented patients is highly visible and is therefore not suitable in these skin types. Several types of commercial hair bleaches are available: neutral oil bleaches, color oil bleaches, cream bleaches, and powder bleaches—all of which contain hydrogen peroxide as the active ingredient.

While a 6% concentration of peroxide bleaches, softens, and oxidizes the hair, the addition of 28% ammonia accelerates its bleaching action. The addition of persulfate to intensify peroxide hair bleach has resulted in generalized urticaria, asthma, syncope, and shock in sulfide-sensitive patients.⁵ While bleaching is a quick, painless, and relatively inexpensive process that can last up to 4 weeks, disadvantages of its use include skin irritation, hair discoloration, and a lack of desired efficacy.^{6,7} Bleaching should not be performed on skin that is broken or has signs of infection.

Trimming

Trimming of hair is the treatment of choice for young children with either localized or generalized hypertrichosis. It is safe and does not accelerate hair regrowth.

Shaving

Shaving is one of the oldest and most frequently used methods of hair depilation. Shaving is usually performed with a manual or electric razor on skin that is wet and lathered or covered with a special foaming product. Contrary to popular belief, shaving does not affect the width or rate of regrowth of individual hairs⁸; however, the rough stubble following shaving may be undesirable. Safety razors have been preferred over electric razors by both men and women because a closer shave can be achieved. Although most women report little difficulty shaving their legs, it remains an unpopular method for the removal of unwanted facial hair. Shaving is convenient and of low cost; however, its disadvantages include abrasions, stubble, and skin irritation, which can develop into pseudofolliculitis barbae (PFB). PFB is common in men of African heritage and can be prevented with a less clean shave. Extreme cases may require treatment with corticosteroids, retinoic acid, or laser-assisted hair removal (see below).

Tweezing

Tweezing or plucking is a temporary and effective method to remove a small number of hairs. Tweezing lasts longer than shaving because the hair is extracted from the follicle in its entirety as opposed to being cut at the surface of the skin. Anagen hair bulbs tear in reproducible patterns which include the typical break conically surrounding the dermal papilla, rupture of the hair around the upper third of the papilla or well above the papilla, or total removal of the proximal follicle epithelium with removal of the dermal papilla.⁹ Drawbacks include treatment discomfort and risk of folliculitis, hyperpigmentation, erythema, follicular distortion, and scarring.^{5,6} Alteration of the mesenchymal sheath of the hair follicle may also lead to pinpoint hemorrhages and perifollicular edema. While rare, plucking of hairs from melanocytic nevi may result in the development of foreign body granulomas

around disrupted hair follicles which can develop into Nanta's osteonevus (metaplastic ossification).¹⁰ Electronic tweezers provide an inconsequential transmission of electric current into the follicle with subsequent rapid hair regrowth. Erroneously believed to be a permanent means of hair removal, its use has declined after the Food and Drug Administration (FDA) reported it is "no better than nonelectrified household tweezers."¹¹ They also emit measurable levels of radiation and are not recommended for use by pregnant women or those with pacemakers.

Mechanized tweezers with a rotating, fine, coiled spring can grasp and pull out the hair shaft for more diffuse areas of hypertrichosis, most commonly on the legs. The hand-held device is relatively easy to operate, but can be painful due to large areas of synchronous epilation.

Waxing

Waxing provides a uniform method of plucking hair. The technique involves the application of melted wax to hair-bearing skin. Upon drying, the wax is rapidly peeled away from the skin in the direction opposite to hair growth. Care should be taken during application because excessively hot wax can cause thermal burns to the skin. Although waxing can be used to remove unwanted hair in every skin type and any hair length, best results are obtained when the hair is trimmed to a quarter of an inch in length prior to waxing. Waxing is inexpensive and the results are longer-lasting than with shaving or chemical depilatories because hairs are removed from the hair bulb rather than at the skin surface. Six weeks of relatively hair-free skin is typically achieved.⁵

Cold semisolid waxes are also available, but are usually more expensive and cannot be reused. Potential allergic sensitizers in waxes are beeswax, rosin (colophony), fragrance, and benzocaine.⁵ In addition to treatment discomfort, waxing has been reported to cause folliculitis, skin irritation, and keloid scars.^{6,12} The long-term effects of waxing on the follicle are not known, but many patients use it repeatedly for several years without experiencing significant problems. It may even be possible to reduce the amount of hair regrowth due to repeated waxing-induced follicular trauma.⁶

The non-Western technique of sugaring is another temporary hair removal method. Sugaring is similar to waxing except that a sticky paste is applied to the skin instead of melted wax or a cold polymer. The paste is formed by mixing sugar, water, lemon juice, and gum arabic or gum ovaline and heating it until the mixture forms a syrup. Sugaring is often preferred for large surface areas, such as the back or legs.

Mechanical Epilation

Mechanical abrasives come in many different forms and range from pumice stones and abrasive gloves to small sticks or wands lined with fine sandpaper. The skin is

held taut with one hand while the other rubs over a hair-bearing area in a circular motion to remove hair at the skin surface. Skin irritation and follicular distortion are common side effects of this treatment and is, thus, seldom used.^{5,6} Traumatic folliculitis has also been reported from home epilation devices that produce skin surface friction via circular motions over hair-bearing areas.¹³

Threading, also known as “banding,” is a method of hair removal used extensively in Arabic countries. A fine cotton string is used to capture hairs, which leads to removal of some hairs at their roots while others are simply cut off by the scissoring action of the twisted thread. Clinical results usually last 2 to 6 weeks. Side effects include folliculitis, erythema, and secondary pigmentary changes.^{6,14}

Chemical Depilatory Agents

Chemical depilatories exert their effects through separation of the hair from its follicle and the surrounding skin surface by reduction of disulfide bonds. Because the hair shaft is composed of more disulfide-containing cysteine than is epidermal keratin, sulfur compounds of calcium, arsenic, antimony, barium, and strontium can effectively dissolve the hair shaft.^{5,8} Newer chemical depilatory agents contain mercaptan thioglycolic acid mixed with alkali.⁸ With these formulations, the hair shaft is hydrated and disulfide bonds broken. Since chemical depilatories frequently penetrate into portions of the infundibulum, it usually takes several days before any hair regrowth is observed.⁵ Therefore, chemical depilatories are most appropriate for weekly hair removal from small areas.

An irritant contact dermatitis caused by the alkalinity of chemical depilatories is the most frequent adverse reaction and can be avoided with the concomitant application of a topical corticosteroid. Allergic contact dermatitis may also occur because of the presence of fragrances in the preparations and cross-reactions have been observed between mercaptan and dimercaprol.⁵ Less than 1% of patients are thus able to tolerate facial application of depilatories. Additionally, many find the procedure to be excessively messy and the depilatory’s smell offensive.⁶ Thioglycolate-containing depilatories are not recommended for men’s beards because they do not penetrate the hair shafts quickly enough to be a practical alternative to shaving.⁸ Although strontium and barium sulfides are effective in this setting, the hydrogen sulfide gas released by these compounds yields an unpleasant odor. In addition, barium sulfide is more irritating to the skin than the more commonly used calcium thioglycolate.

Surgery

Surgical excision of axillary apocrine glands in patients with hirsutism and hyperhidrosis has been found to cause hair loss in the area.¹⁵ Eventual hair regrowth may be expected because of the varying depths of anagen, catagen,

and telogen hair follicles. The scars that result from surgery are often a major obstacle because of their cosmetically unacceptable appearance.

Radiation Therapy

In the 1920s, hypertrichosis was managed with x-ray treatment resulting in radiation-induced cutaneous malignancy, including basal cell carcinomas, trichoblastomas, and trichoblastic carcinomas on the scalp with a mean of onset of tumor development of 39.4, 38.3, and 35.6 years, respectively.¹⁶ Although more than 80% of the x-ray treatments were performed before 1930, reports persisted into the 1940s with multiple basal cell carcinomas and a spindle cell carcinoma documented 52 years after x-ray epilation of the limbs.¹⁷ As safer treatment alternatives were introduced over the years, radiation therapy fell out of favor and is not currently considered an acceptable treatment option for hair removal.

PERMANENT METHODS OF HAIR REMOVAL

Electrolysis and Thermolysis

Electrolysis, thermolysis, and a combination of both are three popular procedures used for epilation or permanent hair removal and are performed more often in the United States than anywhere else in the world.⁵ All three methods involve the insertion of a small needle or probe into the hair follicle through which an electric current is delivered, resulting in the production of a microscar that surrounds the follicle, but is barely perceptible at the skin surface.¹⁸ Focal erythema and edema following treatment usually resolve within a few hours.¹⁹

Electrolysis is performed by passing low flow direct or galvanic current through tissue between two electrodes which causes a chemical reaction to occur at the electrode tip, resulting in tissue damage and destruction of the hair follicle. The production of local hydroxides destroys the hair bulb and enclosed dermal papilla. While galvanic electrolysis is effective, it is a slow process, requiring a minute or more for each hair.²⁰ Its advantage lies in its ability to effectively treat curved or distorted follicles because hydroxyl ions, being in a fluid medium, can flow to all portions of the follicle.¹⁹

Thermolysis (diathermy) is performed using high-frequency alternating current at low voltage to thermally destroy or epilate hair follicles—a process termed electroepilation. Thermolysis has a somewhat higher risk of scarring and pain, although modern electroepilation devices have precise automatic timers and insulated probes that reduce the risk of scarring.²¹ The process requires only a few seconds per follicle and is much faster than galvanic electrolysis; however, the results are not as consistent, particularly when treating distorted or curved hair follicles.^{19,20}

Following each thermolysis treatment session, hair regrows in 20–40% of treated follicles.

The blend method—a combination of both electrolysis and thermolysis—subjects the hair follicle to both chemical and thermal destruction through the use of galvanic and low-intensity high-frequency currents, respectively. Although the combination treatment is slower, it is significantly more effective and less painful than the individual use of each method.^{18,19}

While pain tolerance to electrolysis has been shown to develop over several sessions,²⁰ the use of topical anesthetics can decrease treatment pain significantly. Correct needle placement is relatively painless; however, premature or delayed activation of the electrode during its insertion or withdrawal may cause pain as well as damage to the superficial skin, which could lead to scarring.²¹ Electrolysis is more effective on anagen hairs; therefore shaving within a few days before electrolysis greatly increases its efficacy because it ensures that only growing anagen hairs are epilated.²⁰ This is particularly important during the initial treatment of an area because as many as 60% of the hairs may be in telogen, which are difficult to eradicate permanently. Hair regrowth rates following treatment are highly variable and range from 15–50%. The wide variation has been attributed to the differences in equipment used and to the skill of the operator. Multiple treatment sessions are necessary because of the practice of avoiding simultaneous treatment of adjacent hair follicles (within 3–4 mm of each other) in order to reduce unnecessary thermal skin injury. As many as 100 hairs can be removed in 20 minutes with thermolysis.

Infectious diseases potentially transmissible through electrolysis include bacterial and viral infections such as impetigo, verrucae, molluscum contagiosum, and herpes simplex (HSV).^{5,22} As such, the area of skin to be treated should be completely examined and clear of bacterial and viral infections prior to treatment in order to avoid autoinoculation.⁵ For patients at known risk of HSV reactivation, prophylactic oral antiherpetics should be considered for upper lip or chin treatment. While relatively rare, other contagious skin diseases such as leprosy, syphilis, tuberculosis, acquired immune deficiency syndrome, and hepatitis can also be spread from one patient to another through electrolysis.⁵ Cutaneous sporotrichosis has also been reported on the anterior neck of a patient after electrolysis in the same area.²³ Electrolysis needles must be of either the prepackaged sterile disposable type or sterilized with the steam autoclave, chemiclave, or dry heat and stored to ensure sterility prior to use. The use of unsterilized and/or reusable electrolysis needles could lead to these infections and, thus, are contraindicated.^{5,20}

Underlying medical conditions should be taken into consideration in patients undergoing electrolysis, including a history of bacterial endocarditis, heart valve surgery or anomalies, and presence of cardiac pacemakers or joint prostheses. Antibiotic prophylaxis in patients at high risk

for the development of bacterial endocarditis as well as in patients with prosthetic devices should be considered.^{24,25} Short bursts of electric current (< 5 seconds) are generally safe in patients with cardiac pacemakers; however, as a precaution, peripheral pulse or cardiac monitoring is suggested. True galvanism is considered safe in the presence of cardiac pacemakers and is most often used by nonmedical personnel.^{5,21}

Patients who are prone to hypertrophic scarring, keloids, postinflammatory hyperpigmentation, or other cutaneous dyschromias should be advised that these complications may result from electrolysis treatment. Of particular risk are scar-prone areas of the face such as the mandible and upper lip⁵. Pigment tattooing has also been described as a complication of electrolysis.^{26,27} Other drawbacks include the discomfort, cost, and extensive time necessary for each treatment session.²⁸

Autoelectrolysis is a heavily advertised method of home electrolysis that usually involves the use of a galvanic device. It has been declared unsafe by the British Medical Association and has been noted to be unsatisfactory because of its difficulty of use and associated treatment pain and scarring.²⁹

Recently, an over-the-counter device for personal use has been developed to thermally remove unwanted hair.³⁰ The hand-held self-treatment device (no!no! Thermicon™, Radiancy Inc, Orangeburg, NJ) uses the principle of thermal transference to heat the hair shaft through a thermodynamic wire. This device is purported to remove unwanted hair from all parts of the body excluding the face, ears, neck, and genitalia.

Lasers

The FDA approved the first hair removal laser system in 1995. Laser-assisted hair removal can be used to treat large areas of unwanted excess hair with fewer complications and less discomfort than electrolysis or thermolysis.²¹ Improved clinical results are ascribed to the laser's ability to specifically target pigment-containing hair when an appropriate wavelength, pulse energy and duration are selected. Laser treatment is targeted to the bulb and bulge of the anagen hair follicle, each of which absorb red or infrared wavelengths. The pulse duration (or exposure time of the laser light on the skin) is matched to the thermal relaxation time of these targets so that adequate (but not over) heating of the unwanted hair is achieved. The epidermis has a short thermal relaxation time of up to 7 ms while the hair follicle has a much longer thermal relaxation time of 40–100 milliseconds (ms). Shaving the hair-bearing site is performed preoperatively in order to prevent conduction of thermal energy to the adjacent epidermis from overlying hairs. Additional unwanted epidermal heating is prevented by application of a cooling gel, spray, or air device concomitant with laser energy delivery. Epidermal cooling also minimizes treatment discomfort as does application of

topical anesthetic creams. Pneumatic skin flattening (PSF), whereby the skin is pulled taut during laser irradiation, has also been shown to decrease laser-associated discomfort.³¹ The use of PSF for pain control is based on the gate theory of pain transmission, as the process involves activation of tactile and pressure skin receptors to block transmission of pain to the brain during laser activation.

The energy density necessary to coagulate a hair follicle is dependent on the color, diameter, and depth of the hair shaft. The hair follicle can be selectively targeted by light absorbed by an endogenous component of the follicle, such as melanin or keratohyalin, followed by thermal necrosis limited to the follicular zone. Hair shafts of lighter color and smaller diameters require the use of higher energy densities or an exogenous material or chromophore that will be absorbed by the hair or placed in the follicular orifice to absorb the light.²¹ The latter technique is exemplified by the SoftLight process which uses a Q-switched neodymium:yttrium-aluminum-garnet (QS Nd:YAG) laser

to target a topically applied carbon-based solution that has presumably penetrated the hair follicle.³² The carbon particles within the follicle absorb the light and undergo a rapid temperature increase. The thermal energy results in selective injury to the germinative cells of the follicle that are in contact with the solution. The shock wave produced by increasing temperature causes mechanical damage to the hair follicle, which delays hair regrowth. Topical application of carbon solution has not been proven to be redundant more effective than using the pigment-specific lasers alone, particularly in patients with dark terminal hairs.³³ Melanin-encapsulated liposomes have also been used with limited success in laser-assisted removal of blonde and white hair.³⁴

The systems that have been used for selective hair removal include ruby (694 nm), alexandrite (755 nm), diode (800 nm) and Nd:YAG (1064 nm) lasers with relatively long pulses (millisecond pulse durations). (Table 39-2). A 2- to 6-month growth delay is typically observed

TABLE 39-2—Hair Removal Lasers and Light Sources

LASER AND LIGHT SOURCES	Wavelength (nm)	Pulse duration
Long-pulsed ruby lasers	694	1-3 ms
Chromos™ 694 (SLS Biophile, Ltd, Carmarthenshire, UK)		
EpiLaser™ (Palomar Medical Technologies, Inc., Burlington, MA, USA)		
EpiTouch™ Ruby (ESC Sharplan, Norwood, MA, USA)		
Palomar E2000™ (Palomar Medical Technologies, Inc., Burlington, MA, USA)

after a single laser treatment. A meta-analysis of hair removal laser trials from 1998 to 2003 documented hair reductions of 52.8, 54.7, 57.5, and 42.3% for the ruby, alexandrite, diode, and Nd:YAG lasers, respectively, at least 6 months after the final of three laser treatments.³⁴ Observed hair regrowth after laser-assisted hair removal is sparse and individual hairs are thinner and paler in color. Incomplete elimination and hair regrowth are presumably caused by incomplete follicular destruction. Multiple treatment sessions are timed so that the unwanted hairs are in the anagen phase which may further reduce hair regrowth. Minimal edema and transient erythema may be evident in the treated areas for the first 24–48 hours post-treatment.

A drawback to using shorter wavelengths (e.g., 694 nm ruby) is that a more deeply pigmented epidermis impedes light penetration of the dermis with a subsequent decreased effect on germinal cells. In addition, unwanted epidermal injury may occur, resulting in hypopigmentation. The ideal treatment candidate for laser-assisted hair removal should have untanned, pale skin (phototypes I-II) and dark hair. Patients with darker skin tones (Fitzpatrick skin phototypes IV– VI) should only receive treatment with the alexandrite, diode or the Nd:YAG lasers, which safely deliver longer wavelengths and avoid unwanted postoperative skin dyspigmentation.^{35–37} The Nd:YAG laser with its longer wavelength is the safest type to treat darker skin tones, but the alexandrite and diode lasers are more effective because their shorter wavelengths are more greatly absorbed by melanin in the hair shaft and follicle.

Side effects are minimal in a majority of cases. When present, they include mild discomfort, transient erythema, perifollicular edema, purpura, skin dyspigmentation, crusting, vesicular formation, folliculitis or pseudofolliculitis, and rarely, erosions, scarring, reticulate erythema and urticaria vasculitis.^{38–41} A topical corticosteroid may help minimize the duration of these side effects. The direct insertion optical method, which delivers laser energy directly to the hair bulb through an optical needle, has also been successful in preventing these complications in a pilot study.⁴² The incidence of pigmentary alteration and vesication increases in patients with tanned skin or intrinsically darker skin phototypes.

One notable side effect of laser-assisted hair removal is the stimulation of new hair growth within previously irradiated areas or in close proximity to the treatment regions.^{43,44} This “paradoxical effect” has been reported after treatment with each of the laser and light hair removal systems. Its development has been attributed to activation of dormant hair follicles by either the application of subthreshold fluences or the conduction of heat to surrounding areas which eventuates in synchronization of the hair growth cycle. Pili bigemini, the extrusion of two hairs from the same follicular opening, has been reported following sublethal damage to hair follicles.⁴⁵ Higher energy may enable complete destruction of the hair

follicles as long as consideration is given to the skin type and an effective epidermal cooling system.

Acneiform lesions have been described following laser hair removal with a predilection in younger patients, those treated with the Nd:YAG laser and Fitzpatrick skin type V.⁴⁶ The severity of the reaction is usually mild and lasts only for a short duration. A significant increase in sebum excretion occurs 4 to 12 months after laser hair removal even though there is a reduction in sebum gland size. This may be attributed to decreased resistance to sebum outflow following absence of the hair shaft.⁴⁷ Hyperhidrosis, bromhidrosis, and leukotrichia have also been documented in 11, 4, and 2% of patients, respectively, after laser-assisted axillary hair removal.⁴⁸

Non-Laser Light Sources

Noncoherent light sources with a spectrum of wavelengths ranging from red/yellow (590 nm) to infrared (1200 nm) can be used to deposit optical energy along the length of the hair shaft. Similar clinical responses to those outlined with the long-pulsed laser systems have been reported with a significant reduction in hair after a series of intense pulsed light (IPL) treatment sessions.⁴⁹ A lower energy IPL system has even been introduced for at-home hair removal with slightly diminished (but still adequate) clinical hair reduction.⁵⁰

Other variations of IPL technology have included pulsed light and heat energy (LHE) systems which have also demonstrated clinical hair reduction.^{51,52} The addition of bipolar radiofrequency (RF) to IPL treatment enables lower levels of optical energy to be applied with good clinical effect, fewer side effects, and the potential to be used across a wider range of skin types.⁵³ A bipolar RF device has two electrodes through which current passes and travels at a fixed distance to provide a tissue penetration depth of 4 mm. Optical and RF energies are produced as high as 30 J/cm² and 25 J/cm³, respectively, with pulse durations up to 200 ms. While RF devices are not used to affect hair removal alone, the synergistic combination with IPL may improve the efficacy of optical energy delivery and produce effective epilation of even blond and white hair phenotypes.⁵⁴

Variable pulsed light (VPL) can also affect long-term removal of unwanted hair with minimal and transient side effects.⁵⁵ The VPL system creates output wavelengths from 610 to 950 nm and delivers a pulse train of filtered visible light, in which each train contains up to 15 micropulses.

Side effects of IPL therapy include vesication, erosions, crusting, leukotrichia, folliculitis, paradoxical hypertrichosis, and postinflammatory hyperpigmentation.⁵⁶ Second-degree skin burns on the bilateral upper arms have also been reported, presumably from the use of excessive energies.⁵⁷

TABLE 39-3— Comparison of Hair Removal Methods

Methods	Advantages	Disadvantages
Temporary		
Bleaching	Fast, inexpensive, widely available	Unsuitable for dark skin, irritation /allergy possible to persulfate/peroxide
Trimming	Safe, widely available, good for children	Impractical for large areas
Shaving	Fast, wide available, inexpensive	Rough stubble, irritation, folliculitis possible
Tweezing	Good for small areas	Slow, painful, impractical for large areas
Waxing	Fast, good for large areas	Painful, thermal burns/folliculitis possible
Mechanical Epilation	Fast, inexpensive, widely available	Skin irritation/folliculitis possible
Chemical Depilatories	Inexpensive, widely available	Irritation possible, not suitable for thick hair (beards)
Surgery	N/A	Expensive, scarring possible
Radiation Therapy	N/A	Carcinogenic, impractical
Permanent		
Electrolysis/Thermolysis	Moderate price, good for small areas and all skin colors	Painful, operator-dependent, infections/dyspigmentation/scarring possible
Lasers/Light Sources	Expensive, good for all skin types, most clinically effective	Expensive, limited to dark hair, professional expertise required
Photodynamic Therapy	Highly effective, may be useful for light hair	Expensive, slower process due to ALA incubation

Photodynamic Therapy

Photodynamic therapy (PDT) with topical application of aminolevulinic acid (ALA) followed by red light exposure has also been used for the destruction of excess or unwanted hair.⁵⁸ ALA induces the follicular synthesis of the potent photosensitizer, protoporphyrin IX.⁵⁹ Prior to treatment, hair is first wax-epilated and then an ALA-containing solution is applied to the skin surface. Over several hours, the ALA is more selectively absorbed in the hair follicles than in the epidermis. The treatment site is then exposed to red light that activates the photosensitizer, causing cell membrane damage from the creation of singlet oxygen. A 40% decrease in hair regrowth has been reported 6 months after a single treatment.^{58,59} Using PDT, it is possible to treat large areas independent of skin or hair color. Because the method is still in the developmental stage, further studies are needed to determine its long-term safety and efficacy.

SUMMARY

The presence of excessive hair can be a source of distress that can lead to anxiety, depression, and a reduced quality of life in affected individuals. Current nonmedical methods of hair removal include shaving, waxing, depilatories, electrolysis, and laser and light-based devices (Table 39-3). Unfortunately, no single treatment method can achieve complete hair eradication in every skin and hair type.

Lasers and light sources can be used for expedient treatment of large areas of skin with minimal discomfort and lead to a prolonged delay in hair regrowth. In addition,

the selectivity and therefore effectiveness of these methods are less operator-dependent than other modes of therapy. The noninvasive and needless technology greatly reduces the risk of disease transmission and scarring. Darker skin phototypes are more prone to side effects which can be minimized by utilizing lasers with longer wavelengths. Combined treatments are becoming more popular and trials are underway to determine if the delivery of multiple wavelengths with or without topical medication improves clinical outcomes. Additional studies are needed to assess the appropriate number and timing of treatment sessions in order to obtain even longer and, perhaps, permanent hair removal.

What We Know: Laser-Assisted Hair Removal

- Multiple lasers and light sources (including alexandrite, diode, and Nd:YAG) are available to remove hair
- Prolonged/permanent hair reduction (50-80%) is typical after a series of 3 to 5 monthly treatments
- All skin phototypes can be safely treated, but greater safety margin of Nd:YAG laser in darkest skin tones
- Most effective for elimination of dark (brown or black) hair
- Minimal side effects are observed with proper device use
- Professional delivery of treatment is advised to rule out medical contraindications and to prevent untoward side effects

Tattoo Removal

40

Uwe Wollina, M.D., and Christa De Cuyper, M.D.

INTRODUCTION

Tattoos are marks on the skin made by inserting pigment. This can occur either be by accident (accidental or traumatic tattoos) or by intention as a part of culture, fashion, or individual expression and less frequently as a medical procedure.^{1,2} The latter can be professional or nonprofessional that will have an impact on possible options for their removal. Amateur tattoos are less dense, placed at variable depths, and composed of carbon-based ink. Professional tattoos contain a variety of densely packed, colored pigments at a uniform depth. Most tattoo colorants are industrial pigments, and chemical industries have never produced them for human use, but only to stain consumer goods. Once implanted, the ink particles are phagocytosed by resident dermal fibroblasts, where they permanently remain in the superficial dermis.

Tattoos have become a common a part of fashion and body art. Tattooing is associated with risk-taking activities. In a representative US-survey in the age of 18 to 50 years, 24% had tattoos. Tattooing was equally common in both sexes, but body piercing was more common among women. Other associations were a lack of religious affiliation, extended jail time, previous drinking, and recreational drug use.³

The National Longitudinal Survey of Adolescent Health Public Use Dataset, which provides a nationally representative sample of 6072 adolescents collected in 1995 and 1996, has been evaluated for tattoos. Of the total sample of youths, 4.5% reported having permanent tattoos. Tattooing was significantly associated substance use, violent behaviors, and school problems.⁴

A study among US undergraduate students enrolled 454 students. The prevalence of body piercing was 51%, and that of tattooing was 23%. There was no significant difference in the prevalence of tattooing by sex. Male athletes were more likely to be tattooed than male nonathletes. No relationships were shown between piercing/tattooing and age or measures of body somatotype.⁵

In a recent study from Germany, the total prevalence of tattooing was 8.5 %. In the age between 14 and 44 years 15 % are tattooed. Unemployment and lack of partnership correlate positively with body modifications. Tattooing

correlates with the perception of reduced mental health and both, tattooing and body piercing correlate highly with increased "Sensation-Seeking" behavior.⁶

In Australia, a random sample survey of individuals aged 14 years and over had been performed, collected between June and September 1998 (n = 10,030). The results show that 10% have had a tattoo at some point in their lives. Men are more likely than women to report tattooing, while females are more likely to report body and ear piercing. The prevalence of tattooing and body piercing is considerably higher among injecting drug users.⁷

In a study that examined autopsy records from the New Mexico Office of the Medical Investigator from 2002 to 2005, a total of 3430 individuals (1666 white Hispanics; 1764 white non-Hispanics), aged 18 to 100 years, with homicidal or accidental manners of death were investigated for tattoos. Results indicate statistically significant differences in tattoo frequencies by ethnicity (52% Hispanic vs. 29.5% non-Hispanic), sex (46.8% men vs. 25.9% women) and age cohort. Hispanics were more likely to have multiple tattoos than non-Hispanics (41% and 19%, respectively), and were 4.67 times more likely to have a religious tattoo, and 7.13 times more likely to have a gang tattoo than non-Hispanics. Significant patterns in language of text tattoos and correlations with manner of death were also noted.⁸

MOTIVES OF TATTOO REMOVAL

Studies suggest that at least 50% of individuals later regret their tattoo.⁹ The motives for tattoo removal are manifold from improved self-esteem to increased credibility. Some individuals want removal because of the tattoo design or improper performance or because of religious reasons.^{10,11}

In a US-study of 2006, more women than men were asking for tattoo removal compared to 1996. The women were white, single, college educated, and between the ages of 24 and 39 years; they reported being risk takers, having stable family relationships, and moderate to strong religious beliefs. Commonly, tattoos were obtained at approximately 20 years of age, providing internal expectations of uniqueness and self-identity. In both the 1996 and the 2006

studies, a shift in identity occurred, and removal centered on dissociating from the past.¹²

PRE-TREATMENT MEASURES

Patients seeking advice for tattoo removal need information about the available techniques and their benefits and limits. A realistic expectation of the patient is necessary. In general, tattoo removal is a time-consuming procedure and more expensive than tattooing. It is very helpful if the patient can provide detailed information about the inks used. This should be rounded up by manufacturer's material safety leaflets. Since inks are often mixed by the tattooist, this information remains mostly incomplete.

A small area should be treated first to evaluate tolerability and skin reaction to treatment. Photographs should be taken before and during therapy. A signed patient's information and consent is mandatory.

Since tattooing bears a higher risk of transmissible disease like hepatitis B, tuberculosis or HIV infection, both doctor and nurse should take preventive measure to avoid infection. Females during gravidity and lactation should not be treated.

TECHNIQUES OF TATTOO REMOVAL

Lasers

The use of lasers has been effective in the removal of some but not all tattoos (Table 40-2). Q-switched lasers have been found to be safe and effective in the treatment of tattoos. Q-switching allows the production of laser pulses with extremely high peak power. In all such Q-switched lasers, the risk of scarring is less than 4.5% with proper use.¹³

The precise mechanisms of tattoo lightening are still largely unknown, but it appears that laser therapy leads to instant alteration of optic properties of the tattoo pigments, partly by destruction and partly by thermal, photochemical (cleavage of pigment molecules by laser irradiation and oxidation), or photoacoustic (fracturing molecules by virtue of acoustic or pressure waves) reactions.¹⁴

Histologic and electron microscopic analyses of biopsies have shown the disintegration of pigments into smaller fragments which were then phagocytosed by macrophages or carried away via the lymphatic system. There are also detectable structural changes in the pigment particles. About 4 weeks after treatment, pigment released from the cells can be observed intracellularly which may contribute to lightening.^{15,16} The response to laser treatment can vary greatly because of the wide range of tattoo ink. Previous in vitro quantitative chemical analysis of tattoo pigments found that the most common elements were aluminium, titanium, and carbon. Titanium overrepresentation was identified as the main reason for a poor response to laser treatment. Picosecond (ps) lasers were found to be more effective in achieving a greater degree of clearing than nanosecond (ns) lasers.¹⁷

For most tattoos a series of laser applications is necessary to achieve a sufficient level of pigment lightening. In between the treatments and for sometimes after the last procedure, sun protection and avoidance of tanning beds is highly recommended to prevent hyper- or hypopigmentations at the laser-treated sites.¹³

Ablative Lasers

Ablative lasers have been used for laser-assisted dermabrasion in traumatic (accidental) tattoos (Figure 40-1). In a study with four patients with traumatic tattoos in the face, a variable pulsed erbium:YAG laser was employed. The fluence of the ablative pulses was 5 J/cm². The endpoint for the treatment was the macroscopic removal of the foreign bodies. Postoperatively, silver sulphadiazine, or polyvinylpyrrolidone was applied daily until wound closure occurred. Use of a total sun block was mandatory for a period of 6 months. Pre and postoperative photographs were taken of all cases. The results were evaluated by a panel of four independent observers, who were asked to judge the percentage of tattoo clearance as well as any evidence of pigmentation problems or scarring. All results were rated from good to excellent. In all patients, a nearly complete clearance of the traumatic tattoo was achieved in one laser session. No scarring, skin atrophy, or hypo or hyperpigmentation was observed. Furthermore, a high patient satisfaction rate was achieved. Compared to mechanical

FIGURE 40-1 Ablative erbium-YAG laser treatment of an accidental tattoo. Before (A) and after (B) three treatments (3 mm spot size, 1000 J, 10 Hz). There is a marked improvement of discoloration but slight telangiectasias have been developed.

dermabrasion, the procedure is more reliable and causes fewer side effects.^{18,19} Mafong et al. (2003) used a pulsed CO₂-laser for removal of a cosmetic lip-liner tattoo.

Non-Ablative Lasers

In order to selectively remove tattoo pigments placed in the dermis, pulsed lasers must meet the following criteria:

1. The laser wavelength must be well absorbed by the targeted ink.
2. The heat generated should be spatially confined to the target.
3. The energy delivered must be sufficient to cause the desired effects.²⁰

The basic principles of the theory of selective photothermolysis imply that the wavelength used for tattoo removal should match the absorption spectra of the tattoo pigment and that the pulse duration should be less than the thermal relaxation time of the target.²¹ Consistent with this theory, the current standard of treatment for tattoo removal rests with the use of Q-switched lasers with nanosecond pulse durations and wavelengths of 755 nm (Alexandrite) for black, blue and green tattoos and 1,064 nm (neodymium [Nd]:YAG) for blue and black tattoos; 694 nm (ruby) for blue, black, and green tattoos; and 532 nm (Nd:YAG) for red tattoos.²² (Table 40-1).

TABLE 40-1—Suitability of Various Q-switched Laser Types for Tattoo Dyes

Color	(694nm)	(1064nm)	(532nm)	(755nm)
Black	+	+	-	+
Blue	+	+	-	+
Green	+	-	-	+
Red	-	-	+	-
Yellow	-	-	(+)	-

Q-switched lasers enable the deposit of energy very quickly, thereby producing an additional “photoacoustic” effect. The intense heat transients cause some particles to shatter and kill the cells in which the pigment resides. The rupture of pigment-containing cells eventually triggers phagocytosis and the packaging of tattoo fragments for lymphatic drainage.^{23,24}

Q-SWITCHED RUBY LASER (694NM)

Ruby lasers operate with a wavelength of 694 nm, pulse times of < 40 ns (usually 25 ns), and fluences up to 8–10 J/cm². Black, blue-black, and dark blue dyes are most responsive while the results are mixed for green and blue dyes. Red, orange, and light blue dyes respond poorly.²⁵ The Q-switched ruby laser is effective for the removal of black, blue, and green inks. The laser penetrates to a depth

TABLE 40-2—Laser Tattoo Removal—An Overview

Author(s)	n	Laser type (tattoos)	Wavelength (nm)	Spot size (mm)	Fluence (J/cm ²)	Pulse width (ns)	Outcome
Levine & Geronemus (1995)	48	QSNdYAG*	1064/532	2	10-14/5-7	5-10	better effect of 532 nm vs. 1064 nm
Ferguson & August (1996)	148	QSNdYAG	1064/532	2/1.5	10/2.5	10	>75% lightening after 1-11 treatments (black, blue and red)
Ross et al. (1998)	16	QSNdYAG	1064	1.4	0.65	35 ps	12/16 tattoos cleared better with ps pulses
		QSNdYAG	1064	2.5	8	10	than with ns pulses
Werner et al. (1999)	93	QSNdYAG	1064/532	2-6	12/5	10-20	13.2-18.6 treatments for lightening
Leuenberger et al. (1999)	42	QSNdYAG	1064	3	5-10	10-20	2nd best for black-blue tattoos
		QSRL**	694	5	4-10	25-40	best for black-blue tattoos
		QSAL***	755	3	6-8	50-100	least effective
Ho et al. (2006)	144	QSNdYAG	1064	3	3.6-4.8	6	107 tattoos achieved clearance >80%
Fitzpatrick & Goldman (1994)	25	QSAL	755	3	4-8	100	>95% clearance after 8.9 treatments (black & blue)
Alster (1995)	42	QSAL	755	3	4.75-8	100	4.6-8.5 treatments for complete clearance
Bukhari (2005)	20	QSAL	755	3	4-7.5	100	>75% clearance in 50% after 3 to 6 sessions

* QSNdYAG, Q-switched Nd:YAG laser; ** QSRL, Q-switched ruby laser; *** QSAL, Q-switched alexandrite laser.

of approximately 1 mm and has spot sizes up to 6.5 mm. Because this wavelength is well absorbed by melanin, caution should be used, as injury to melanocytes can lead to transient hypopigmentation and even depigmentation as well as textural change. The goal of treatment should be immediate tissue whitening (corresponding to water vapor in the skin) with minimal or no bleeding, and as with all laser treatments, no more than 10%–20% spot overlap should be employed. When compared to the other Q-switched lasers, the Q-switched ruby laser was shown to have the highest clearing rate after four and six treatments of blue-black tattoos. However, >95% clearance was only obtained in 38% of the tattoos.²⁶ For amateur tattoos, it has been reported that a mean of 4.92 treatments are needed to achieve clearance of >90% of pigment.²⁷ Other studies suggest only 11%–28% of professional tattoos achieve >75% clearance after more than six treatments.^{28,29} Schreibner et al.,³⁰ and colleagues compared treatment outcomes in 101 amateur and 62 professional tattoos. After an average of four sessions 87% of amateur, but only 11% of professional tattoos were at least 80% lighter. Lowe et al.,³² found different results with 10 J/cm². After 5 treatments, 22 of 28 professional tattoos were more than 75% lighter. Levins et al.,³¹ also reported similar results with excellent outcomes and minimal side effects. Kilmer and Anderson³⁴ have reported that black, blue-black, and green tattoos respond best to ruby laser treatment. Amateur tattoos required 4–6 sessions and professional tattoos usually 6–10, but sometimes more than 20. In general, it can be said that professional tattoos, tattoos on distal sites, and recent or deep tattoos require a greater number of sessions for removal.³³

Q-SWITCHED Nd:YAG LASERS (532 NM AND 1064 NM)

The Q-switched neodymium: yttrium aluminium garnet (Nd:YAG) laser emits infrared light with a wavelength of 1064 nm and a pulse duration of <20 ns. Systems are available with a spot size of up to 8 mm and energy densities up to 12 J/cm². A frequency-doubling crystal, in this case a potassium titanyl phosphate (KTP) crystal, cuts the wavelength in half to 532 nm, which is within the spectrum of visible light (green) and is primarily absorbed by red dyes and melanin. The repetition rate of up to 10 Hz and the larger beam diameter, now up to 8 mm at 1064 nm or 6 mm at 532 nm, allow rapid and effective treatment of close-together and deep tattoos. The Q-switched Nd:YAG laser system overcomes the obstacle of excessive melanin absorption and is used to remove blue and black ink and tattoos in darker skin types (1064 nm), or red pigment (532 nm). The clinical endpoint following laser treatment is whitening of the skin with occasional mild pinpoint bleeding. Current models offer a spot size range of 1.5–8 mm, which may be more appropriate for eyeliner tattoos. Generally, more than 75% of red pigment can be removed in 3 sessions.^{17,35,36}

The 532 nm wavelength (green light) is absorbed by hemoglobin, and as a result, purpura lasting 1 week to 10 days frequently occurs after treatment. This wavelength is also effective for red, orange, and occasionally yellow ink. In 63% of red tattoos, >75% clearance was achieved after one to five treatments at 2.5 J/cm². In this same study, only two of eight yellow tattoos faded.³⁵

Some reports have detailed the paradoxical darkening of red tattoo pigment as well as other skin-toned, yellow, and pink tattoos.^{37,38} It is seen quite often during laser removal of permanent make-up (De Cuyper 2008; Figure. 42-2). Brown may turn into orange and green/yellow (Jimenez et al. 2002). One reason for darkening is that the laser pulse reduces ink from rust-colored ferric oxide (Fe_2O_3) to jet black ferrous oxide (FeO).⁴¹ Similarly, bright colors may contain white ink made up of titanium dioxide (TiO_2 , Ti^{4+}) that is reduced to TiO_2 or blue Ti^{3+} upon laser treatment.

The long 1064 nm wavelength has the deepest penetration and carries the least risk of hypopigmentation; however, it is also the least effective in removing brightly colored pigments. Of all the laser systems, it is the one we recommend for use in darker skin types. This wavelength may also be useful when residual, more deeply placed ink particles are all that remain, as well as in the treatment of eyeliner tattoos, because it is less likely to damage the hair follicle.

Ferguson and August found that 79% of amateur black tattoos were >75% clear after one to five treatments at 1064 nm, and 74% of professional tattoos achieved similar clearance but required up to 11 treatments (average 6.3).³⁵

Q-SWITCHED ALEXANDRITE LASER (755 NM)

Although this laser system has the least amount of tissue splatter owing to its slightly longer pulse duration of approximately 50 ns - 100 ns (compared to 5–15 ns for the Nd:YAG and 15–40 ns for the ruby laser), and a density of 9 J/cm² it is not as successful as the other models. The effectiveness increases with energy density. On average, 4–10 sessions at intervals of 1–2 months are needed.^{42,43}

Similar to the Q-switched ruby laser, the alexandrite is most effective for removing black, blue, and green inks. As with the other lasers, the clinical endpoint is tissue whitening. In a study by Stafford, et al. an average of 11.6 treatments was required to completely remove professional blue-black tattoos, compared to 10.3 treatments for the same results in subjects with amateur tattoos. Hypopigmentation occurred in 80% of treated subjects, which resolved within 3–4 months of treatment.⁴⁴ In an uncontrolled study, removal of tribal tattoos in Arabic women of skin type III-IV was performed by using the Q-switched alexandrite laser. Twenty female subjects aged 35–50 years from similar racial and ethnic backgrounds with amateur tattoos were treated. Q-switched alexandrite laser with a fluence range 4.0–7.5 J/cm² (mean 6.05) was used at 6–12-week intervals. Total treatment numbers ranged from three to six sessions

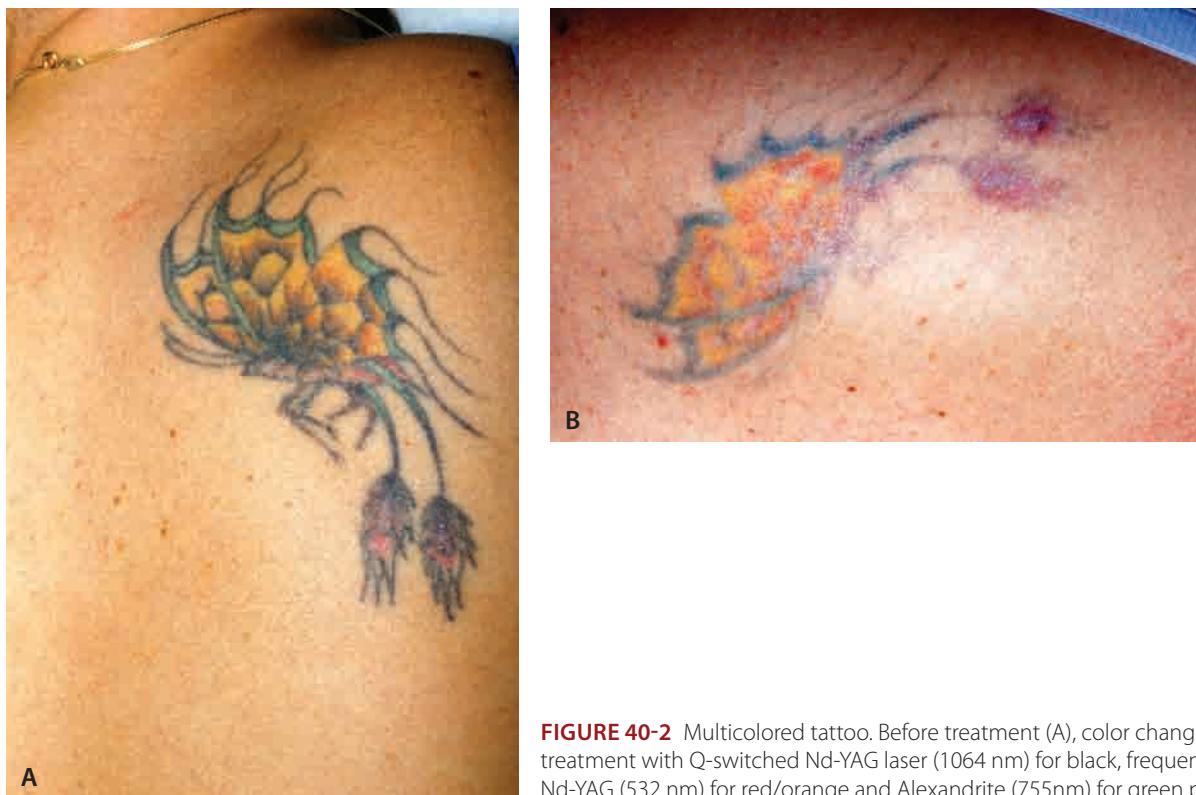

FIGURE 40-2 Multicolored tattoo. Before treatment (A), color changes during laser treatment with Q-switched Nd-YAG laser (1064 nm) for black, frequency-doubled Nd-YAG (532 nm) for red/orange and Alexandrite (755nm) for green pigments (B).

(mean 4.15) with single-pulse technique application. More than 95% lightening was achieved in five patients, after three to six sessions at fluence range of $6\text{--}7.5\text{ J/cm}^2$ and >75% lightening in 10 subjects, after three to six sessions of treatment at fluence range of $4\text{--}7.5\text{ J/cm}^2$. Pinpoint bleeding was observed in one case but no pigmentary alteration or scarring was seen. Tattoo pigment removal by Q-switched alexandrite laser is an effective method in skin type (III-IV) with minimal side effects, which gives high patient satisfaction.⁴⁵

Amalgam tattoos result from deposition of metallic particles (e.g., silver, mercury, copper, zinc, and tin) into the oral mucosa. Their clinical and histologic appearance is similar to that of decorative tattoos. An amalgam tattoo on the buccal mucosa and gingiva was treated with a Q-switched 755 nm alexandrite laser. Three treatments were delivered at 8-week time intervals (average fluence = 6.8 J/cm^2). Significant lightening of the tattoo was achieved after each of the three treatments without adverse sequelae.⁴⁶

Complications of Laser-Assisted Tattoo Removal and Their Management

Wenzel et al.⁴⁷ reported on 12 patients who received treatments with improper treatment parameters. In all patients, they diagnosed hypo- or hyperpigmentations and scar formation at the treatment site. In particular, the pulse

duration of the light sources or lasers applied were considerably longer than those required by the principles of selective photothermolysis. The light intensities of those devices are normally not sufficient to destroy the pigment particles. Instead of destruction, the pigment particles in the skin are heated up and the heat is conducted to the adjacent tissue causing unspecific tissue injury. Lasers or intense pulsed light sources with millisecond pulses and low light intensities are clearly not suitable to be applied for tattoo removal.

Multicolored professional tattoos require numerous sessions for complete removal, and it is not uncommon that some dye remains. Purple and yellow dyes appear to be particularly therapeutically challenging.⁴⁸ If pigment remains, often as irregular, lighter patches, or if it does not respond to laser therapy, treatment may be attempted with a combination of ablative laser and Q-switched laser. Remaining pigment located in deeper layers of the skin can be reached by the Q-switched laser after ablation of the surface tissue.

In rare instances, patients with tattoos containing metal salts—mercury (red), cadmium (yellow), chrome (green) and cobalt (blue)—may experience local allergic or photoallergic skin reactions or, very rarely, systemic reactions. Ashinoff et al.,⁴⁹ reported a woman who experienced an allergic reaction and whose tattoo was more than 75% lighter after only two sessions. It is conceivable that the profound inflammatory and immunologic reaction that developed after laser treatment helped lighten the tattoo. Two patients developed transient immunoreactivity that

presented as regional lymphadenopathy, after laser tattoo removal of professional black and blue-green tattoos. These reactions resolved without any complications.⁵⁰

Allergic reactions most often occur to red tattoo dye (Figure 40-3). These reactions are often not responding to topical or intralesional corticosteroids.⁵¹ In less inflamed cases, selective laser-assisted removal of red pigment, (e.g. with a Q-switched frequency-doubled Nd:YAG laser at 532 nm might be helpful), in other cases surgical excision might be the only option.^{52,53}

A case of an immediate urticarial reaction has been observed in a 26-year-old female after Q-switched Nd:YAG laser tattoo removal. The patient was treated with 3 days of prednisone, cetirizine, and ranitidine before subsequent laser treatments. Prophylactic treatment suppressed all subsequent reactions to laser therapy. Prophylactic treatment with steroids and antihistamines prevented reactions with subsequent laser treatments. Reactions after laser removal are rare, but may increase as popularity of skin art increases with the need for subsequent removal.⁵⁴

In recent times, industrially-manufactured organic pigments (mono- and di-azo dyes, polycyclic pigments of phthalocyanine, dioxazine, and quinacridone pigment classes) have been used instead of metal salts. Samples of 30 tattoo inks were examined using quantitative electron x-ray microanalysis. The technique reliably identifies all elements with the exception of those elements with atomic numbers less than 11.

In this study, professional inks were analyzed and compared with the material safety data sheets supplied by the tattoo ink manufacturers. Of the 30 tattoo inks studied, the most commonly identified elements were aluminum (87% of the pigments), oxygen (73% of the pigments), titanium (67% of the pigments), and carbon (67% of the pigments). The relative contribution of elements to the tattoo ink compositions was highly variable between different compounds. Overall, the manufacturer-supplied

data sheets were consistent with the elemental analysis, but there were important exceptions. The composition of elements in tattoo inks varies greatly, even among like-colored pigments. Knowledge of the chemical composition of popular tattoo inks might aid the clinician in effective laser removal.⁵⁵

Titanium—a constituent of blue tattoo ink, seems to be responsible for resistance to treatment with Q-switched Nd:YAG laser. In an animal study using rabbits, blue tattoos were unresponsive and quantitative energy dispersive spectrometry revealed a high amount of titanium in this particular ink.⁵⁶

Based on a recent analysis of tattoo pigments, two widely used azo compounds were irradiated in suspension with laser and subsequently analyzed by using quantitative high-performance liquid chromatography and mass spectrometry. The high laser intensities cleaved the azo compounds, leading to an increase of decomposition products such as 2-methyl-5-nitroaniline, 2,5-dichloraniline and 4-nitro-toluene, which are toxic or even carcinogenic compounds. Moreover, the results of the chemical analysis show that the tattoo colorants already contain such compounds before laser irradiation. Because of a high number of patients undergoing laser treatment of tattoos and based on the results of these findings in vitro, it would be an important goal to perform a risk assessment in humans regarding laser-induced decomposition products.⁵⁷ Although there is no data available that this happens in vivo, or that it is clinically relevant, findings are not yet conclusive.

The monoazo compound pigment yellow 74 (PY74; CI 11741) was found to be the major pigment in several of the tattoo inks. In vitro studies suggest that PY74 photodecomposes to multiple products. Three of the major photodecomposition products were identified by nuclear magnetic resonance and mass spectrometry as N-(2-methoxyphenyl)-3-oxobutanamide (*o*-acetoacetaniside), 2-(hydroxyimine)-N-(2-methoxyphenyl)-3-oxobutana-mide and N,N'-bis(2-methoxyphenyl)urea. These findings suggest that the use of PY74 in tattoo inks could potentially result in the formation of photolysis products, resulting in toxicity at the tattoo site after irradiation with sunlight or more intense light sources.⁵⁸ Newer dyes are also not “tissue inert,” but instead act as a chronic stimulus possibly leading to the development of reactive lymphoid hyperplasia (pseudolymphoma).¹³

The trauma caused by the placement of the dye can lead to a Köbner response or micro-scarring, visible after pigment removal as textural changes. Depending on energy density, wheals, punctate bleeding, blisters, and crusts may form following treatment. Textural changes usually resolve within 4–6 weeks; hence there should be a minimum of 4 weeks between sessions (Figure 40-4). Topical antiseptics may be used to prevent infection.¹³

A common side effect is the appearance of (usually transient) hypopigmentations, which occur in more than

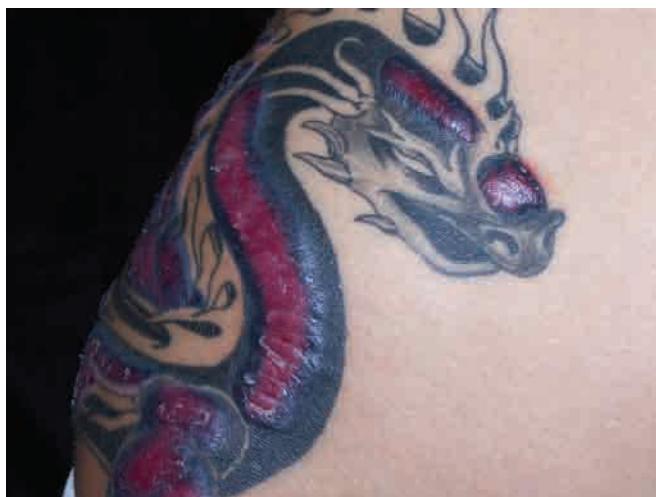

FIGURE 40-3 Allergic reaction to red tattoo dye in a multicolored professional tattoo.

FIGURE 40-4 Texture changes after multicoloured tattoo removal (A) before, (B) after treatment with Q-switched Nd-YAG laser (1064 nm) for black, frequency-doubled Nd-YAG (532 nm) for red/orange and Alexandrite (755nm) for green pigments.

38% of patients treated with Q-switched ruby lasers and typically remain for 2–6 months. The number of sessions is considered a risk factor in the development of hypopigmentations, (i.e., the greater the number of sessions the higher the risk of their developing). Pfirrmann¹³ reported approximately 10% of patients who develop permanent hypopigmentations. This side effect is observed much less often in Nd:YAG laser therapy because melanin absorbs less of the light in the emitted wavelength. This makes it especially suitable for darker or tanned skin.⁵⁹

In patients with persistent hypopigmentation, repigmentation using an excimer laser may be attempted. Hypopigmented skin developed following tattoo removal with the Q-switched Nd:YAG laser in patients. The hypopigmented area remained unchanged for more than 4 years, until the use of the 308-nm xenon-chloride excimer laser induced a significant repigmentation in 40 sessions more than 14 months. The excimer laser has the potential to influence the reduced activity of the melanocytes, as demonstrated with electron microscopy.⁶⁰

Hyperpigmentation tends to depend more on skin type than laser treatment. Lasting scarring or textural alterations (e.g., a puckered appearance resembling cigarette paper, mild erythema, or a waxy surface) can occur in rare instances.^{24,31} Hyperpigmentations usually depend on skin type. According to Fitzpatrick there is increased risk among patients with darker skin. Patients should avoid sun exposure or ensure adequate sun protection before and after treatment. Treatment may consist of hydroquinone and regular use of sun protection; fractional photothermolysis may be another option.^{61,62}

Permanent color changes from red, skin color, white, yellow, or brown tones to black, gray-black, or dark green

are not uncommon. Absorption spectra of common tattoo pigments and their reaction to irradiation at 532 and 752 nm have been evaluated in an in vitro study with samples of 28 tattoo pigments and India ink. The pigments were mixed in agar and analyzed with a spectrophotometer. These agar plates were irradiated with Q-switched wavelengths of 532 and 752 nm. The highest absorbance of red was in the complementary spectrum, while blue, yellow, and orange had peaks in the adjacent portion of the visible light spectrum. There is great variability in the absorbance of green tattoo material. In general, pigment darkening was more likely when treated with the 532-nm wavelength than with the 752-nm wavelength. Pigment darkening was noted at both wavelengths in all iron-containing pigments except black. It was variable in those containing titanium. Pigments tested responded with either clearance or darkening at 532 nm; however, response at 752 nm was more limited. This leads to the following conclusions: (1) Tattoo pigment absorption spectra can explain why some colors are more resistant to removal. (2) Pigment darkening is a complex process.⁶³

Tattoos can darken after laser treatment because of the reduction of ferric oxide to ferrous oxide. This can be rectified with repeated Q-switched laser treatment and the use of a resurfacing laser. Peach et al.⁶⁴ observed color changes in 33 of 184 (17.9%) multicolored tattoos. This effect is attributed to titanium dioxide, which is used as a lightener, and the reduction of iron-containing pigments to iron oxide. These usually respond to further laser treatments, but there is no guarantee. It is thus advisable to test an unnoticeable area for color changes as well as lightening associated with repeated treatment.⁴⁸

For textural alterations and scarring, possible treatments consist of erbium:YAG laser or pulsed carbon

dioxide laser as well as fractional photothermolysis.⁶⁵ A study by Ho et al.⁶⁶ used onion extract, heparin, allantoin gel (Contractubex® gel, Merz) prophylactically to prevent scarring. In the study, Contractubex® was applied to 61 tattoos while the comparison group of 58 tattoos did not receive any topical therapy. Twice daily application between laser treatments led to a significant reduction in the frequency of scarring.⁶⁵

An unusual reaction to laser removal has been observed in traumatic tattoos among three patients with dermal inclusions of gunpowder who were shot at close range. Treatment was tried in each patient with a Q-switched Nd:YAG laser at a medium fluence (4–6 J/cm²). But during treatment of our patients, each pulse provoked sparks and the immediate formation of bleeding transepidermal pits. After the healing process was completed, poxlike scars and the spreading of pigments in the skin around the initial points of the tattoo developed. The authors hypothesize that the rapid transfer of high-energy pulses to powder particles creates microexplosions of these fragments resulting in cavitation and provoking transepidermal holes and subsequent scars. This adverse effect was only produced if the tattoo resulted from gun powder being shot at a short distance from the skin.⁶⁷

Hair growth may be affected by laser removal. A 32-year-old skin phototype III male underwent 10 intense pulsed light (IPL; Photoderm PL, Lumenis, Yokneam, Israel) sessions to remove a multicolored (green, yellow, black, and red) nonprofessional tattoo situated in his back. In the 9th session, the appearance of lanugo hairs located in part of the treated area was noted. In the 10th session, the hair became thicker and was exactly located in the whole treated area.⁶⁸

Pain Management for Laser Therapy

Tattoo removal with a Q-switched laser is often a painful procedure. The sensation of pain associated with the treatment is immediate and acute.

Topical anesthetics are commonly used to make the treatment more comfortable. Although the use of topical anesthetics like EMLA-cream for alleviating the pain associated with cutaneous laser procedures, has been shown to be effective in several studies, most require a lengthy application time (1–2 hours) to be effective.⁷³

A multicentered, randomized, double-blind, placebo-controlled study has been performed using S-Caine Peel (ZARS, Inc (Salt Lake City, UT, USA). S-Caine Peel is composed of a 1:1 (w:w) eutectic mixture composed of lidocaine base 7%, USP, and tetracaine base 7%, USP. It is applied as a cream, dries on exposure to air, and forms a flexible membrane, which can be easily peeled off. Thirty adult patients undergoing laser-assisted tattoo removal were enrolled. Each subject received both the S-Caine Peel and placebo simultaneously for 60 minutes. The

primary efficacy parameter was a 100 mm visual analog scale (VAS) for patient self-assessment of pain. Mean VAS scores were 42 mm for the S-Caine Peel and 66 mm for placebo treatment sites ($p=.001$). Patients received adequate pain relief in 50% of S-Caine Peel sites versus 7% of placebo sites ($p=.002$). One occurrence of moderate to severe erythema was noted at both an S-Caine Peel and a placebo treatment site on removal of the S-Caine Peel after 60 minutes, which self-resolved quickly. Other side effects were limited to local mild, transient erythema at the application sites. Administration of the S-Caine Peel for 60 minutes prior to laser-assisted tattoo removal, was effective in significantly reducing pain levels associated with the procedure.⁷⁴

Application of topical anesthesia to the treated area of the skin is time-consuming, with moderate pain relief. Therefore new options have been evaluated to control the pain during treatment. Pneumatic skin-flattening (PSF) technology utilizes an evacuation chamber that generates skin compression and activates tactile neural receptors in the skin, resulting in afferent inhibition of pain transmission in the dorsal horn ('gate theory'). Eleven patients aged 17–25 years old who were treated for tattoo removal were enrolled in a pilot study. The patients were treated by a Q-switched Nd:YAG laser. Acute pain evaluation was performed on all 11 patients: one to two sites per patient with PSF, and one to two control sites without PSF. The study was limited by the fact that patients knew they were being treated with a device that might reduce pain. This may have influenced the outcome. The evaluation was based on a pain score. A lower pain score with PSF was observed in all but one patient (10/11 or 91%). The average reduction of pain is by two levels: from very painful to very mild pain. The energy transmission of the PSF window is 95%, resulting in essentially identical efficacy of the PSF treatment and the regular non-PSF treatment. This pilot study indicates that PSF technology may reduce pain in tattoo removal with medium energy density Q-switched lasers (3–5 J/cm²).⁷⁵

Alternative and Adjunctive Procedures

Surgery

Complete excision is only possible for smaller tattoos. Larger areas can be removed by shave-excision with healing by second intention (Figure 40-5). A bloodless field can ensure a complete removal of dermal pigment and reduce the operation time.⁷⁷ The wound can be covered with polyurethane dressings or dermal overgrafting.^{76,78}

A small study has been performed to evaluate precise, thin, tangential excisions of professional tattoos. Five healthy white males had their professionally placed tattoos excised at a depth of 0.2 mm using a Brown dermatome. Pre and posttreatment biopsies were used to measure the depth of

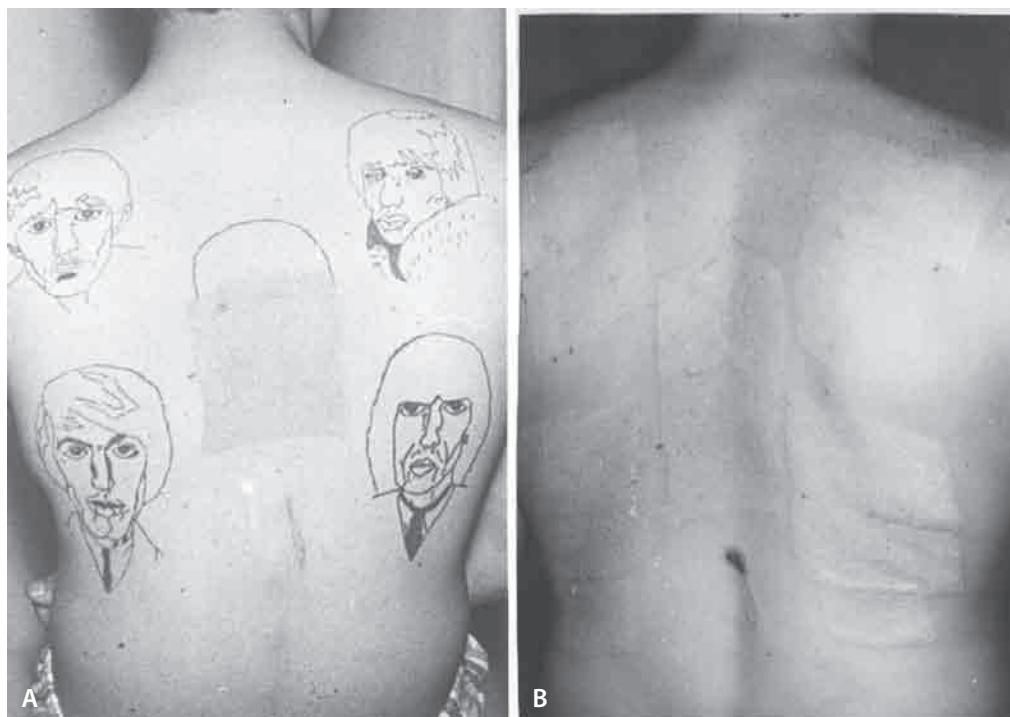

FIGURE 40-5 Tattoo removal by shave excision (From: Wollina U, Köstler E. Tattoos: surgical removal. *Clin Dermatol*. 2007;25:393–7).

the tattoo pigment. At 3 months posttreatment, four patients had no significant scarring and three patients retained only scattered flecks of tattoo pigment. Each patient demonstrated migration of the deeper dermal pigment to a more superficial level.⁷⁹ A superficial, tangential excision of a professional tattoo by a dermatome is a viable, low-risk, inexpensive procedure as long as the pigment lies superficially.

A method of tattoo removal in which the enzymatically (disperse) separated epidermis of an excised tattoo was grafted *in situ* was applied to three patients. Unlike the conventional skin-grafting procedure, this method resulted in the complete obliteration of the tattoos without donor site scars. The thinning of the tattooed skin using a Paget's-type dermatome before its exposure to an enzymatic solution facilitated the enzyme's infiltration of the basal layer of the epidermis. Hence, the time taken for the epidermis to separate from the tattooed skin was shortened.⁸⁰

Larger tattoos may need a sequential excision. Suture tension can be minimized using placation with presuturing, dynamic skin suture, or tissue expansion.⁸¹ Dermabrasion generally produces excellent results in the removal of congenital or acquired nonesthetic skin changes. Superficial traumatic (accidental) tattoos should be removed immediately after the accident. Dermabrasion is a useful method. Decorative tattoos can be successfully removed by repeated surface dermabrasion. In case of granuloma formation in traumatic tattoos, however, dermabrasion will not produce satisfactory results.⁶⁹

Salabrasion is the use of abrasion with table salt and a moist gauze pad to achieve a mixture of mechanical and chemical deep peeling.

In an open trial, 22 patients have been treated with a 3-minut salabrasion, once for repeatedly, on skin areas around 41 tattoos. In tattoos performed by laymen on forearm, upper arm or posterior, a single salabrasion produced acceptable to good results in the removal of tattoos. Frequently, single or repeated salabrasion resulted in hypopigmentation of the interfollicular epidermis with a more or less intensive skin-colored to brownish pigmentation of the follicle regions. The general impression of hyperpigmentation only occurred occasionally after single salabrasion and was independent of location. Single or repeated salabrasion resulted in an emphasis of the surface structure and increased wrinkling of the skin in due course, but not scar formation.⁷⁰

In a study in the UK, 33 patients, some with multiple tattoos were treated by salabrasion. In 14 patients with 28 tattoos only tiny flecks of pigment remaining visible; eleven showed a fair response, (i.e., the tattoo, although much lighter in color, was still legible but the patient was satisfied with the result); three showed a poor response, (i.e., the tattoo appeared as if untreated); four (two patients) defaulted. In general, as could be expected, the darker the tattoo the more difficult was its removal and those on fingers were particularly resistant.⁷¹

To reduce the risk of scarring, the salt should be removed completely after finishing the procedure, (i.e. by irrigation).⁹

Chemical Clearing Agents

In guinea pig studies on tattoo removal, glycerol was used as a clearing agent. Intradermal injection of clearing agents

induced dermal clearing but resulted in necrosis and scar. Transdermal application of clearing agents resulted in moderate reversible clearing, which was localized to the superficial layers of the skin and did not result in complications. Temporary clearing of superficial skin layers may be performed in an apparently safe and reliable manner. Clearing should lead to increased penetration of laser light to tattoos and should, therefore, increase treatment efficiency. Further study is needed to determine the degree to which this change is of clinical value.⁷²

Several cream removal systems have been introduced to the market. These consist of chemicals that penetrate the skin and gradually digest the tattoo pigment. Among these are Tattoo-Off (BeauPlexa, Sarasota, FL), which claims to contain only natural botanicals such as aloe leaf juice, lemon extract, orange peel, rosemary and sage leaves, and calendula flower extract in conjunction with hydroquinone, salicylic acid, and a variety of preservatives. The manufacturer claims that dramatic results are seen after 7 months of daily application. Another topical cream is Tat B Gone (Sandy Springs, GA), whose Website does not disclose the ingredients in the product.⁸² The Rejuvi Tattoo Remover solution (Rejuvi Lab, South San Francisco/CA) contains cosmetic deionized water, zinc oxide, magnesium oxide, calcium oxide, isopropanol, triethanolamine, and benzoic acid. The composition is said to have low skin toxicity and antiseptic efficacy. The Rejuvi Tattoo Remover is inserted into the dermis by a coil tattoo gun or a cosmetic rotary machine after topical anesthesia. It has claimed that this product is capable of mobilizing tattoo pigments from the skin and forms a scab with tattoo pigments on the treated skin area, which then peels off in 10–20 days. It is recommended to perform the treatment on a tattoo area not greater than 15 cm² in order to control the discomfort level after treatment. If needed, a second treatment should be performed on the same area after sufficient skin healing (usually about 3 months).

Cheng⁸⁶ reported that Rejuvi Tattoo Removal has been found to be non-color-selective (it removes all tattoo pigments). In the initial study with 98 patients, the success rate was 100% for removal of cosmetic facial tattoos (tattooed eyebrows) and 92% for body tattoos. The scarring rate was zero for cosmetic facial tattoos and 6% for body tattoos. No pigmentary change was found for either type of tattoo.⁸⁵ There has been no study found from another group using this chemical mixture.

A 27-year-old Latino man with a 24 × 10 cm tattoo on his right lower leg had received 7 treatments using Rejuvi Tattoo Removal at weekly intervals. He subsequently developed hypertrophic scars in the area treated using Rejuvi Tattoo Removal. He had no personal or family history of hypertrophic or keloid scars.⁸²

Veysey and Downs reported two patients who developed hypertrophic and hypopigmented scars, after treatment with Rejuvi Tattoo Removal on the forearms.⁸⁷ More recently, a patient experienced full-thickness skin loss requiring grafting after just one treatment on the lower leg.⁸⁸

Topical Imiquimod

Imiquimod is an immune-response modifier for topical use. It has been shown that topical application of 5% imiquimod cream to acute phase tattoos results in successful removal in an animal model, although fibrosis and loss of dermal appendages also occurred.⁸⁹ Less frequent application of topical imiquimod over a longer treatment period in the same animal model resulted in tattoo fading and fibrosis, without appendageal loss.⁹⁰

In a recent study, 14 albino guinea pigs were tattooed with black ink, and then randomly assigned into two groups: one underwent sequential laser treatments with a Q-switched alexandrite laser in conjunction with triweekly applications of 5% imiquimod cream, while the other group underwent laser therapy alone. Subjects were evaluated with clinical photographs and skin biopsies after six laser treatment sessions. The combination laser and imiquimod-treated group was clinically and histologically rated as having less pigment than the tattoos that were treated with laser alone ($p=.012$ and $p=.047$, respectively). Adjuvant imiquimod treatment had greater inflammation ($p=.002$) and fibrosis ($p=.002$) on post-treatment skin biopsies. The authors concluded that imiquimod appears to be a useful adjuvant to experimental laser tattoo removal in guinea pigs.⁹¹

Human experience seems to be different. Twenty subjects with two similar tattoos were enrolled in a randomized, prospective, double-blinded, case-controlled study. Tattoos were treated with either imiquimod or placebo daily and laser therapy every 4 to 6 weeks for a total of six sessions. The primary efficacy parameter was tattoo clearance (5-point scale, poor through complete). Secondary efficacy parameters included textural changes (5-point scale, minimal through severe), pain during and between laser procedures, and undesirable pigment alterations. Nineteen subjects completed the study. The mean score for tattoo clearance with imiquimod versus placebo was 3.2 versus 2.9 and, for textural changes, was 1.37 versus 1.21 (differences not statistically significant). There was no difference in subjective pain during and between laser sessions and no undesirable pigment alterations were reported. Adverse reactions were more frequent with imiquimod compared to placebo. Based on this study, the authors come to the conclusion that topical imiquimod is an ineffective adjunct to laser-assisted tattoo removal.⁹²

Magnets

To improve the clinical outcome, more recent developments have included the external application of magnets to improve the removal of magnetite skin tattoos after Q-switched laser treatment. The extraction of magnetite ($\text{Fe}_3(\text{O}_4)$) ink tattoos by a magnetic field was investigated, with and without Q-switched laser treatment. Magnetite particles (1.4 μm) were used to make mature, black skin

tattoos on hairless albino rats. A Q-switched ruby laser - fluence 3.5 J/cm^2 , 6.5 mm spot size, 40 ns pulse width was used for treatment. Permanent magnets (1.4 T, 6 mm diameter) were tested to extract the magnetite particles, alone and after laser light application. A magnetic field applied immediately after laser treatment extracted some ink when epidermal injury was present, and caused significant redistribution of magnetite into the upper dermis with vertical banding along magnetic field lines. When applied for 3 weeks following Q-switched ruby laser, magnets caused darkening of tattoos.⁹³ Magnetically-extractable tattoos may be feasible.

CONCLUSIONS

Tattoo removal has been studied in many trials, some randomized controlled but most uncontrolled. The best evidence is available for Q-switched laser treatment that allows in most tattoos a significant lightning that is color-dependent. The most challenging colors are white and yellow. The best results are obtained in black, blue and red tattoos. The composition of the pigment dyes needs to match with the wavelength of the laser to obtain an optimal result.

In contrast to Q-switched lasers, IPL is not recommendable because of long pulses and increased risk of scarring by tissue heating.

Surgical procedures are available from simple abrasive therapies (salabrasion, dermabrasion) to complex procedures using tissue expansion techniques, flaps, and grafts. In many parts of this World, simple procedures are often used as an alternative to lasers because of cost issues. Sometimes surgery is the only option to deal with a prolonged inflammatory response to tattoo dyes. No comparative randomized trials are available for surgical procedures.

Chemical clearing agents seem to offer a soft effect not depending on tattoo colors. A single study suggested efficacy, but more studies are needed. The technique has been used as an adjunct to laser treatment. In some patients chemical clearing agents can cause scarring.

Topical imiquimod cream has shown efficacy as an adjunct to laser treatment in animal models but published experience in humans is disappointing.

Consumer safety may increase if regulations for tattoo dyes would ban the use of harmful substances. New dye developments like microencapsulation of ink could be used to allow a complete and safe removal on demand.⁹⁴

What We Know

- Tattoos are skin marks that may contain a variety colored pigments. The removal of tattoos is not as easy as the tattooing itself, although this might be an art. *In general tattoo removal is a time-consuming procedure and more expensive than tattooing.*
- In tattoo removal laser is the treatment of choice in many cases. Q-switched lasers have been found to be safe and effective in the treatment of tattoos with a low risk of scarring. Q-switched lasers with nanosecond pulse durations and wavelengths of 755 nm (Alexandrite) and 1,064 nm (neodymium [Nd]:YAG) are effective for blue and black tattoos; 694 nm (ruby) for blue, black, and green tattoos; and 532 nm (Nd:YAG) for red tattoos. Ablative lasers like pulsed erbium:YAG or pulsed CO₂ have been used for laser-assisted dermabrasion in

traumatic (accidental) tattoos. In contrast to Q-switched lasers IPL is not recommendable due to long pulses and increased risk of scarring by tissue heating.

- Complete excision is only possible for smaller tattoos. Larger areas can be removed by shave-excision with healing by second intention. Larger tattoos may need a sequential excision. Suture tension can be minimized using placation with pre-suturing, dynamic skin suture, or tissue expansion.
- Dermabrasion is a cheap and useful method but the cosmetic outcome often is not as good as with lasers. Several cream removal systems have been introduced to the market that should gradually digest the tattoo pigment but multicenter randomized controlled trials are missing.

Treatment of Photodamage

Hina Ahmad, M.D., William W. Huang, M.D., M.P.H., and Victoria H. Barbosa, M.D., M.P.H., M.B.A.

INTRODUCTION

Photodamage refers to the complex progressive process of chronic ultraviolet radiation (UVR) exposure of the skin and its effects on skin aging and photocarcinogenesis. Indeed ultraviolet light is the primary external factor contributing to age-associated changes in the skin including wrinkling, dyspigmentation (hyperpigmentation and hypopigmentation), atrophy, and telangiectasias. The perceptions of both age and beauty are largely dependent on the appearance of the skin, which can be dramatically altered by chronic sun exposure. Thus, patients are increasingly seeking interventions to reduce or eliminate the signs of photodamaged skin.¹

The aging process of the skin is related to both genetic (intrinsic) and environmental (extrinsic) biologic mechanisms. Intrinsic aging is believed to occur because of DNA damage and telomere shortening. DNA damage, in addition to an inability to repair this damage, leads to cellular senescence. In addition, the telomeres at the end of chromosomes get progressively shorter with each cell cycle. Eventually a critical point is reached leading to cell signaling for apoptosis, or programmed cell death, suggesting a defined and finite life for cell functionality. Our expanding knowledge of external skin aging is centered around the effect of ultraviolet light on the skin, including direct DNA damage, the production of reactive oxygen species, and chronic inflammation.² In addition to ultraviolet radiation, smoking, poor nutrition, and excessive alcohol consumption are other extrinsic factors that contribute to skin aging. The two mechanisms, intrinsic and extrinsic, likely share a final common pathway as ultraviolet radiation has been shown to damage telomeres and induce cellular apoptosis through reactive oxygen species.³

At a cellular level, photodamaged skin is characterized by several changes within the epidermis and dermis of the skin. Within the epidermis, keratinocytes may show atypia and loss of polarity in addition to a general increase in the thickness of the epidermis of chronically sun-exposed skin. Within the dermis, fibroblasts are more numerous and hyperplastic, collagen I and III are decreased, and abnormal elastin accumulates. In addition, photodamaged skin shows signs of chronic inflammation, including mast

cells, macrophages, and T cells on histologic examination. This combination of cellular changes leads to the clinical appearance of photodamaged skin.²

The Ultraviolet Light Spectrum

The ultraviolet light spectrum is subdivided into several categories based on wavelength and biologic behavior. The skin represents the body's primary barrier to ultraviolet radiation, as UVR does not penetrate any deeper than the epidermis or dermis, depending on the wavelength. Ultraviolet A (UVA, 320 nm to 400 nm) accounts for approximately 95% of all the sun's ultraviolet radiation that reaches the earth's surface. Its longer wavelength readily reaches the dermis and is believed to play a significant role in both photoaging and immediate pigment darkening. Compared to photoaging, which take years of cumulative sun exposure, immediate pigment darkening occurs during and immediately after ultraviolet radiation exposure and fades rapidly, usually over a number of hours. It is a result of alteration of preexisting melanin within melanocytes.⁴

Ultraviolet B (UVB, 290 nm to 320 nm) is mostly filtered by the earth's atmosphere. However, some does reach the earth's surface, albeit in much smaller quantities than UVA. UVB has a shorter wavelength than UVA, and hence is primarily absorbed in the epidermis and contributes to the induction of cutaneous malignancies as well as delayed pigment darkening. The induction of cutaneous malignancies occurs through a complex interplay of angiogenesis, DNA damage, and formation of mutations, and failure of native repair mechanisms. Delayed pigment darkening occurs days after ultraviolet radiation exposure and is a result of increased activity of melanocytes including an increase in the number of melanocytes and increased melanin synthesis. Ultraviolet C (UVC, 200 nm to 290 nm) is undetectable at the earth's surface as it is absorbed by the earth's atmosphere entirely.⁴

Clinical Effects of Photodamage

Chronic ultraviolet radiation induces common clinical changes in the skin including wrinkling, dyspigmentation,

atrophy, telangiectasias, and the induction of cutaneous malignancies. Sun-induced wrinkling involves a combination of changes within the dermis of the skin including collagen, elastin, and the extracellular matrix (ECM). Collagen production is greatly reduced in photodamaged skin through a complex interaction of fibroblasts, ultraviolet radiation, and damaged collagen. Activator Protein 1 (AP-1) and Transforming Growth Factor B (TGF-B) are thought to play a primary role in the down regulation of collagen synthesis in photodamaged skin. In contrast to decreased levels of collagen, the production of elastin increases with subsequent exposure to ultraviolet radiation. However, the elastic fibrils are abnormal and accumulate within the dermis leading to solar elastosis and laxity of the skin. Lastly, changes within the extracellular matrix mediated through the upregulation of matrix metalloproteinases lead to collagen degradation and the breakdown of the ECM.⁵⁻⁶

As discussed earlier, sun exposure can lead to both immediate pigments darkening (primarily through UVA) as well as delayed tanning (primarily through UVB). In addition, changes in pigment such as lentigines, ephelides, poikiloderma of Civatte, and idiopathic guttate hypomelanosis can be seen in photodamaged skin. Although the mechanism is not completely understood, an interaction between ultraviolet radiation, melanocytes, and chronic inflammation is thought to mediate these changes.⁵⁻⁶

Studies have documented the effects of ultraviolet radiation and the induction of telangiectasias. Through upregulation of factors such as vascular endothelial growth factor (VEGF) and platelet derived endothelial growth factor (PDGF) and the downregulation of inhibitors such as thrombospondin-1 (TSP-1), UVR promotes local angiogenesis of the skin. In addition, this increase in cutaneous vascularity is thought to play a role in supporting the growth of cutaneous neoplasms.⁵⁻⁶ Cutaneous malignancies are beyond the scope of this chapter and are discussed elsewhere in the book.

EPIDEMIOLOGY

Changes in the skin from chronic ultraviolet radiation exposure affect both men and women equally, as well as all races. Patients with lighter skin types, with a tendency to burn easily, living in areas with more cumulative sun exposure, and with occupations requiring more outdoor exposure are at greater risk for photodamage to the skin. Women may seem disproportionately affected by chronic photodamage, but this is a reflection of medical-seeking behavior, especially for tertiary interventions to reduce or reverse photoaging.⁷ In 2002 alone, over 5 million nonsurgical and 1.5 million surgical procedures were performed costing over 13 billion dollars in order to improve the appearance of photodamaged skin.⁸

ETIOLOGY AND DIAGNOSIS

Ultraviolet radiation is considered the primary etiologic factor in photodamaged skin. Biologically, ultraviolet A (UVA) penetrates into the dermis and induces many of the changes of chronic photodamage. However, ultraviolet light should be considered on a spectrum with contributions from ultraviolet B (UVB) as well. Through its effects on DNA damage, the production of reactive oxygen species (ROS) and promotion of a chronic inflammatory state, ultraviolet radiation can accelerate the cutaneous aging process as well as induce cutaneous malignancies.^{2,5,6,9}

The diagnosis of photodamaged skin is made clinically as skin exposed to chronic ultraviolet radiation displays several characteristic features including fine and deep wrinkling, laxity, dyspigmentation, telangiectasias, variable thickness, and cutaneous malignancies. These clinical signs are most pronounced on areas of the body receiving the most sun exposure including the face, neck, dorsum of hands, and extensor forearms, and in persons with lighter skin types. Areas of the body that are "double-covered"- that is covered by two layers of clothing- such as the buttocks can often be used as comparison between photodamaged and photoprotected skin within an individual patient. Although not typically performed, the diagnosis of photodamaged skin can be confirmed by skin biopsy. Histopathologically, photodamaged skin displays several characteristic features including epidermal thickening, flattening of the dermoepidermal junction, disorganization of collagen, altered microvasculature, and solar elastosis.^{2,5,6,9}

OBJECTIVES

Over 1300 journal articles have been written on the subject of photodamage, along with countless book chapters. This work seeks to review recently published literature that provides strong evidence regarding effective prevention and treatment of photodamage.

Specifically, five research questions are posed:

1. How can photodamage be prevented?
2. What topical agents are effective in treating photodamage?
3. Are chemical peels effective in treating photodamage?
4. Are injectables and fillers effective in treating photodamage?
5. Are laser and light sources effective in treating photodamage?

These questions are answered through systematic PubMed searches, with the specific search criteria described in each section that follows.

PREVENTION

The sole etiologic agent that initiates the process of photodamage of the skin is the chronic exposure to ultraviolet

radiation. As such, reducing the amount of ultraviolet light one receives remains the cornerstone of the prevention of photodamage. Indeed, many visits to dermatologists involve a discussion regarding photoprotection, using sunscreens and photoprotective clothing. In addition, the medical community, the cosmetics industry, and various media outlets have each worked to educate the public about the importance of photoprotection. Although the emphasis of photoprotection has historically focused on blocking ultraviolet B, because of its contribution to skin cancer, a better appreciation of the effects of ultraviolet A on photoaging has led to “broad-spectrum” protective measures. Despite increased efforts at public education regarding photoprotection and advances in photoprotective technology, a segment of the population intentionally increases their exposure for a more “tanned” or “healthy” appearance.

Using the MEDLINE (PubMed) database to identify articles and abstracts relating to the prevention of photodamage, the term “Photoprotection” was used as a medical search heading (MeSH). Articles were limited to those written in English, published within the last 10 years, and that involve only human subjects. This search yielded 281 articles. Articles were hand searched and excluded if the articles did not deal with photoprotection as it relates to photodamage to the skin. For example, articles discussing photoprotection and vitamin D or photoprotection and the treatment of dermatologic disease were not included. In addition, reference lists of review articles were searched and studies included, when appropriate, as supporting evidence. For consideration for evidence, letters, case reports, case series, and basic science/animal studies were also excluded after reviewing individual articles. Fourteen articles were included as evidence for the utility of photoprotective clothing, sunscreens, and antioxidants for the prevention of photodamage.

Photoprotective Clothing

Photoprotective clothing and hats offer a convenient and effective means for the prevention of photodamage of the skin. In order to standardize and compare photoprotective abilities, the industry has adopted the ultraviolet protection factor (UPF) as a measurement standard. Many factors contribute to the UPF, including fabric materials, thickness of fabric, tightness of weave, as well as chemical treatments including UV absorbers and optical brightening agents. Photoprotective clothing offers the advantage of broad-spectrum UV protection and immediate and continuous effectiveness as compared to sunscreens where patients must apply the sunscreen a half hour before expected UV exposure and reapply thereafter.¹⁰

Despite claims of photoprotection, several recent studies have brought the issue of effectiveness into question. One study by Gambichler et al. examined 236 fabric

textiles from spring/summer clothing line collections during the period of 2000-2001 and tested their level of UPF. The authors discovered that a third of clothing products tested (78/236) provided poor protection from ultraviolet light (defined as UPF <15) and less than half (113/236) provided an UPF >30.¹¹ A review article by Hatch et al. summarized the current knowledge regarding sun protective clothing. Four separate studies conducted during the 1990s were reviewed in that article and found between 50-80% of summertime clothing delivered at least a SPF 15 photoprotective level.¹² In 2003 the European Committee for Standardization proposed guidelines for photoprotective clothing specifically marketed with UPF labeling. Photoprotective clothing must cover the area from the neck to the hip and at least three quarters of the upper arm, have a minimum UPF of 40, and have less than 5% UVA transmission.¹³

The evidence regarding the use of photoprotective clothing in the prevention of photodamage of the skin is mixed at best. Much of the conflicting evidence stems from the relative recent advent of clothing specifically marketed for photoprotection. The use of UPF as a measurement of photoprotection as well as higher standards for photoprotective clothing has led to more reliable clothing products for UV photoprotection. Biologically it makes sense that any product that blocks UVB and UVA from reaching the skin will prevent photodamage, however more studies are needed to elucidate the exact extent of such products.

Sunscreens

Sunscreens remain the most widely available and popular method for the prevention of photodamage of the skin. The oldest sunscreens utilize inorganic particles (physical blockers) such as titanium dioxide and zinc oxide to scatter and absorb ultraviolet radiation. Initially cosmetically displeasing because of the larger particle size and subsequent whitening appearance, newer products utilize nano- or micro-sized particles while maintaining broad-spectrum photoprotection. In contrast, newer sunscreens incorporate a variety of organic particles (chemical blockers) that absorb ultraviolet radiation and convert the energy into heat. Most current organic sunscreens combine both a UVB filter such as aminobenzoates, cinnamates, salicylates, and octocrylene with a UVA filter such as benzophenone, avobenzone, and ecamulse.¹⁰

The strongest evidence regarding sunscreens and photoprotection relates to the reduction of skin cancers. Sunscreens have been shown to reduce the number of actinic keratoses and squamous cell carcinomas in several studies.¹⁴⁻¹⁶ The evidence is not as strong in regards to basal cell carcinoma prevention, although several studies by Green et al. suggest a benefit.^{15,16} The role of sunscreens in the prevention of melanoma has been controversial with some studies actually suggesting an increased risk

of melanoma. A recent meta-analysis by Dennis et al. concluded that sunscreen use was safe and did not increase the risk of melanoma.¹⁷ Much of this discrepancy may be explained by earlier sunscreens offering little to no UVA photoprotection.¹⁸

An appreciation of the use of sunscreens in the prevention of photodamage of the skin is evidenced by the marketing of products, including daily moisturizers with sunscreens incorporated into the product itself. As discussed previously, many of the signs of photoaging including wrinkling, dyspigmentation, atrophy, and telangiectasias are brought on or accelerated by the chronic exposure of the skin to ultraviolet light. A study by Seite et al. demonstrated that daily sunscreen use could slow down the process of photoaging by preventing ultraviolet radiation from enacting its biologic effects on the epidermis and dermis.¹⁹

The evidence regarding the routine use of sunscreens in the prevention of photodamage of the skin is strongest for the prevention of cutaneous tumors including actinic keratoses and squamous cell carcinomas. The evidence behind the routine use of sunscreens in the prevention of basal cell carcinoma is not as strong, and the data regarding sunscreen and its relationship to melanoma is controversial. More research is needed in these areas. Finally, our knowledge regarding the effects of ultraviolet light, especially ultraviolet A, on photoaging provides indirect evidence supporting routine sunscreen use in the prevention of photoaging.

Antioxidants

Besides the direct damage caused by ultraviolet light on the DNA of cells within the epidermis and dermis, indirect damage through the production of reactive oxygen species (ROS) contributes to photodamage of the skin. Although the body has innate mechanisms to neutralize these reactive oxygen species, excess amounts can cause damage to the DNA, lipid membranes, and proteins within the skin. Antioxidants act by reducing and reversing the build-up of potentially harmful reactive oxygen species produced by ultraviolet radiation.

Although systemic antioxidants are commonly supplemented in diets, inadequate levels are delivered to the skin to produce any appreciable benefit. However, topical antioxidants such as vitamin C, vitamin E, green tea polyphenols, and other natural extracts work directly on the skin's surface. Special considerations regarding stability of the antioxidant, achievement of a biologically active concentration of the antioxidant, and formulating the antioxidant into an acceptable vehicle are all challenges in delivering antioxidants to the skin.

The evidence regarding the topical use of antioxidants in the prevention of photodamage of the skin should be considered within the realm of complementary and alternative medicine (CAM). Several studies by Jurkiewicz et al.

and Lin et al. have demonstrated the photoprotective ability of topical vitamin C and vitamin A within the skin.^{20,21} Other studies by Elmets et al. and Kim et al. have shown photoprotective effects through the topical application of green tea polyphenols.^{22,23} The additional benefit of topical antioxidants should be considered supplementary to other photoprotective measures such as sunscreens and protective clothing.

What We Know: Prevention of Photodamage

- Clothing can provide protection from ultraviolet light, though studies demonstrating a causal reduction in photodamaged skin are lacking
- Sunscreens have been demonstrated to reduce photoaging, actinic keratoses and squamous cell carcinomas
- Evidence regarding sunscreen use and decreased risk of basal cell carcinoma is not as strong
- The role of sunscreen in the prevention of melanoma has been a source of controversy, but it does not seem to increase the risk of melanoma
- Use of topical antioxidants are a reasonable additional step in sun protection, with sun avoidance, protective clothing and sunscreen being first-line approaches

TOPICAL THERAPIES

The topical treatments available for photodamaged skin are vast, with new treatment options becoming available continually (Table 41-1). It is the job of the physician to guide treatment based on the patient's degree of photodamage and the clinical evidence available, as well as the patient's preferences and expectations. Historically, topical retinoids have been shown to be the gold standard in the treatment of photodamaged skin,²⁴ however, many other topical agents are currently available. For those patients who are willing to comply with a daily treatment regimen and understand that results may take weeks to become clinically visible, topical therapies are a good option. However, in patients who want more immediate and obvious results, therapies such as botulinum toxin injections, fillers, chemical peels, and lasers may be used in addition to or instead of a topical regimen.

Because of the large number of topical treatments available, the goal of this review is to focus on the newest therapies currently available, those therapies that appear promising and are on the horizon, as well as older therapies that have good clinical evidence to support their use. A PubMed search was performed using the search criteria "photodamage treatment", limiting the search to human studies published in English within the past 5 years. This yielded 152 studies. Studies focusing on pathogenesis and

prevention of photodamage and laser and light treatments were excluded. Thirty-three articles remained for review. In addition, eight review articles discussing different topical therapies were reviewed. Of these, only those articles, which presented the highest level of evidence, were used. Results are summarized in Table 23-1.

Retinoids

Retinoids exert their effects by modulating gene transcription through the activation of the retinoid X receptor or the retinoic acid receptor.²⁵ Numerous randomized-controlled trials have been performed that show topical retinoids are effective at treating many of the signs of photodamage, namely fine wrinkles, lentigines, and tactile roughness. As a matter of fact, tretinoin 0.02% and 0.05%, as well as tazarotene 0.1% have been approved for the treatment of photodamage by the Food and Drug Administration.²⁵ Recently, other formulations of retinoic acid were tested in their efficacy for treating photodamaged skin. Weiss et al. conducted a randomized, double-blinded, placebo-controlled trial that evaluated the efficacy of 0.1% tretinoin microsphere gel.²⁶ The gel was applied once nightly for a total of 6 months. At completion of the study, statistically significant improvement was noted in fine wrinkling, mottled hyperpigmentation, yellowing/sallowness, and lentigines.

Retinol is another therapeutic option and is a cosmetic agent that is very similar to retinoic acid. Since skin keratinocytes are thought to metabolize retinol to retinoic acid, and since the latter have been shown to be effective for photodamaged skin, it has been hypothesized that retinol may be an effective treatment agent as well. Tucker-Samaras et al. completed an 8-week, double-blind, split face, randomized clinical study comparing a 0.1% retinol moisturizer against a vehicle, applied once daily.²⁷ At both 4-week follow-up and at completion of the study, significant improvement was noted in fine lines, wrinkles, pigmentation, elasticity, firmness, and overall photodamage, suggesting that this may be a viable treatment option. Although it is less irritating than retinoic acid and conveniently available over-the-counter, it is less effective than retinoic acid.

Topical Chemotherapeutics

Photodamage can lead not only to aesthetically displeasing features, such as wrinkles and lentigines, but can also cause precancerous lesions like actinic keratoses. There are many topical options available to treat actinic keratoses, including fluorouracil, imiquimod, and diclofenac. Fluorouracil, a topical chemotherapeutic cream, has been shown in multiple studies to be an effective treatment option for general photodamage as well. Sachs et al. examined the effects of topical fluorouracil on photodamaged skin both clinically and molecularly in a nonrandomized, open-label trial.²⁸ Patients were treated with fluorouracil

twice daily for a total of two weeks. Clinical improvement as well as an increase in the gene expression of keratin 16 (effector of epidermal injury), interleukin-1 beta (inflammatory marker), and matrix metalloproteinases 1 and 3 (extra cellular matrix degradation products) were noted. These results prove that topical fluorouracil causes epidermal injury, which stimulates wound healing and dermal remodeling, similar to that seen in the laser treatment of photodamage.

Combination Therapy

Leyden et al. performed a 24-week investigator-blinded randomized study that evaluated treatment of the decolletage area with a proprietary copper zinc malonate lotion and 4% hydroquinone applied twice daily, as well as tretinoin cream applied once daily.²⁹ Improvements were noted as early as 2 weeks, with tactile roughness improving first, followed by improvement in mottled hyperpigmentation, lentigines, wrinkling, and laxity. This study is particularly interesting because most of the therapeutic options available tend to focus on the treatment of photodamaged skin of the face, however patients often inquire about treatment of the decolletage area (neck and anterior chest) as well.

Lowe et al. compared the treatment outcomes of tazarotene 0.1% monotherapy versus tazarotene plus hydroquinone 4% in a randomized, double-blinded trial. Combination therapy proved to be more efficacious in the treatment of lentigines, mottled hyperpigmentation, and overall global improvement.³⁰

Combination therapies can also aim to decrease the side effects caused by the main treatment agent, and thus improve compliance and overall outcome. A double blind, placebo-controlled pilot study done by Jacobson et al. evaluated the effects of combining myristyl nicotinate (MN) with retinoic acid.³¹ Myristyl nicotinate is a lipophilic derivative of niacin that enhances skin barrier function and thus decreases the irritation that is often associated with retinoid use. Patients were treated with MN the month prior to initiating retinoid therapy. Once retinoids were begun, patients reported less side effects and easier tolerability.

A more tolerable and effective treatment for hyperpigmentation associated with photodamage involves the combination of 0.3% retinol with 4% hydroquinone. When compared to 0.05% tretinoin applied once daily, the combination regimen was as effective, if not more so effective, at treating hyperpigmentation, fine wrinkles, and roughness.³²

Growth Factors and Antioxidants

Growth factors are known to be involved in the mechanism of skin repair.³³ With this fact in mind, a multitude of topical growth factor preparations have been tried for the treatment of photodamaged skin. There have been numerous

clinical reports that show that these topicals may be effective in the treatment of photodamaged skin. A randomized, controlled, double-blinded study done by Mehta et al. studied the effects of a topical gel containing a mixture of over 110 growth factors, cytokines, and soluble matrix proteins in the treatment of facial photodamage, versus a vehicle gel applied twice daily.³⁴ After 3 months of therapy, a statistically significant reduction in fine lines and wrinkles were noted in the treatment group. Atkin et al. also conducted a similar trial in a 3 month, open-label, single center study using a serum containing multiple growth factors, cytokines, peptides, antioxidants, and depigmenting agents, and found a clinically significant reduction in fine and coarse wrinkles, along with improvements in skin texture, tone, and radiance.³⁵

Oresajo et al. observed the effects of a topical antioxidant mixture containing vitamin C, ferulic acid, and phloretin in a randomized-controlled clinical trial. Study participants applied the antioxidant preparation to one-half of the back and a vehicle control to the other. After exposing the patients to UV light, it was noted that the antioxidant-treated side had a higher minimal erythema dose, suggesting photoprotective effects of the antioxidant mixture.³⁶ Antioxidants alone are often marketed in over-the-counter skin care formulations. Due to their broad availability, they are further being explored for their effects on photodamage, wrinkles, and inflammation.³⁷

Other Therapies

There are a multitude of treatments available in the skin care industry that claim to improve the look of photodamaged skin; however only a few therapeutic agents actually have literature supporting their use. A single blinded study performed by Hussain et al. examined the effects of a manganese peptide complex applied twice daily for the treatment of photodamaged skin. At 12 weeks, both the individuals in the study and the blinded investigator noted

improvement in the signs of photodamage, most notably hyperpigmentation.³⁸

A randomized-controlled trial performed by Hsu et al. evaluated the effects of twice-daily application of a cream composed of green and white teas, mangosteen, and pomegranate extract. After 60 days, skin texture was improved, with notable reduction in pore size and roughness.³⁹

Wallo et al. performed a double-blind randomized-controlled trial that looked at the efficacy of a soy moisturizer for treating photodamaged skin. After 12 weeks of therapy, improvement was noted in mottled hyperpigmentation, blotchiness, dullness, fine lines, overall texture, skin tone, and overall appearance.⁴⁰

Future Trends

Niacin may have some role in future treatments of photodamaged skin. Niacin deficiency has been shown to cause photosensitivity in both animal models and human keratinocyte cell cultures, indicating that niacin may be involved in the pathway responsible for responding to UV damage.⁴¹ Further studies are needed to see its effect clinically.

Recently, the Liver X receptor (LXR) was found to be expressed in the skin and was considered to induce keratinocyte differentiation and improve epidermal barrier function.⁴² In vitro models have shown that targeting the LXR induces the expression of differentiation markers, ceramide biosynthesis enzymes, and lipid synthesis, therefore suggesting that LXR may be a novel target for developing therapies that target photodamage and skin aging.

Phosphocreatine is another potential therapy for photodamaged skin.⁴³ Retrospective reviews have revealed that phosphocreatine levels are elevated in burn victims and those with extensive skin necrolysis, and therefore is thought to aid in wound healing and skin remodeling. It has also been shown to protect the skin from UV damage. Given these findings, phosphocreatine may be a viable treatment option for photodamaged skin.

TABLE 41-1—Summary of Topical Treatments Reviewed

Drug	Dosage/Frequency	Level of Evidence	Strength of Recommendation
Rhytids and Lentigines			
Tretinoin (cream/gel)	0.02% and 0.05%/daily	1	A
Tretinoin micro sphere (gel)	0.1%/daily	1	B
Tazarotene (cream/gel)	0.1%/daily	1	A
Retinol moisturizer	0.1%/daily	1	A
Cytokine, growth factor, matrix protein gel	Unspecified/twice daily	1	B
Manganese peptide complex	Unspecified/twice daily	2	B

Drug	Dosage/Frequency	Level of Evidence	Strength of Recommendation
Combination Therapies:			
Copper Zinc malonate lotion	Twice daily	2	B
Hydroquinone cream Tretinoin cream	4%/twice daily Unspecified/daily		
Tazarotene cream Hydroquinone cream	0.1%/daily 4%/daily	1	B
Actinic keratoses			
Fluorouracil cream	5%/twice daily	2	A
Glycolic acid and fluorouracil	70% and 5%/weekly pulses	1	B
Jessner's solution and trichloroacetic acid peel	35%/one time	1	A
Overall texture and appearance			
Green and white tea, mangosteen, pomegranate extract	Unspecified/twice daily	1	B
Soy moisturizer	Unspecified/daily	1	B

What We Know: Topical Preparations

- Retinoids are the gold standard for topical treatment of photodamaged skin
- Retinols provide a less irritating but less effective alternative to retinoids
- Topical fluorouracil is effective in treating actinic keratoses and other manifestations of photodamage
- Topical preparations may effectively combine more than one active ingredient and usually include either a retinoid or retinol along with hydroquinone
- Growth factors have been shown to be effective in improving photodamage

obtained. Searches that are more specific were done using the search criteria “glycolic acid peels,” “Jessner’s solution peels,” “trichloracetic acid peels,” “salicylic acid peels,” “pyruvic acid peels,” and “phenol peels.” Studies that did not specifically address the changes associated with photodamage, such as acne and melasma treatment, were excluded. Only studies using the highest level of evidence to support the use of chemical peels in the treatment of photodamage were used.

Peeling agents are typically classified into very superficial, superficial, medium, and deep peels. The very superficial and superficial peels consist of the same peeling agents, with differing concentrations and treatment times based on the depth of peel desired. These agents include glycolic acid, lactic acid, lipohydroxy acid, pyruvic acid, resorcinol, salicylic acid, and Jessner’s solution (combination of lactic acid, salicylic acid, and resorcinol). Other combination peels are also commercially available. Trichloroacetic acid is the primary medium depth peeling agent. Deep peeling agents include Baker-Gordon phenol formula and phenol. The depth of chemical peeling can be judged by observing the change in color of the skin. The development of diffuse erythema in the treatment area indicates epidermal penetration. A white frost on the other hand indicates coagulative necrosis and thus penetration into the papillary dermis. A gray-white frost suggests that there is coagulative necrosis of the reticular dermis.⁴⁴ It should be noted that salicylic acid peels leave behind a white precipitate that is not the same as a true white frost. By having the ability to clinically observe treatment depths, the physician can easily tailor treatment based on each individual patient.

CHEMICAL PEELS

Chemical peels are another topical modality that helps to improve the appearance of photodamaged skin. There are numerous types of chemical peels available, each of which can help diminish the appearance of fine rhytids and lentigines. Depending on the depth of the pathology to be corrected and the type and concentration of peeling agent used, multiple treatments may be necessary to achieve the desired outcome, and treatment regimens are tailored to individual patients based on the depth of peel needed and their tolerance of the peeling agent.

In order to evaluate the efficacy of individual peeling agents, multiple PubMed searches were performed. Initially review articles discussing chemical peels were

Glycolic Acid

Glycolic acid peels have been used for years with successful outcomes in the treatment of photodamaged skin and other chronic conditions such as acne and melasma.

Glycolic acid is available in strengths ranging from 20-70% and different strengths are used depending on the condition being treated.⁴⁵ There are also numerous studies in the literature that support the use of glycolic acid peels as monotherapy and as a part of combination therapy for the treatment of photodamaged skin. Al Samahy et al. performed a histologic analysis of skin after treatment with a medium depth peel using 70% glycolic acid and 35% trichloroacetic acid. The study revealed decreased epidermal intracytoplasmic vacuoles, decreased elastic fibers, increased activated fibroblasts, and organized arrays of collagen fibrils.⁴⁶ These findings suggest that chemical peels, especially medium to deep peels, clinically and histologically can improve photodamaged skin through dermal remodeling. Kitzmiller et al. compared the effectiveness of multiple superficial peels using glycolic acid, versus one medium level peel with trichloroacetic acid, and showed that clinical outcomes are very similar; however, the superficial peels are better tolerated and often associated with less morbidity.⁴⁷

Recently, case reports have shown that patients with extensive histories of actinic keratoses and nonmelanoma skin cancer were successfully treated with 5-fluorouracil 0.5% cream in conjunction with glycolic acid peels.⁴⁸ A prospective, randomized-controlled study performed by Marrero et al. looked at the efficacy of 70% glycolic acid alone versus 70% glycolic acid and 5-fluorouracil (fluor-hydroxy therapy), applied in weekly pulse doses. This study also showed that actinic keratoses could be successfully treated with combination therapy. Patients were treated for 8 weeks total and post-treatment had a 92% clearance rate when combination therapy was used, in comparison to a 20% clearance rate when treated with glycolic acid alone.⁴⁹ In these cases, fluor-hydroxy pulse therapy offered a better clinical outcome by decreasing the morbidity associated with 5-fluorouracil monotherapy. The fluor-hydroxy pulse peel was also shown to be effective in the treatment of actinic porokeratosis.⁵⁰

Jessner's Solution

Jessner's solution is an alternative peeling treatment; however, upon review of the recent literature, it was noted to be most commonly referenced in combination with other agents. There are numerous studies that support the use of Jessner's solution in combination with varying strengths of trichloroacetic acid in order to achieve a medium depth peel. Combination therapy has been shown to be effective in the treatment of moderate rhytids and actinic keratoses.⁵¹ When compared with 5-fluorouracil monotherapy, combination therapy with Jessner's solution

and 35% trichloroacetic acid was found to be equally effective at treating actinic keratoses. Some patients preferred the one-time application of the chemical peel versus the twice daily application of 5-fluorouracil for several weeks. In noncompliant patients this may be an useful alternative treatment regimen.⁵²

Trichloroacetic Acid

Trichloroacetic acid peels can be used in concentrations up to 50% and can be used as either monotherapy or combination therapy. Techniques for use in monotherapy include the use of the Blue peel, which is a popular and widely utilized method.⁵³ The Blue peel allows the physician to more accurately control the depth of the peel achieved. By applying multiple coats of the Blue peel, and visually gauging the color changes with each coat, different treatment depths are achieved. A light blue color is suggestive of treatment in the papillary dermis, whereas a medium blue indicates treatment of the immediate upper reticular dermis. This allows for a more standardized approach to treatment, as trichloroacetic acid peels may be associated with higher morbidity when compared to other peeling agents.

Because trichloroacetic acid peels typically achieve a medium depth of peel, they are associated with longer healing times. Hevia et al. performed a randomized, double-blind, placebo-controlled study that showed healing times were significantly reduced after a 35% trichloroacetic acid peel if skin was pretreated with tretinoin 0.1% for two weeks.⁵⁴ Although healing times were reduced, there was no appreciable difference in cosmetic outcomes.

Salicylic Acid

Salicylic acid peels are typically used in 5-30% concentrations for the treatment of fine rhytids and dyschromia. A split face study performed by Oresajo et al. evaluating the clinical efficacy and tolerability of salicylic acid versus glycolic acid revealed similar clinical outcomes. A 5-10% salicylic acid peel was found to be just as safe and effective as a 20-50% glycolic acid peel.⁵⁵ It has also been suggested that a one-time application of 50% salicylic acid ointment, used after pretreatment with 20% trichloroacetic acid and tretinoin, is effective at treating lentigines and actinically damaged skin from the hands and forearms.⁵⁶

Pyruvic Acid

Pyruvic acid is an alpha-keto acid and is used as a medium chemical peeling agent. It has been used successfully in the treatment of rhytids, lentigines, and actinic keratoses. Prospective studies have shown that 50% pyruvic acid peels applied every 2 weeks, with four sessions on average,

produced significant improvement in the clinical appearance of photodamaged skin. Side effects were limited to erythema and stinging during the peeling procedure, with minimal discomfort reported in the post-peel period.^{57,58}

Phenol

Phenol is typically used to obtain a deep chemical peel. The use of this peel has decreased tremendously as laser and light devices have been developed that achieve similar results with fewer side effects. In skilled hands with careful patient selection, the phenol peel remains an effective means of treating disease processes that lie deeper in the dermis. It has also been suggested as an alternative treatment option for patients with numerous actinic keratoses. A prospective pilot trial performed by Kaminaka et al. evaluating 46 Japanese patients with actinic keratoses and Bowen's disease revealed that approximately 85% of patients were noted to clinically and histologically be clear of their actinic keratoses after 1 to 8 treatments with 100% phenol.⁵⁹

Side Effects

Superficial chemical peels can be used on all Fitzpatrick's skin types, and adverse outcomes are rare.⁶⁰ Patients must be carefully selected and warned about the development of erythema, irritation, and desquamation, which are normal and desired side effects of the peel. Medium and deep peels are associated with greater morbidity, healing time, and adverse outcomes such as scarring and dyspigmentation. Other postprocedure complications include an irritant contact dermatitis, secondary bacterial infection, and reactivation of the herpes simplex virus. In patients with a history of recurrent herpes labialis, prophylaxis with the appropriate antivirals should precede the chemical peel.⁶¹ Although toxic blood levels have never been shown after a phenol chemical peel, systemic absorption of phenol may be associated with cardiac toxicity, liver and kidney damage, and respiratory distress.⁶²

What We Know: Chemical Peels

- Several acids used for superficial and medium depth chemical peels are effective in treating photodamage, including glycolic acid, Jessner's solution, trichloroacetic acid, salicylic acid and pyruvic acid
- Deep chemical peels have largely been replaced by the use of laser and light devices and should only be used by experienced physicians
- Proper patient selection and physician experience are essential to minimize complications of medium and deep chemical peels

INJECTABLES

While topical treatments and chemical peels are good options for those patients who have dyspigmentation and superficial rhytides, more correction that is significant is needed to treat deeper rhytides. Injectables including botulinum toxin and injectable fillers are commonly used, and provide an alternative that is less invasive than surgery. The minimal invasion and the lack of downtime make injectables an attractive option for many patients.

Given the vast amount of literature available on botulinum toxin and injectable fillers, the goal of this summary was to focus on review articles published within the past 5 years discussing injectables. A review performed by Ogden et al. discusses the different types and uses of both botulinum toxin and injectable fillers.⁶³ Botulinum toxin is marketed as Botox[®] and more recently as Dysport[®] in the United States. One unit of Botox[®] is equivalent to 2.5-5.0 units of Dysport[®]. Botox[®] is primarily used to treat dynamic rhytids, which can be associated with both aging and photodamaged skin. The first large prospective, double-blinded, randomized, placebo-controlled trial was done in 2002 by Carruthers et al.⁶⁴ This study revealed that Botox[®] was effective at treating glabellar rhytids and that results were still visible 3 months after therapy. Adverse side effects were few and included headaches and blepharoptosis. Treatment doses vary depending on the area being treated and the individual patient. Crows feet have been treated successfully with a total dose of 6, 12, or 18 units per side.⁶⁵ Other studies have shown no clinical difference between 12 and 18 units.⁶⁶ Treatment of the glabellar area has been successful with 20-40 units of Botox[®] in females, and 40-80 units in males.^{67,68}

The first randomized-controlled trial examining Dysport[®] was performed in 2004 by Ascher et al.⁶⁹ These patients achieved softening of dynamic rhytids when treating the glabellar area. Fifty units of Dysport[®] was thought to be the adequate dose when treating glabellar rhytids, and headache was the most common side effect reported. Furthermore, a head-to-head comparison of Botox[®] and Dysport[®] was performed for the treatment of glabellar rhytids. Lowe et al. compared 20 units of Botox[®] with 50 units of Dysport[®] and found that at 12 weeks postinjection, the Botox[®] treatment group achieved a higher level of satisfaction with glabellar rhytid improvement. These results were also evident at 16 weeks postinjection.⁷⁰

There are a multitude of fillers available for the treatment of fine and coarse rhytids associated with photodamage and aging. Nonpermanent and biodegradable fillers include autologous fat, hyaluronic acid (Hyalform[®], Juvederm[®], Perlane[®], and Restylane[®]), and collagen products which have been taken off the market due to the superior performance of hyaluronic acid. Semipermanent and biodegradable fillers include calcium hydroxylapatite (Radiesse[®]), and poly-L-lactic acid (Sculptra/New Fill[®]). Semipermanent but nonbiodegradable fillers include polymethylmethacrylate micro spheres (PMMA) and collagen fillers (Artecoll/

Artefill® and Dermalive/Dermadeep®). The only permanent filler available is silicone, which is nonbiodegradable.¹ Fine rhytids are treated by injection of the filler intradermally; whereas deeper rhytids require injection in the deep dermis or subcutaneous space. All of the different fillers are effective at treating rhytids; the choice of which filler to use is shaped by patient needs and physician preferences.

Bovine collagen was available as Zyplast® or Zyderm® before being taken off the market in 2010. Zyderm® was used to treat superficial lines, whereas Zyplast® was used to treat deeper and coarser facial lines. Because the collagen is obtained from nonhuman sources, skin testing is required prior to therapy.⁶³ Adverse reactions included hypersensitivity, bruising, reactivation of latent herpes virus infection, and necrosis. Most cases of localized necrosis were reported in treatment of the glabellar area, therefore Zyplast® is not recommended for glabellar rhytids.⁷¹

Porcine collagen was another treatment option and was marketed as Evolence® before being discontinued. Porcine collagen has been associated with less hypersensitivity reactions than its bovine counterpart, however, not many studies have been done discussing its effectiveness.⁶³ Porcine collagen has been compared with Zyplast® and a small phase I clinical trial performed by Monstrey et al. revealed that porcine collagen may be more effective in improving wrinkle severity.⁷² Another study performed by Narins et al. comparing Evolence® and Restylane® showed no clinically significant difference in wrinkle severity.⁷³

Human collagen is no longer available but was marketed as Cosmoderm® and Cosmoplast®. Cosmoderm® was indicated for the treatment of fine and more superficial wrinkles, whereas Cosmoplast® was used for deeper wrinkles.⁶³ As this collagen was obtained from human sources, the incidence of hypersensitivity reactions was low. Cymetra® was another type of human collagen that typically required several treatments to obtain clinically evident results. A randomized trial done by Sclafani et al. compared the effects of Cymetra® (human collagen) with Zyplast® (bovine collagen) and found that measurable differences in the treatment of upper lip rhytids were significantly more prevalent in the Cymetra® treatment group.⁷⁴

Hyaluronic acid (Hyalform®, Juvederm®, Perlane®, and Restylane®) is a nonspecies-specific substance and therefore has a lower incidence of hypersensitivity reactions.⁶³ Restylane® and Juvederm®, have been compared to Zyplast® for the treatment of nasolabial folds in randomized-controlled trials. The study evaluating Restylane® was performed by Narins et al. Immediately following treatment, patients reported similar improvements in the wrinkle severity scale; however, at 6-month follow-up a higher proportion of patients reported improvement in the Restylane® treatment group.⁷⁵ Similarly, Pinsky et al. compared Juvederm Ultra® and Juvederm Ultra Plus® to Zyplast® in the treatment of nasolabial folds. Even after >9 months, 75% of the Juvederm Ultra® and 81% of the Juvederm Ultraplus® treatment areas maintained significant

correction, while the Zyplast® treatment areas did not. Side effects were comparable for the Juvederm® and Zyplast® products.⁷⁶ Hyaluronic acid fillers have also been shown to stimulate new collagen production in photodamaged skin.⁷⁷ Side effects from hyaluronic acid fillers are generally short lived and include edema, bruising, induration, and erythema.⁶³ There are reports of developing visible blue nodules with Restylane® if the filler is placed too superficially.⁷⁸ In these situations, hyaluronidase can be used to break up excessive or misplaced filler.

Polymethylmethacrylate microspheres (PMMA) are injected subdermally to treat coarse and deep rhytids. The microspheres may be suspended with bovine collagen (Artefill/Artecoll®) or hyaluronic acid (Dermalive®). Cohen et al. performed a randomized, multicenter clinical trial comparing the effectiveness of Artecoll® with bovine collagen. At 1-month follow-up, bovine collagen was found to be more effective at treating glabellar rhytids. However, at 3 and 6-month follow-up, Artecoll® was more effective at reducing the wrinkle severity in the nasolabial folds and the corners of the mouth.⁷⁹ Comparative studies for Dermalive® are lacking. PMMA fillers have been associated with nodular inflammatory reactions and granuloma formation.⁶³

Calcium hydroxylapatite (Radiesse®) is filler which is semipermanent and has been shown to have clinical results that last up to 1 year.⁶³ Comparative studies have been done looking at the effects of Radiesse® and Cosmoplast® (human collagen). Smith et al. performed a randomized, double-blind trial that showed significantly greater improvement of rhytids in the Radiesse® treatment group at both 3- and 6-month follow-up.⁸⁰ Side effects of Radiesse® include edema, erythema, and transient lumpiness. There have also been reports of submucosal nodule development, and therefore Radiesse® is oftentimes not recommended for lip augmentation.⁶³

What We Know: Injectables

- Botulinum toxin is useful in the treatment of dynamic rhytides
- Autologous fat, hyaluronic acid, calcium hydroxyapatite, poly-L-lactic acid, polymethyl methacrylate and collagen are all effective for improving the appearance of rhytides
- Selection of appropriate filler material is based on several factors, including location and depth of rhytides to be treated, desired duration of treatment effect and physician preference

LASERS, LIGHT SOURCES AND RADIOFREQUENCY DEVICES

The field of lasers, light sources, and radiofrequency devices has advanced rapidly in the last 20 years. Each

year there are new models introduced to the market, and many devices are appropriate for more than one indication. This section seeks to examine the best evidence for use of specific lasers, light devices, and radiofrequency devices for treatment of photodamage. In order to do so, the clinical manifestations of photodamage are separated here, with PubMed searches undertaken looking for randomized-clinical trials in the last 5 years, supporting the use of these modalities in addressing the individual manifestations of photodamage.

Treatment of Facial Telangiectasias

A wide variety of lasers and light sources are available to treat vascular lesions including facial telangiectasias from photodamage, erythema from rosacea, hemangiomas and port wine stains. Focusing on the relatively small caliber vessels that become evident, as part of photodamage, there are several devices that are used most commonly. Lasers in the 532-595 wavelength are popular choices because they effectively treat smaller, more superficial vessels with minimal bruising or down time. However, these wavelengths do not penetrate the skin deeply enough to treat larger, deeper vessels that the 940-1064 nm lasers can address. The long pulse dye 595 nm laser is a mainstay of treatment, while the pulsed KTP 532 nm, pulsed Nd:YAG 1064 nm, diode 800 nm, and pulsed alexandrite 755 nm are also frequently used.⁸¹

In order to compare laser and light treatments for facial telangiectasia, a PubMed search was conducted using the strategy (facial telangiectasia) AND (laser or light), and the search was limited to humans, randomized-controlled trials, English language publications in the last 5 years. This search revealed ten studies, four of which were omitted either because they did not compare efficacy of two treatments or because they limited their study to rosacea patients, when photodamage is the primary concern of this investigation.

Efficacy of IPL

Hedelund et al. evaluated 32 women in a split face RCT to demonstrate the efficacy of intense pulsed light (IPL) in the treatment of photodamage. Improvement in telangiectasia was one of several outcomes measured. Subjects received three IPL treatments to half of the face at 1 month intervals. The other half of the face received no treatment. Significant improvement in telangiectasia was demonstrated.⁸²

Comparison of LPDL and IPL

Nyman et al. evaluated 40 patients with facial telangiectasia in a randomized clinical trial with a split-face comparison of long-pulsed dye laser 595 nm and IPL, with single-blind evaluations. Patients received three treatments spaced 6 weeks apart, and evaluations were made 3 months after

completion of treatment. While both methods were effective in treating the telangiectasias and neither were associated with any adverse events in this study, excellent results (defined as 75% to 100% clearance of lesions) was noted in 46% of the LPDL group and 28% of the IPL group ($p=.01$). In addition, significantly fewer patients experienced pain with the LPDL, and 64% of patients preferred the LPDL while 21% preferred the IPL ($p<.001$).⁸³

Jorgensen et al. also conducted a study comparing LPDL 595 nm and IPL. This study included twenty patients who received three split-face treatments every 3 weeks. Outcomes were evaluated by the patient and by blinded evaluators at 1, 3, and 6 months. The LPDL achieved greater clearance of telangiectasias than IPL at 1, 3, and 6 months ($p\le .03$). In addition, pain scores were significantly higher for the IPL than for the LPDL ($p<.001$). No differences were noted in the efficacy of treating irregular pigmentation or skin texture, and neither was effective in reducing rhytides.⁸⁴

Comparison of Sequential Treatment with PDL 595 nm and Nd:YAG 1,064 nm to Each Treatment Alone

Karsai et al. compared sequential treatment of telangiectasias on the nose with PDL 595 nm and Nd:YAG 1,064 nm to treatment with PDL 595 nm alone and Nd:YAG 1,064 nm alone in a split-face design. Study participants received one treatment and were evaluated 4 weeks later by a blinded evaluator. The treatment group that received sequential treatment had greater improvement in lesions than did either group receiving single treatment ($p<.05$), and there was no difference in improvement between the single wavelength PDL 595 nm group and the Nd:YAG 1,064 nm group.⁸⁵

Comparison of Pulsed KTP 532 nm and PDL 595 nm

Uelehoer et al. compared the pulsed KTP 532 nm to the PDL 595 nm in a split face trial of 15 patients. Each was treated three times, and evaluated 3 weeks after treatment. The KTP laser was more effective, achieving 62% clearing after the first treatment and 85% 3 weeks after the third treatment, compared to 49% and 75% for the PDL. In terms of adverse events, the PDL had a more favorable profile. Seventy-nine percent of the KTP treatment group had swelling more than 1 day after treatment versus 71% of the PDL group, and 58% noted more erythema on the KTP side compared to 8% on the PDL side.⁸⁶

Comparison of IPL and AFT

Braun conducted a study with eight subjects who received split-face treatments with IPL and with fluorescent-pulsed

light, advanced fluorescent technology (AFT). Each subject received 3 to 5 treatments, three weeks apart. No differences were seen in efficacy of treating telangiectasia, dyspigmentation, or skin texture, and there were no adverse events noted in either treatment group.¹¹²

Comparison of 532 nm and 940 nm Diode

Tierney et al. conducted an RCT comparing 532 nm and 940 nm diode lasers for treatment of facial telangiectasias. Twenty-four treatment sites received two treatments and were evaluated for efficacy and for side effects 2 months after treatment. The 940 nm laser treatment sites achieved a mean clearance of 63%, while the 532 nm treatment sites achieved a mean clearance of 47.8% ($p < .05$). The two lasers were equally effective in treating smaller caliber vessels, but the 940 nm laser was superior in treating the larger vessels. In addition, pain and post-treatment erythema were significantly less in the 940 nm group, and significant crusting and swelling was only noted in the 532 nm group.¹¹³

In summary, IPL has been demonstrated to be effective in treating facial telangiectasia, with AFT showing equal efficacy. PDL 595 is more effective than IPL, and causes less pain. PDL 595 nm and Nd:YAG 1064 nm show similar efficacy, but sequential treatment with PDL 595 nm and Nd:YAG 1,064 nm is more effective than either treatment alone. Finally, KTP 532 nm is more effective than PDL 595 nm but has greater side effects.

Pigmentation

Dyspigmentation is a common feature of photodamage. Ephelides, lentigos, and mottled pigmentation are often

noted in chronically sun-exposed skin, and are usually displeasing to patients. Several lasers and light devices can be used to treat the dyspigmentation of photodamage. This section seeks to review recent studies these modalities.

A PubMed search was conducted using the following search strategy: (photodamage OR lentigo OR dyschromia) NOT (vitiligo OR melasma or acne) AND (laser OR light). The search was limited to randomized-controlled trials involving humans published in English in the last 5 years. This revealed 29 studies. This search was further limited by excluding studies that involved diseases other than photodamage, such as skin cancer, dermatosis papulosa nigra, and hemangiomas. It also excluded studies that did not have a laser or light sources as at least one of its treatment groups, studies that evaluated adjunctive therapies and techniques such as hydroquinone pretreatment and the use of cooling, and studies that did not measure dyschromia as one of the outcome measures. This limited the number of studies reviewed to ten.

Several lasers and devices have been studied recently for the treatment of facial pigmentation. This includes various long-pulsed Nd:YAG lasers, long-pulsed dye lasers, the Er:YAG laser, the KTP 532 laser, and intense pulsed light (IPL). Most of the studies comparing two treatment modalities reported good results with both, and no significant difference in efficacy between the treatments, as demonstrated in Table 41-2. It is important to note, however that many of these studies had other outcome parameters where significant differences were noted.

Dover et al. compared IPL with topical 5-aminolevulinic acid (5-ALA) to IPL alone in a split-face study of 20 subjects. Four treatments were administered 3 weeks apart. The first two treatments consisted of IPL preceded by 5-ALA or IPL alone. The second two treatments were IPL alone to the whole face. More improvement was noted

TABLE 41-2—Studies Comparing Treatments for Dyspigmentation with no Significant Difference in Efficacy

First Author	Year	Treatments Compared	N	Study Design	
Geraghty LN	2009	1,440 nm Nd:YAG fractional laser	1,320/1,440-nm multiplex Nd:YAG fractional laser	20	2 treatment arms
Jorgensen GF	2008	LPDL	IPL	10	Split Face
Galeckas KJ	2008	PDL with a compression handpiece	IPL	10	Split Face
Hantash BM	2008	Er:YAG	IPL	10	2 treatment arms
Braun M	2007	IPL	AFT		Split Face
Mezzana P	2008	IPL	IPL+low intensity diode+topical agents	100	2 treatment arms, patients matched for age, skin type and degree of damage
Butler EG 2 nd	2006	KTP 532 nm	IPL	17	Split Face

in the pretreatment side in the global photoaging score as well as treatment of fine lines and mottled pigmentation.⁸⁹ In a different study, Ruiz-Rodriquez et al. demonstrated no effect a red light device using either 1 hour or 3 hour pretreatment with 5-methyl aminolevulinate.⁹⁰ Li et al. demonstrated the efficacy of IPL on Asian skin.⁹¹

Skin Laxity

A PubMed search using the strategy (skin laxity) and (laser or radiofrequency), limited to controlled trials, humans and English language publications yielded 25 journal articles. Studies that did not measure laxity as an outcome were excluded. In addition, studies that were conducted on body skin or only on periocular facial skin were also excluded since the laxity evaluated was unlikely to involve a component of photodamage. The eight remaining studies were reviewed.

Four studies evaluated the effectiveness of different radiofrequency devices in treating facial skin laxity. Bogle et al. utilized a monopolar radiofrequency device with multiple passes on 66 subjects with moderate laxity of the lower face and neck. 92% had measurable improvement in overall appearance at 6 months, and 84% had improvement as measured by independent photographic review.⁹² Friedman and Gilead demonstrated the efficacy of a hybrid radiofrequency device for treating rhytides and lax skin on sixteen subjects, each of whom received between two and six treatments at 2 to 3 week intervals. Over half of patients noted significant or excellent improvement in laxity in the cheek and jowl areas.⁹³ Alexiades-Armenakas et al. compared unipolar versus bipolar radiofrequency devices for the treatment of laxity and rhytides. Ten subjects each received multiple passes per treatment at 1 week intervals for 4 weeks total. Both showed improvements in laxity and rhytides but the results were not statistically significant. This could be because of the small size of the study.⁹⁴ In a more recent study, Alexiades-Armenakas compared a fractional radiofrequency device to surgical face-lift for the treatment of skin laxity. The FRF device provided 16% improvement in skin laxity, which was statistically significant. Not surprisingly, the face-lift provided a greater improvement, with an average of 49% improvement in laxity.⁹⁵ These studies suggest that radiofrequency devices offer an effective alternative to traditional surgery for the treatment of skin laxity, although the results are more modest than the more invasive gold standard.

While the majority of recent studies evaluate radiofrequency devices for the treatment of skin laxity, Goldberg et al. Chan et al. and Alexiades-Armenakas have each conducted studies demonstrating efficacy of infrared devices in improving facial skin laxity.⁹⁶⁻⁹⁸ Alexiades-Armenakas has also demonstrated significant improvement in facial laxity using a 1310 nm near-infrared laser with sapphire contact cooling.⁹⁹

Rhytides

Rhytides are the most troubling part of photoaging for many patients. In order to evaluate recent advances in the use of lasers and light devices, a search was performed using the strategy (rhytides OR fine wrinkles) AND (laser or light or radiofrequency). Limits included randomized-controlled trials, humans, English language, and studies published in the last 5 years. This search revealed seventeen studies, eight of which were excluded because either they did not use rhytides as an outcome measure or because they did not use a laser, light or radiofrequency device as a treatment arm. Nine studies remained and are reviewed here.

Four studies demonstrated efficacy of specific treatments in reducing rhytides. Dual depth fractional carbon dioxide laser, 1310-nm wavelength laser with surface cooling, fractional resurfacing followed by PDT with 5-ALA and red light, and 5-ALA combined with IPL were all effective methods.^{89,99-101} In a study by Karsai et al. ablative fractional CO₂ and ablative fractional Er:YAG were equally effective in treating periorbital rhytides.¹⁰² In a study by Hantash et al. no difference was noted in the efficacy of Er:YAG versus IPL for treatment of rhytides.¹⁰³

Two studies did not yield statistically significant improvement in rhytides. In a study by Alexiades-Armenakas et al. radiofrequency did not demonstrate improvement in rhytides either with unipolar or bipolar handpieces, though a trend toward improvement was noted.⁹⁴ In a study by Jorgensen et al. neither LPDL nor IPL demonstrated reduction of rhytides, although they were effective in treating pigmentation and telangiectasia as noted previously.¹⁰⁴

One study in recent years has demonstrated superiority of one method over another in the treatment of rhytides. Hedelund et al. compared CO₂ laser treatment to IPL treatment in a study of 27 women randomized to one of the two treatment groups. The patients treated with the CO₂ laser had greater reduction of their rhytides, but also had more side effects.¹⁰⁵

CONCLUSIONS

Ultimately, the physician uses the best available scientific evidence combined with experience and professional judgment to make suggestions to patients regarding disease prevention and treatment options. Photodamage is no exception. While there is strong evidence for the effectiveness of many methods of photodamage prevention and treatment, every good study leaves the reader, and undoubtedly the authors, with additional research questions left to be addressed. However, the unanswered questions do not prevent one from drawing conclusions based on the evidence available.

As with any medical condition, prevention of photodamage should be the primary goal, with appropriate treatment modalities being implemented when needed.

What We Know: Lasers, Light Sources and Radiofrequency Devices

Facial Telangiectasias

- LPDL is more effective than IPL
- Sequential treatment with PDL 595 nm and Nd:YAG 1,064 nm is more effective than either treatment alone
- KTP 532 nm is more effective than PDL 595 nm, but also has a less favorable profile of side effects
- No differences in efficacy are seen between IPL and AFT
- Diode 940 nm is more effective and has less fewer side effects than diode 532 nm

Pigmentation

- Nd:YAG 1440 nm, PDL, IPL, Er:YAG and AFT are all effective for treating dyspigmentation

Laxity

- Radiofrequency devices and infrared devices have been demonstrated to improve skin laxity
- Surgical face-lift remains the gold standard for treatment of skin laxity

Rhytides

- Fractional carbon dioxide laser, 1310-nm wavelength laser with surface cooling, fractional resurfacing followed by PDT, 5-ALA with IPL and ablative fractional Er:YAG, are all effective
- Neither radiofrequency nor LPDL were demonstrated to reduce rhytides
- Conflicting data exists regarding the effectiveness of IPL

Evidence suggests that photodamage can, in fact, be prevented. Certainly, clothing provides an obvious first layer of protection from the sun. Improved education of patients regarding the types of fabrics to look for, helping them to understand the meaning of UPF, and even guiding them to specific brands at the discretion of the individual physician are all ways that physicians can help patients improve the usefulness of their clothing. However, while there are good studies documenting the UPF of various clothing, more studies are needed to specifically address the effectiveness of clothing in preventing photodamage. Because of the variable amount of protection provided by different types of clothing, and because even with the best clothing many areas of the body remain sun-exposed, sunscreens remain the most important tool in the arsenal to protect against photodamage, with strong evidence of their effectiveness, particularly in preventing skin cancers. The patient is often overwhelmed by the array of products available, and the physician can be helpful in providing guidance regarding the most appropriate ingredients and formulations to meet the individual's needs and to address their specific risks. The use of oral and topical antioxidants is often appealing to patients and is certainly appropriate as a compliment to traditional photoprotective measures.

For patients with mild to moderate photodamage, and for those who are not interested in more aggressive forms of treatment, there is strong evidence for the use of a topical regimen to reduce the signs of photoaging. Topical retinoids, alone or in combination, are the cornerstone of a topical regimen. Depending on the level of patient compliance and whether additional treatments are necessary or will be tolerated by the patient, growth factors, antioxidants or other treatments can be added. Superficial or medium depth chemical peels can be added for patients

with more photodamage, patients looking for faster results, and patients who do not comply well with daily skin care routines. There is strong evidence for the effectiveness of several different peeling agents and the selection of the agent is generally based on desired outcomes, patient parameters and physician preferences. In general, it is recommended that patients undergoing chemical peels be started on topical retinoids first to enhance the penetration of the peels.

Moderate to severe photodamage often requires correction that is more aggressive. The appearance of deep wrinkles results not only from photoaging, but also from facial expression and chronologic aging. Evidence confirms that these lines can effectively be treated with injectable botulinum toxin and fillers, although much of the published data does not focus on photodamage specifically since they address the more cosmetic aspect of photodamage. With proper patient and product selection and a well-trained administrator, these products can achieve natural-looking results.

The field of lasers, light sources and radiofrequency devices is one that is perhaps most difficult to address using strict evidence-based measures. There is certainly strong evidence for the effectiveness of several treatment devices. However, comparing devices to determine what is "best" is difficult. The research available often uses different methods of evaluation for different clinical parameters, making direct comparison of studies difficult. In addition, each device may address several treatment indications, but no one device does all things equally well. Ultimately, there are many factors that are considered as the individual physician outlines a treatment plan for a specific patient. The patients' skin type, treatment indications, tolerance for side effects and expectations, as well as the modalities available to the physician and his or her experience level are some of the considerations that must be made.

Chemoprevention of Skin Cancer

Brittney DeClerck, M.D., Nicole Mau, M.D., and David Peng, M.D.

INTRODUCTION

Although sun safety and sunscreen have been promoted since the 1940s, studies have shown insufficient implementation and efficacy of these measures.¹⁻³ Dermatologists have subsequently been faced with an increasing incidence of skin cancer worldwide and a large cohort of high-risk patients with irreversible histories of significant sun damage.^{4,5} In the United States, skin cancer is more common than all other cancers combined. Over 100,000 new cases of melanoma and over 1 million new cases of nonmelanoma skin cancer (NMSC), such as squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), were expected to occur in 2008.^{6,7} Both types of skin cancer are commonly associated with significant morbidity and high healthcare costs. NMSC is the fifth most costly cancer within the Medicare population with an annual cost of \$650 million per year.⁸ Additionally, mortality becomes a realistic threat for melanoma and advanced NMSC. Patients with malignant melanoma have a median survival of 6-8 months and <5% will survive for 5 years or more.⁹ Over 8,000 melanoma-related deaths were expected to occur in 2008.¹⁰ Thus, it is imperative that new prevention strategies continue to be developed.

Chemoprevention is a pharmacologic intervention that prevents, arrests, or reverses carcinogenesis.¹¹ Primary chemoprevention prevents initial carcinogenesis, secondary chemoprevention prevents premalignant cancers from becoming malignant, and tertiary chemoprevention prevents cancer recurrence in patients with no further signs of disease. Chemoprevention is particularly important for high-risk patients.^{12,13} Examples of chemopreventative agents used for other types of cancers include tamoxifen for breast cancer, finasteride for prostate cancer, and nonsteroidal anti-inflammatory drugs (NSAIDs) for colon cancer. An example of a chemopreventative agent used in dermatology is diclofenac, a NSAID, to prevent actinic keratoses from progressing to invasive SCC.¹⁴⁻¹⁸

The potential of skin cancer chemoprevention has been increasing over the past three decades because of better understanding of the molecular pathways leading to skin cancer.¹⁹ For all types of cancer, carcinogenesis involves

genome destabilization with various alterations in genes responsible for cell-cycle regulation, checkpoint regulation, detoxification of carcinogens, DNA repair, proto-oncogenes, and tumor suppressor genes.²⁰⁻²¹ Within this framework, however, it is now well-known that SCC, BCC, and melanoma have multiple, distinct, and sometimes overlapping molecular pathways of carcinogenesis.

SCC carcinogenesis appears to depend primarily upon p53 gene mutations in keratinocytes, since 90% of sunlight induced SCCs have cytosine-thymine transition mutations in this gene.²²⁻²⁴ Mutations in the Ras proto-oncogene, the epidermal growth factor (EGF) gene, the nuclear factor KB (NFKB) gene, the extracellular signal-regulated kinase (ERK) gene, and the cyclin-dependant kinase inhibitor gene may also contribute to SCC carcinogenesis.^{25,26} Additionally, SCC tumorigenesis has been associated with cyto-oxygenase (COX) overexpression.^{27,28}

Basal cell carcinoma carcinogenesis also appears to be associated with p53 mutations in keratinocytes, because over 56% of sunlight-induced BCCs have mutations in this gene.^{29,30} However, this is clearly not the only mutation causing BCC because greater than 33% of sporadic BCCs have patched protein transmembrane receptor (PTC) tumor suppressor gene mutations.³¹ Furthermore, mutations in the PTC tumor suppressor gene are known to cause the rare and inherited nevoid basal cell carcinoma syndrome (NBCCS), which is characterized by a propensity for multiple BCCs. Additionally, studies have shown deregulation of the hedgehog pathway in a large proportion of sporadic BCCs.³²

Melanoma carcinogenesis appears to be associated with p16 tumor suppressor gene (also known as CDKN2A or INK4A) mutations in melanocytes, since up to 40% of hereditary melanomas have mutations in this gene. Mutations in the p16 tumor suppressor gene also occur in a significant proportion of sporadic melanomas.^{33,34} Other genes which may play an important role in melanoma carcinogenesis include p53, PTEN, and mdm2.^{28,29} Additionally, studies have shown inappropriate activation of the MAP kinase pathway with subsequent overproduction of endothelial growth factor (VEGF) and matrix metalloproteinases (MMPs) in melanoma carcinogenesis.³⁵

Many distinct SCC, BCC, and melanoma carcinogenesis pathways overlap by sharing common mutations, like the p53 mutation. For this reason, processes or molecules upstream or downstream of these common mutations can serve as targets for combined SCC, BCC, and melanoma chemoprevention. Such targets include polyamine or prostaglandin synthesis, retinoid receptors, and components of the Ras and MAP kinase-signaling pathway.³⁶

Examples of potentially chemopreventative agents that exploit these targets include retinoids, 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors, cyclooxygenase (COX) inhibitors, difluoromethylornithine (DFMO), vaccines, and botanicals such as tea polyphenols, apigenin, ginger, curcumin, grape seed proanthocyanidins, and resveratrol. Retinoids have long been known to regulate epithelial differentiation. However, recent studies have shown that retinoids alter a variety of pathways involved in the later stages of carcinogenesis. The HMG-CoA reductase inhibitors, also known as the statin class of lipid-lowering agents, are thought to disrupt angiogenesis and the isoprenylation of the Ras and Rho small GTPases. COX inhibitors are well known anti-inflammatory and analgesic agents that have recently gained support as chemopreventive agents against colorectal, bladder, and skin cancers. Recent studies have shown that childhood vaccines may reduce melanoma incidence and mortality by stimulating immune responses to cancerous and precancerous melanoma cells. Difluoromethylornithine, an ornithine decarboxylase inhibitor is an old compound that has gained recent support as a chemopreventive agent. Botanicals have also shown promise in the prevention of ultra violet (UV) radiation-induced skin damage and cancer. This review article will explore the above topics with emphasis on the most recent chemoprevention studies.

RETINOIDS

Retinoids are defined as natural or synthetic molecules with structural or functional similarities to Vitamin A (retinol). Natural retinoids include and retinoic acid (RA) and retinol itself, which the body derives from dietary retinyl palmitate, retinyl acetate, or carotenoids in animal products, supplements, or vegetables. Synthetic retinoids include tretinoin (Retin A or all-*trans* retinoic acid), isotretinoin (Accutane or 13-*cis* retinoic acid), alitretinoin (Panretin or 9-*cis*-retinoic acid), acitretin (Soriatane),

etretinate (Tegison), tazarotene (Tazorac), bexarotene (Targretin), and adapalene (Differin).

The correlation between Vitamin A deficiency and squamous metaplasia was first described in 1925.³⁷ That same year, vitamin A-deficient animal models were shown to have higher rates of gastric carcinoma.³⁸ Eight years later, vitamin A administration was shown to reverse epithelial metaplasia.³⁹ The resultant theory that retinoids could be used as chemopreventive agents gained support with further investigations regarding how retinoids affect cellular function. It is now known that retinoids modulate cellular differentiation, G1 cell cycle arrest, and apoptosis by binding nuclear receptors affecting growth factors, caspases, signal transduction molecules, and extracellular adhesion molecules (Figure 42-1).⁴⁰⁻⁴⁶ The exact mechanism by which retinoids decrease cancer incidence, however, remains unclear. Japanese studies have proposed retinoid-induced reductions in COX-2 and PGE2 as a potential mechanism, as COX-2 and PGE2 are constitutively expressed in skin cancer cells.⁴⁷ Austrian studies have proposed retinoid-induced increases in p53 and caspases as a potential mechanism as p53 and caspases promote apoptosis.⁴⁸ An American study has proposed retinoid-induced gap junction inhibition as a potential mechanism, as gap junctions are utilized in growth related cellular communication.⁴⁹ Still other studies have proposed retinoid-induced activator protein-1 (AP-1) inhibition as a potential mechanism, as AP-1 is a transcription factor for many growth-related proteins.^{50,51} More recently, microarray studies have proposed retinoid-induced inhibition the Raf/Mek/Erk branch of the MAP kinase pathway as a potential mechanism, as the MAP kinase pathway promotes mitosis.⁵² Thus, it is possible that retinoids may have multiple mechanisms of skin cancer chemoprevention.

Oral Natural Retinoids

Conflicting or insufficient data exists regarding the value of oral natural retinoids as chemopreventive agents. In animal models, oral retinyl palmitate was shown to decrease chemical and UV-induced tumor burden.^{53,54} In another animal model, oral retinyl acetate was shown to reverse epidermal hyperplasia, papilloma, and dysplasia, but not SCC in situ or SCC.⁵⁵ In human patients, however, limited data exists. Only one study has indicated that oral retinyl palmitate increased human RA serum concentrations.⁵⁶

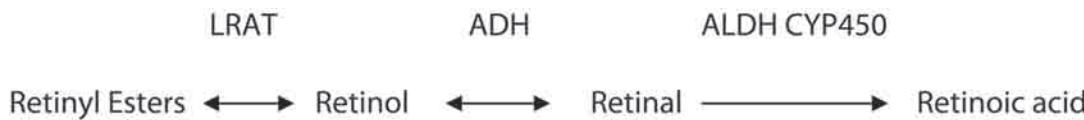

FIGURE 42-1 The retinoids; LRAT = lecithin retinol acyl transferase; ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; (DeLuca)

More evidence is thus needed before recommendations can be made regarding oral retinyl palmitate or retinyl acetate as chemopreventive agents.

In animal and *in vitro* models, oral carotenoids have been shown to prevent UV-induced cutaneous erythema, immunosuppression, and carcinogenesis.^{57,58} Similarly, in human patients with erythropoietic protoporphyria, oral carotenoids have been shown to decrease photosensitivity.⁵⁹ Nevertheless, the chemopreventive value of oral carotenoids in patients with normal skin is controversial. Although several randomized clinical studies involving patients with normal skin have shown oral carotenoids to decrease UV-induced erythema, many well-powered studies involving such patients have not shown oral carotenoids to decrease the risk of skin cancer.^{60–68} Furthermore, several clinical studies have demonstrated a positive correlation between oral carotenoids (lutein, zeaxanthin, and beta-cryptoxanthin) and SCC.⁶⁹ These results were consistent with *in vitro* studies showing carotenoids to have prooxidant effects.^{70–72} Beta carotene-treated murine models had increased incidences of DMBA and TPA-induced papillomas, but decreased incidences of papilloma transformation into carcinoma.⁷³ Consequently, more evidence is needed before recommendations can be made regarding oral carotenoids as chemopreventive agents.

A randomized-controlled trial of 2297 moderate-risk patients reported that 25,000 IU of oral retinol was effective in preventing squamous cell carcinoma (SCC), but not basal cell carcinoma (BCC).⁷⁴ Individuals treated with oral retinol were 74% (HR 0.74, 95% CI = 0.56–0.99, P = 0.04) as likely to develop a new SCC compared to placebo with a 5-year follow-up period. Another randomized-controlled trial of 525 subjects did not demonstrate a significant difference between placebo and treatment with 25,000 IU oral retinol.⁷⁵ The follow-up period of this study was shorter, however, and could account for the difference in results. Furthermore, this study enrolled only 525 subjects compared with the 2297 subjects examined in the previous study. Based on these results, it is clear that further investigation is warranted in the evaluation of oral natural retinoids as chemopreventive agents.

Oral and Topical Synthetic Retinoids

Unlike natural retinoids, oral and topical synthetic retinoids have been proven as effective chemopreventive agents for high-risk patient groups by a significant number of studies. These high-risk patient groups include xeroderma pigmentosum (XP) patients, NBCCS patients, organ transplant recipients (OTRs), and recessive dystrophic epidermolysis bullosa (RDEB) patients.

Xeroderma pigmentosum patients are ideal chemoprevention candidates caused by a DNA repair enzyme defect, which places them at a 1000-fold increased risk of

skin cancer compared to the general population. A controlled, prospective study of five XP patients showed a 63% decrease in tumor incidence with 2 mg/kg oral isotretinoin treatment for 2 years.⁷⁶ However, in the 1 year following treatment cessation, the incidence of skin tumors rapidly increased 8.5-fold. This decreased effect without active treatment suggests that oral isotretinoin does not correct underlying DNA repair defects but, rather, acts later in the multistep carcinogenesis pathway.

Nevoid basal cell carcinoma syndrome patients are ideal chemoprevention candidates because of a tumor suppressor gene defect, which predisposes them to multiple BCCs.⁷⁷ Two case reports have demonstrated a marked response of NBCCS patients to oral etretinate at 1 mg/kg/day and oral isotretinoin at 0.4 mg/kg/day respectively.^{78,79} Oral isotretinoin at 0.2 mg/kg/day was reported to be much less effective than 0.4 mg/kg/day.⁸⁰ Two additional case reports showed that NBCCS patients treated with oral retinoids experienced a reduction in tumor burden and incidence during active treatment.^{81,82} Additionally, these patients developed less aggressive tumors that were more amenable to surgical treatment even after cessation of retinoid therapy. Peck et al. described a significant chemoprotective effect with lower doses of oral isotretinoin (0.25 to 1.5 mg/kg/day) in a study including non-NBCCS patients with multiple BCCs.⁸³ It is important to note, however, that this result may have been caused by the involvement of non-NBCCS patients. Thus, there is convincing evidence supporting the chemoprotective effect of oral synthetic retinoids in NBCCS patients.

Organ transplant recipients are ideal chemoprevention candidates because of immunosuppressive regimens resulting in significantly elevated incidences of significantly more aggressive skin cancers.^{84–87} A study of 455 Australian heart transplant recipients showed the overall incidence of skin cancer to be 31% at 5 years and 43% at 10 years.⁸⁸ Furthermore, skin cancer was the cause of 27% of deaths after 4 years of follow-up. Studies investigating oral retinoids in OTRs initially used etretinate and later used acitretin. In the 1990s, four noncontrolled studies of oral etretinate in OTRs showed a dramatic decrease in SCC incidence compared to before treatment.^{89–92} Five noncontrolled studies of oral acitretin in OTRs showed a dramatic decrease in SCC incidence compared to before treatment.^{93–97} Two, subsequent, randomized, controlled studies of oral acitretin in OTRs showed a statistically significant decrease in skin cancer incidence compared to the control group. The oral acitretin dosages used in these studies were 30 mg acitretin/day for 6 months and 25 mg/day for 2 years, respectively.^{98,99} A third randomized-controlled study of oral acitretin in OTRs showed a statistically significant decrease in actinic keratosis incidence, but not in skin cancer incidence.¹⁰⁰ Thus far, no studies have compared oral etretinate to oral acitretin. However, today it seems the chemopreventive

retinoids of choice are oral acitretin and oral isotretinoin. A recent survey of 28 dermatologists experienced in managing OTRs indicated that, of the 80% using chemopreventive retinoids for OTRs, 88% used primarily oral acitretin and 12% used both oral acitretin and oral isotretinoin.¹⁰¹ In 2004, De Graaf et al. published a comprehensive review of both oral and topical retinoid skin cancer chemoprevention for OTRs.¹⁰² Two randomized-controlled trials using 0.05% topical tretinoin daily and 0.3% topical adapalene daily both reported a significant reduction in actinic keratoses after 3 and 6 months, respectively.^{103,104} These findings support the recommendation that synthetic retinoids should be routinely used to prevent skin cancer in OTRs.

Recessive dystrophic epidermolysis bullosa patients are ideal chemoprevention candidates caused by chronic blistering and ulceration resulting in significantly elevated incidences of significantly more aggressive SCCs.¹⁰⁵ Approximately 85% of RDEB patients develop a SCC by the age of 45 and most die within 5 years of this first SCC.^{106,107} Only one, phase-1, clinical trial involving 20 RDEB patients on 0.5 mg/kg/day oral isotretinoin for 8 months has been performed to date.¹⁰⁸ This trial showed the studied dose of isotretinoin to be safe and well tolerated in RDEB patients. Although there were theoretic concerns that retinoids would exacerbate RDEB skin fragility, this side effect was shown to be transient, resolving without any decreases in isotretinoin dose. Additionally, some of the study participants reported reduced blister formation while receiving 0.1-0.2 mg/kg/day of oral isotretinoin. Further investigation is thus warranted regarding the chemopreventive efficacy of retinoids for RDEB patients.

Some of the aforementioned chemoprevention studies maintain patients on high dose oral retinoids for a significant amount of time. It is well documented that this practice can lead to numerous problems. In particular, hyperostosis, elevations in serum lipids, liver toxicity, teratogenicity, ocular effects, and depression are just a few of the serious side effects that may arise with long-term systemic retinoid therapy. In regard to topical retinoid use, the most common side effects are skin irritation and dryness. The recent Veterans Affairs Topical Tretinoin Chemoprevention Trial (VATTC) had to be discontinued because of elevated mortality in the tretinoin-treated group even after controlling for age, comorbidities, and smoking status. The authors, however, did not infer a causal link between topical tretinoin and death as a result of current evidence suggesting this to be unlikely.¹⁰⁹ There are several comprehensive reviews on the topic of adverse effects related to retinoids in the literature.¹¹⁰⁻¹⁶ Thus, this topic will not be fully explored in this article. It is imperative, however, that the risks and benefits of systemic retinoid therapy as chemoprevention of skin cancer are weighed carefully before beginning therapy. Although chemopreventive therapy with a potentially toxic agent may be justifiable in high-risk groups, it is difficult to justify use

in the general population or in patients at moderate risk for skin cancer.

HMG-CoA REDUCTASE INHIBITORS

HMG-CoA reductase inhibitors, otherwise known as statins, inhibit the rate-limiting enzyme of the cholesterol-producing mevalonate pathway (Figure 42-2).¹¹⁷ Because of their known efficacy in lowering cholesterol and their limited side effect profiles, statins are among the most commonly prescribed medications worldwide and are distributed without prescription in the UK.

Examples include lovastatin (Mevacor), simvastatin (Zocor), and atorvastatin (Lipitor).

A significant number of in vitro and animal studies have suggested mevalonate pathway inhibition to also result in skin cancer prevention (Table 42-1). For example, lovastatin and simvastatin have been shown to exhibit dose-dependent cytostatic and cytotoxic effects reversible with mevalonic acid addition.¹¹⁸ More specifically, these drugs are thought to prevent skin cancer by preventing the mevalonate pathway from producing farnesyl pyrophosphate and geranyl pyrophosphate (Figure 42-2).¹¹⁹ Farnesyl pyrophosphate activates Ras GTPases, which can promote cell cycle progression and subsequently neoplastic pathogenesis.¹²⁰⁻¹²³ Geranyl pyrophosphate activates Rho GTPases, which can promote cytoskeletal modifications and cell cycle progression via cyclin-dependant kinase inhibitor breakdown. These Rho GTPase functions can subsequently promote neoplastic pathogenesis and neoplastic invasion.¹²⁴⁻¹²⁶ In the 1990s it was suggested that decreased farnesyl pyrophosphate production was the main mechanism behind lovastatin's ability to induce G1 and G2 cell cycle arrest, reduce angiogenesis, and promote TNF-alpha antitumor activity.¹²⁷⁻¹²⁹ However, it has been more recently suggested that decreased geranyl pyrophosphate production plays a larger chemopreventive role. Studies demonstrating lovastatin's cytostatic effects showed these effects to be more compromised by geranyl pyrophosphate addition than farnesyl pyrophosphate addition.^{130,131} A 2004 study demonstrated simvastatin to convert drug-resistant multiple myeloma into drug-susceptible multiple myeloma via decreased Rho GTPase activation.¹³² Most recently, studies have shown decreased Rho GTPase-mediated CDK inhibitor breakdown and subsequently increased CDK inhibitor levels to be associated with G1 cell cycle arrest.^{133,134} Regarding metastasis prevention, studies have also shown Rho GTPase-deficient skin cancer cells to be unable to metastasize and Rho GTPase-negative animals to be less susceptible to skin cancer metastasis.^{135,136} Atorvastatin has been additionally been shown to decrease human melanoma metastasis in vitro and murine melanoma metastasis in vivo.¹³⁷

In vivo human studies, however, have produced varying results. A Cochrane review in 2005 showed no significant

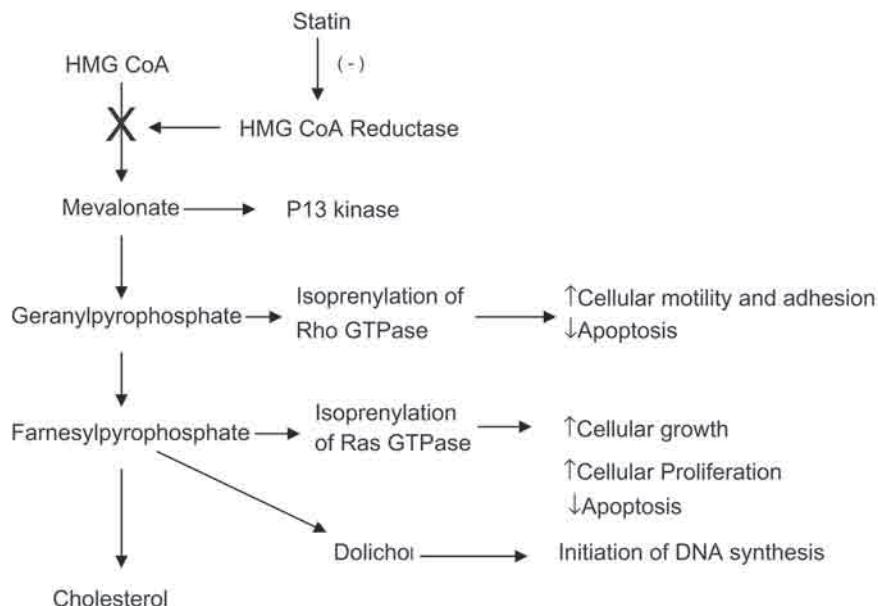

FIGURE 42-2 Pathway Inhibited by Statins

reductions in melanoma incidence and two meta-analyses in 2006 showed no significant reductions in general cancer incidence or mortality.^{138–140} Additionally, two large cohort studies in 2009 showed no significant reductions in BCC or keratinocyte carcinoma incidences.^{141,142} To date, the most convincing evidence regarding the chemoprotective properties of statins comes from cardiovascular studies. In a large, double-blind, randomized, placebo-controlled trial of lovastatin for the primary prevention of acute coronary events, patients exposed to lovastatin had significantly lower incidences of melanoma ($p < 0.05$).¹⁴³ Prompted by this observation, a retrospective, case-control study of 328 melanoma cases revealed that patients who developed melanoma had significantly lower exposures to statins (18% vs. 30%).¹⁴⁴ Thus, further research is warranted regarding the chemoprotective potential of statins for patients at high risk of developing skin cancer.

COX INHIBITORS

COX inhibitors, otherwise known as nonsteroidal anti-inflammatory drugs (NSAIDs), inhibit the principal enzyme needed to convert arachidonic acid into various prostaglandins. This enzyme exists in two forms, which have different patterns of activity. COX-1 is the constitutively expressed form, which produces prostaglandins for normal cell function and COX-2 is the inducible form, which produces prostaglandins for inflammation.¹⁴⁵ Nonselective COX inhibitors inhibit both forms. Selective COX inhibitors inhibit only COX-2. Examples of nonselective COX inhibitors include aspirin, ibuprofen, naproxen, indomethacin, diclofenac (Voltaren), and sulindac (Clinoril). Examples of selective COX-2 inhibitors include celecoxib (Celebrex), rofecoxib (Vioxx), and nimesulide (Mesulid). Rofecoxib and nimesulide, however, were

withdrawn from the market by 2004 because of concerns of cardiovascular and hepatic side effects.

Both nonselective and selective COX inhibitors are thought to have chemopreventive potential secondary to a number of proposed mechanisms. For example, COX inhibition has been proposed to prevent COX itself from producing reactive oxygen species (ROS), which could otherwise damage DNA and activate oncogenes.¹⁴⁶ It has also been proposed, however, that COX inhibitors selectively induce GSH deletion, ROS formation, and mitochondrial toxicity in melanoma cells.¹⁴⁷ Sulindac, specifically, has been shown to produce metabolites that down-regulate epidermal growth factor receptors.¹⁴⁸ COX-inhibitors have also been shown to decrease prostaglandins thought to inhibit antimelanoma macrophage and interferon- γ function.^{149,150} Additionally, in vitro studies have shown COX inhibition to decrease colon cancer angiogenesis, increase colon cancer apoptosis, and decrease melanoma invasion by unknown mechanisms.^{151–154} Other studies have identified potential chemopreventive targets for COX-inhibitors outside the COX pathway. These targets include extracellular kinases, AP-1, NFKB, and peroxisome proliferator activated receptor signaling pathways.^{155–158}

Despite the commonality of these potential mechanisms to COX-1 and COX-2 inhibition, many studies have focused on COX-2 inhibition because COX-2 is more associated with cancer. For example, COX-2 is known to be overexpressed by dysplastic and neoplastic lesions of the colon, stomach, esophagus, breast, cervix, bladder, and skin.¹⁵⁹ Profound increases in COX-2 expression have also been noted following UVB exposure of human skin cell lines, in vivo murine skin cells, and in vivo human skin cells.^{160–163} Increased COX-2 expression has additionally been noted in papillomas, actinic keratoses, SCCs,

and melanomas.^{164,165} According to Denkert et al. COX-2 expression is increased in 93% of human melanoma cells with moderate to strong expression in 68% of these cells.¹⁶⁶ In fact, elevated COX-2 is the first immunohistochemical marker to differentiate early melanoma from benign melanocytic nevi with sensitivity and specificity over 90%.¹⁶⁷ Increased COX-2 expression, however, has not been demonstrated in BCC.^{168,169}

Numerous *in vitro* and animal studies have shown oral and topical COX-2 inhibitors to effectively decrease tumor production.¹⁷⁰ For example, oral celecoxib has been shown to significantly decrease keratinocyte proliferation and increase keratinocyte apoptosis following UV irradiation.¹⁷¹ In murine models, oral celecoxib has also been shown to exhibit a dose-dependent reduction of UV-induced tumor incidence.^{172–174} A dose-dependent response to oral celecoxib was also noted when evaluating subsequent time to tumor appearance and multiplicity following UV exposure.¹⁷⁵ Nimesulide, another oral COX-2 inhibitor, has similarly demonstrated efficacy in decreasing UV-induced murine SCC number, volume, and malignant progression.¹⁷⁶ Topical celecoxib has been shown to reduce edema, dermal neutrophil activity, PGE2 levels, sunburn formation, and tumorigenesis in UV-irradiated mice.^{177,178}

In *vitro* and animal studies of oral, nonspecific COX-inhibitors have also shown promise. For example, oral, nonselective COX inhibitors have been demonstrated to decrease keratinocyte proliferation, increase keratinocyte apoptosis, and reduce tumorigenesis by 78% in murine models.^{179,180}

Human studies of oral and topical COX-inhibitors, however, have shown mixed results. A 2005 cohort study of 86 patients with significant histories of SCC showed SCC patients to be significantly less likely than control subjects to have used nonselective oral COX inhibitors two or more times per week for over 1 year. This study also showed that, among participants without SCC, those regularly using nonselective oral COX inhibitors had significantly lower AK counts than nonusers.¹⁸¹ A 2006 cohort study of 702 patients with significant histories of SCC or BCC, however, suggested a weak and inconsistent chemopreventive effect of nonselective oral COX inhibitors on NMSC. An adjusted odds ratio for the association of SCC or BCC risk and nonselective oral COX inhibitor use at baseline and year of diagnosis was 0.89 and 0.92, respectively, for BCC and 0.95 and 0.94, respectively, for SCC.¹⁸² Similarly, a 2008 cohort study of 349 patients with significant histories of melanoma showed no association between nonselective oral COX-inhibitor use and risk of melanoma or melanoma metastasis.¹⁸³ Most recently, however, a 2009 cohort study of 1402 high-risk patients showed a significant NMSC chemoprotective effect for participants who reported nonselective oral COX-inhibitor use for less than the study duration. Interestingly, this study also showed nonselective oral COX-inhibitor use of shorter duration to be more protective than use of longer duration.¹⁸⁴ To date, a number of studies have shown the topical diclofenac to be effective in preventing *in vivo* human actinic keratoses from progressing to SCC (secondary SCC chemoprevention). A 1997 study of 3% diclofenac in 2.5% hyaluronic acid gel applied twice daily for up to 180 days reported that 81% of patients had complete actinic keratosis resolution and another 15% showed marked improvement.¹⁸⁵ Two randomized, multicenter, placebo-controlled studies of patients with actinic keratoses showed similar results.¹⁸⁶ Currently, there are no studies of the primary chemopreventive potential of topical diclofenac, or comparisons of topical diclofenac to other effective actinic keratosis treatments such as topical retinoids, 5-fluorouracil, or imiquimod. Thus, given the mixed results of human studies regarding oral COX-inhibitors and the promising results of human studies regarding topical COX-inhibitors, more research is warranted.

It is important to note, however, that although topical diclofenac has almost no side effects, oral COX-inhibitors can cause significant side effects. The two most common side effects of nonselective oral COX-inhibitors are dose-dependent dyspepsia and renal toxicity. An estimated 10–20% of nonselective oral COX-inhibitor users experience dyspepsia, which can evolve into gastric ulceration

and perforation, resulting in 103,000 hospitalizations and 16,500 deaths per year in the United States.¹⁸⁷ Although oral COX-2 inhibitors were consequently created in hopes of eluding this side effect, all oral COX-2 inhibitors except celecoxib were pulled from the market when randomized-controlled studies showed them to increase mortality secondary to cardiovascular disease.^{188–191} Thus, when administering oral COX-inhibitor therapy, potential risks and benefits should be carefully weighed according to each patient's preexisting risks.

DFMO

DFMO, otherwise known as eflornithine (Ornidyl), was originally created in the 1970s as a chemotherapy agent. Although it proved unsuccessful in this area, it was subsequently used as an oral African sleeping sickness treatment and a topical cosmetic depilatory (Vaniqua).¹⁹²

DFMO is an irreversible inhibitor of ornithine decarboxylase (ODC).¹⁹³ ODC is the rate-limiting enzyme in the polyamine pathway, which produces polyamines implicated in cellular growth and differentiation.¹⁹⁴ ODC expression is minimal in healthy cells, but greatly increased with cellular injury, regeneration, and tumorigenesis.¹⁹⁵

A chemopreventive role for DFMO was postulated when animal studies showed it to decrease polyamine levels at low doses and with no demonstrable toxicity over long periods of use.¹⁹⁶ It was also noted that decreased radiation-induced ODC activity in some XP patients decreased herpes virus reactivation and skin cancer incidence.^{197,198} DFMO treatment in an XP murine model was subsequently shown to reduce tumor load.¹⁹⁹ Since then, murine studies have shown ODC to be necessary in skin carcinogenesis and DFMO to be a potent chemopreventive agent against UV-induced skin carcinogenesis.^{200–205} Interestingly, DFMO has also been shown to have a synergistic chemopreventive effect with COX-inhibitors.

Several phase I human studies have shown DFMO to be well tolerated with a minimal dose-dependent risk of reversible hearing loss.^{206–210} To date, only one case of irreversible hearing loss has been reported.²¹¹ Regarding colorectal adenomas, a prospective, randomized, placebo-controlled trial of patients treated with DFMO and sulindac for 3 years showed a 70% reduction in incidence and a 90% reduction in recurrence.²¹² Regarding actinic keratoses, a randomized, placebo-controlled study of high-risk patients treated with topical 10% DFMO for 6 months showed a 23.5% reduction in incidence.²¹³ Although the current level of evidence does not support DFMO use at this time, it is encouraging and indicates a need for further investigation of DFMO as a skin cancer chemopreventive agent.

VACCINATIONS

In 1796, Edward Jenner defined a 'vaccination' as an antigenic inoculation stimulating the immune system to

prevent or ameliorate disease. The hypothesis that vaccinations can stimulate an anticancer immune mechanism has existed since 1874, when acute infections were noted to coincide with spontaneous cancer remission.²¹⁴ Purified *Streptococcus pyogenes* and *Serratia marcescens* antigens were subsequently administered to cancer patients, inducing febrile illness and sometimes cancer remission.^{215,216} Although such practices have largely been eclipsed by radiotherapy and chemotherapy, skin cancer vaccinations are still being pursued. In particular, many efforts have been made to develop a melanoma vaccination because of melanoma's incidence, mortality upon metastasis, and typical resistance to radiation and chemotherapy. The potential of this immunologic approach has been highlighted by clinical trials demonstrating the efficacy of melanoma immunotherapies such as interleukin-2 and passive immunization with melanoma-reactive T-cells.^{217–219}

Initial attempts to identify a melanoma vaccination looked for associations between nonspecific febrile illness, BCG vaccination, vaccinia vaccination, or influenza vaccination and decreased melanoma incidence or progression. Although retrospective studies were promising, phase III trials did not show significant benefits. In 2002, a case-control study of 603 melanoma patients and 627 control patients demonstrated an inverse correlation between childhood BCG or vaccinia vaccination and melanoma incidence.²²⁰ The odds ratios and 95% confidence intervals for patients who had received BCG only, vaccinia only, or both were 0.43(0.2–0.93), 0.58(0.35–0.96), and 0.44(0.26–0.72), respectively. In 2003, a study of the same patients by Krone et al. found a history of severe febrile illness to have a similar effect, but a combination of severe febrile illness and vaccination did not produce a cumulative effect.²²¹ Similarly, a 2005 cohort study of 542 melanoma patients demonstrated an inverse correlation between childhood BCG or vaccinia vaccination and melanoma survival.²²² The hazard ratios and 95% confidence intervals for patients who had received BCG only, vaccinia only, or both were 0.75(0.30–1.86), 0.55(0.34–0.89), and 0.41(0.25–0.69), respectively. Regarding influenza vaccination, the 2003 study by Krone et al. showed no association between a history of one influenza vaccination in the previous 5 years and melanoma incidence. A case-control study in 2000, however, showed a history of three to five influenza vaccinations in the previous 5 years to be associated with a 50% lower risk of melanoma.²²³ A 1993, phase III, multicenter, randomized control trial of BCG vaccine involving 327 stage I melanoma patients, showed no significant increases in time to progression ($p = 0.55$) and duration of survival ($p=0.82$).²²⁴ A 2004, phase III, randomized, controlled trial of BCG vaccine involving 734 stage I–III melanoma patients by the Eastern Oncology Group showed no significant increases in disease-free survival ($p=0.84$) or overall survival ($p = 0.4$).²²⁵

Efforts were subsequently refocused on provoking melanoma-specific immune responses with vaccines consisting of whole melanoma cells, melanoma peptides,

dendritic cells loaded with melanoma peptides, melanoma gangliosides, melanoma oncolysate, melanoma RNA, melanoma DNA, or viral vectors of melanoma DNA. These would theoretically be used to treat melanoma or prevent melanoma recurrence. However, although animal studies, retrospective studies, and phase I and II clinical trials have been promising, phase III clinical trials have shown mixed results. In terms of safety, all phase I and II trials have shown predominantly grade I and II toxicities at low incidences. In terms of efficacy, phase I and II trials have shown encouraging results including: tumor regression in 28% of metastatic melanoma patients treated with a MAGE3 melanoma peptide vaccine ($n=39$)²²⁶; progression free survival in 58% of melanoma patients treated with a MART1, gp100, and tyrosinase melanoma peptide vaccine ($n=120$)²²⁷; improved clinical outcomes in metastatic melanoma patients with immune responses to a similar peptide vaccine ($n=25$)²²⁸; improved relapse-free survival with in high-risk, resected melanoma patients with immune responses to a MART-1 vaccine ($n=60$)²²⁹; improved prognosis in relapsed, high-risk, resected staged IIA-IV melanoma patients; treated with a MART-1, MAGE-1, gp100, and tyrosinase melanoma peptide vaccine ($n=24$)²³⁰; 12% objective clinical response in stage IIIb-IV melanoma patients successfully immunized with a similar peptide vaccine ($n=39$)²³¹; improved survival in metastatic melanoma patients mounting immune responses to at least two of four melanoma peptides loaded onto autologous dendritic cells ($n=18$)²³²; 57% immunogenicity in stage IV melanoma patients vaccinated with autologous dendritic cells transduced with adenovirus encoding MART-1 ($n=14$)²³³; 63% vaccine-related CD8+ T-cell response in melanoma patients vaccinated with dendritic cells electrophorated with mRNA encoding gp100 or tyrosinase ($n=11$)²³⁴; 50% T-cell response and 14% resultant clinical response in metastatic melanoma patients vaccinated with protamine stabilized mRNA coding for Melan-A, tyrosinase, gp100, Mage A1, Mage A3, and Survivin ($n=21$)²³⁵; 21% immunogenicity with correlation between MART-1 immunity and time-to-progression in stage IV melanoma patients vaccinated with DNA plasmids encoding MART-1 and tyrosinase ($n=19$)²³⁶; 39% CD8+ T-cell response in melanoma patients vaccinated with mouse and human DNA plasmids encoding tyrosinase ($n=18$).²³⁷

To date, there have been eight, phase-III, randomized melanoma vaccine trials showing mixed results. A 2002 trial of an allogenic, whole-cell melanoma vaccine in 689 stage-II melanoma patients showed no significant improvement in tumor recurrence or overall mortality. However, for those patients expressing HLA-A2 or HLA-C3, this vaccine was associated with a significant increase in relapse-free survival.^{238,239} A 2007 trial comparing Canavaxin allogenic, whole-cell melanoma vaccine plus BCG vaccine to BCG vaccine alone in 1,656 stage III and IV melanoma patients also showed no significant improvement in overall melanoma relapse or survival.²⁴⁰ In fact, this vaccine was

associated with decreased disease-free survival in patients with stage III melanoma. A 1994 trial comparing a GM2 ganglioside (melanoma glycolipid) vaccine plus BCG vaccine to BCG vaccine alone in 122 stage III melanoma patients, showed a significant increase in disease-free interval and overall survival in those patients who had pre-existing or vaccine-induced anti-GM2 ganglioside antibodies.²⁴¹ A 2001 trial comparing a conjugated GM2 ganglioside vaccine to high-dose interferon- α in 880 stage IIb to III melanoma patients was terminated at a median follow-up of 14 months because of inferior survival of the vaccinated group.²⁴² A 1998 trial of an allogenic vaccinia melanoma oncolysate in 217 stage III melanoma patients showed no significant increase in disease-free interval or overall survival.²⁴³ Similarly, a 2002 trial of another allogenic vaccinia melanoma oncolysate in 700 stage IIB and stage III melanoma patients showed no significant increase in relapse-free survival and overall survival.²⁴⁴ A 2005 trial comparing an autologous, melanoma peptide-loaded, dendritic cell vaccine to standard dacarbazine chemotherapy in 108 stage IV melanoma patients showed no significant improvement in overall survival.²⁴⁵ Thus, these eight, phase III, randomized trials do not demonstrate reproducible, significant, overall benefits to the tested melanoma vaccines. There does seem to be promise in the Southwest Oncology Group trial's whole-cell melanoma vaccine in HLA-A2 and HLA-C3 expressing patients, however, suggesting that future trials may benefit from targeting certain patient subsets. For all melanoma vaccines overall, however, there is sufficient evidence to warrant further exploration of vaccinations as potential chemopreventive or primary cancer prevention strategies. Barriers to vaccine efficacy have included melanoma's defense mechanisms against the immune system: Inhibitory cytokines, inhibitory surface proteins, decreased HLA antigen presentation, and reduced expression of molecules required for immune cell adhesion.²⁴⁶⁻²⁵² Other barriers have included the body's normal defenses against autoimmunity, including regulatory T-cells, and CTLA-4.^{253,254} Continuing efforts will subsequently have to be made to overcome these barriers.²⁵⁵⁻²⁵⁷

BOTANICALS

In recent years, considerable interest has been focused on identifying naturally occurring botanicals for the prevention of photocarcinogenesis. Wide varieties of botanicals have been reported to possess anticarcinogenic and antimutagenic activities because of their antioxidant and anti-inflammatory properties. Botanical supplements possessing antioxidant properties are among the most promising group of compounds that can be exploited as ideal chemopreventive agents for skin cancer.²⁵⁸ Such botanicals include tea polyphenols, apigenin, ginger, curcumin, grape seed proanthocyanidins, and resveratrol. These dietary botanicals have demonstrated a photoprotective

potential against UV radiation-induced inflammation, oxidative stress, and photocarcinogenesis in several recent in vitro and in vivo studies.^{259–261} In the remainder of this review, we will briefly discuss the chemopreventive potential of some dietary botanicals.

Tea

After water, tea is the most commonly consumed beverage worldwide. Of the major types of tea, black tea is most popular, followed by green tea.^{262,263} Both types of tea are derived from the same plant, *Camellia sinensis*, but are fermented for different lengths of time, resulting in different concentrations and oxidation states of catechin/epicatechin antioxidants, which are more commonly called “polyphenols.”²⁶⁴ Green tea is thought to have higher polyphenol content and the monomeric green tea polyphenol (-)-epigallocatechin-3-gallate (EGCG) is thought to be the most potent polyphenol antioxidant.²⁶⁵ Green tea has subsequently undergone more thorough clinical investigation of its chemopreventive efficacy.²⁶⁶ Additionally, although oligomeric black tea polyphenols such as the theaflavins have reached clinical trials²⁶⁷, the most abundant black tea polyphenols, the polymeric thearubigins, have yet to be fully described.^{268–270}

Many chemopreventive mechanisms have been proposed for green and black tea polyphenols. One of the first chemopreventive mechanisms proposed for green tea polyphenols was inhibition of IL-1 alpha expression. This hypothesis was based on a murine study showing topical green tea polyphenols to significantly decrease anthratin/mezerin/benzoyl-peroxide-mediated increases in cutaneous IL-1 alpha.²⁷¹ Another proposed mechanism from the same group was inhibition of CD11b+ cell infiltration, inhibition of IL-10 expression, and induction of IL-12 expression. This hypothesis was based on a murine study showing topical EGCG to significantly decrease UVB-induced cutaneous CD11b+ monocyte/macrophage/neutrophil infiltration and IL-10 elevations, both of which are associated with UVB-induced immunosuppression and increased skin cancer risk. This study also showed topical EGCG to significantly increase UVB-induced IL-12 production, which is associated with Th1 immune responses and the repair of UV-induced DNA damage.²⁷² One follow-up study showed topical EGCG to decrease UV-induced DNA damage in mice with functional IL-12, but not in mice without functional IL-12, supporting the hypothesis that EGCG-mediated increases in IL-12 decrease UV-induced DNA damage.²⁷³ Another follow-up study supported the same point by showing topical EGCG to significantly inhibit photocarcinogenesis in terms of tumor incidence, multiplicity, and growth in mice with functional IL-12, but not mice without functional IL-12.²⁷⁴ These results were also supported by a second follow-up study in 2009.²⁷⁵ Another proposed mechanism was stimulation of cytotoxic tumoricidal T-cells. This hypothesis was based on a murine study

showing oral green tea polyphenols to significantly increase CD8+ T cells in tumors.²⁷⁶ A follow-up study testing both oral green tea polyphenols and topical EGCG showed similar results, with topical EGCG proving more effective than oral green tea polyphenols.²⁷⁷ A possible connection to the previous proposed mechanism is that IL-12 is known to increase CD8+ development.²⁷⁸ These studies supporting polyphenol-mediated CD8+ T cell development also supported the hypothesis that green tea polyphenols inhibit skin cancer metastasis and angiogenesis. They showed both oral green tea polyphenols and EGCG to downregulate matrix metalloproteinases, which facilitate basement membrane invasion, and vascular endothelial cell antigens, which facilitate angiogenesis for tumor growth. These results were supported by another murine study showing oral green tea polyphenols to inhibit angiogenesis.²⁷⁹ Previous studies had also shown in vitro treatment with green tea polyphenols to reduce tumor cell invasion by 50% and inhibit UVB-induced protein oxidation by decreasing matrix metalloproteinase production.^{280,281} Another proposed chemopreventive mechanism for green tea polyphenols was inhibition of urokinase, a hydrolase that similarly facilitates basement membrane invasion. This hypothesis was based on a study showing EGCG to directly inhibit urokinase.²⁸² Another proposed chemopreventive mechanism for green tea polyphenols was initiation of apoptosis and cell cycle arrest in cancer cells, possibly via increased caspase-3 expression. This hypothesis was based on an in vitro study on human cancer cells showing green tea polyphenols to induce apoptosis and G0-G1 cell cycle arrest.²⁸³ These results were supported by studies showing EGCG to increase keratinocyte caspase-3 expression and apoptosis in UV-irradiated human subjects.^{284,285} Another proposed mechanism for polyphenol-mediated cancer cell apoptosis was via inhibition of the nuclear transcription factors “nuclear factor kappa-light-chain-enhancer of activated B cells” (NF-KB) and activator protein-1 (AP-1), which are associated with cancer, decreased apoptosis, and inflammation when upregulated.²⁸⁶ This hypothesis was based on a study showing EGCG to inhibit UV-induced NF-KB and AP-1 activity in human fibroblasts.²⁸⁷ A subsequent study elaborated on this hypothesis by showing EGCG to markedly inhibit IL-1 beta-mediated activation of NF-KB, resulting in decreased IL-8, which is a major neutrophil chemoattractant.²⁸⁸ Green tea polyphenols are also thought to prevent carcinogenesis initiation by preventing carcinogen-DNA adduct formation and carcinogenesis promotion by decreasing activation of ornithine decarboxylase, cell signaling kinases (JNK/ERK/p38), and transcription factors.^{289–291} Green tea polyphenols are also known to inhibit UVB-induced COX-2, PGE2, PGF2α, and PGD production, and these molecules are known to be overexpressed in skin cancer.^{292,293} Lastly, given the higher rate of melanoma in females, it has been suggested that green tea’s antiestrogenic properties may contribute to its antimelanoma effects.^{294,295}

Black tea polyphenols and rhealavins have also been shown to inhibit the UVB-induced activation of AP-1, mitogen-activated protein kinase (MAPK), and extracellular receptor-activated kinase (ERK).²⁹⁶ These compounds are also known to inhibit human keratinocyte c-fos expression.²⁹⁷ A 2008 murine study showed black tea polyphenols to decrease benzo(a)pyrene-DNA adduct formation and subsequently cell proliferation to inhibit skin carcinogenesis.²⁹⁸ Another 2008 in vitro study suggested that black tea rhealavins and thearubins exert chemopreventive effects through cell-cycle arrest and induction of the mitochondrial death cascade in skin cancer cells.²⁹⁹

Numerous murine, in vitro, retrospective, and clinical trials have demonstrated the nontoxic, chemopreventive efficacy of green tea polyphenols against UV-induced skin cancer. In 1991, oral and topical green tea polyphenols were shown to significantly increase time-to-tumor-development and significantly decrease tumor yield in a dose-dependent fashion following UV exposure ($p<0.01$).³⁰⁰ A follow-up study showed oral green tea polyphenols to significantly decrease erythema, photoaging, tumor number, and tumor size in a dose-dependent fashion following UV-exposure.³⁰¹ Other studies soon confirmed these effects.³⁰²⁻³¹⁰ A 2003 study more specifically showed oral green tea polyphenols to decrease numbers of UV-induced papillomas by 80%, keratoacanthomas by 53%, and SCC by 32%. This study also showed tumor incidence to be decreased by 60% and multiplicity to be decreased by 86%.³¹¹ Similarly, a 2005 study showed oral green tea polyphenols to decrease tumor incidence (35%), multiplicity (63%), and growth (55%).³¹² Although the 1991 study showed oral administration to be more effective than topical application, several subsequent studies have shown topical application to be more effective, especially when applied in a hydrophilic vehicle.³¹³⁻³¹⁵ Similarly, several studies have indicated EGCG to be the most effective green tea polyphenol in terms of skin cancer chemoprevention.^{316,317} In addition to demonstrating the ability of green tea polyphenols to prevent skin tumor initiation and growth, murine studies have demonstrated the ability of green tea polyphenols to induce partial regression of established skin papillomas.³¹⁸ Such findings have been supported by in vitro studies demonstrating green tea polyphenols to promote G0-G1 cell cycle arrest, promote apoptosis, and reduce metastasis by human tumor cells.³¹⁹⁻³²⁴ Retrospective human studies have also supported this data. A recent retrospective case control study of 770 BCC patients, 696 SCC patients, and 715 control patients demonstrated an inverse association between the regular consumption of tea (at least 1 cup per day for over 1 month) and NMSC after adjustment for sunburns, age, and gender.³²⁵ Clinical trials have similarly demonstrated that green tea and its extracts confer resistance to erythema induction, increase apoptosis in irradiated cells, and reduce DNA damage secondary to UV radiation.³²⁶⁻³²⁹ A 2009 clinical trial showed topical

green and white tea to significantly decrease UV-induced oxidative DNA damage compared to vehicle-only treated skin (n=10).³³⁰

A number of murine trials have also demonstrated the nontoxic, chemopreventive efficacy of black tea polyphenols against UV-induced skin cancer. A 1997 murine study showed that black tea, even when consumed with milk—as it is consumed by many humans, had significant chemopreventive efficacy.³³¹ These efficacies were confirmed by several other murine studies.³³²⁻³³⁴ A 1994 murine study of oral black tea, green tea, decaffeinated black tea, and decaffeinated green tea showed all to decrease UV-induced tumor number and size and each to decrease UV-induced carcinoma numbers by 93, 88, 77, and 72% respectively.³³⁵ Although this study showed black tea to be more effective than green tea, most comparative studies have shown green tea to be more effective. One such study also confirmed what the 1994 study suggested, that caffeine might contribute to the chemopreventive properties of tea. Decaffeinated versions of green and black tea had substantially less chemopreventive efficacy than caffeinated versions, and oral caffeine by itself had a substantial inhibitory effect on UVB-induced carcinogenesis.³³⁶ Another murine study showed oral black tea to decrease UVB-induced keratoacanthoma incidence by 58%, UVB-induced SCC incidence by 54%, and papilloma growth by 35-70%. Tumor volume was decreased by 60% for nonmalignant tumors and 84% for carcinomas. Histologic examination revealed significantly decreased mitotic index (16-42%) and significantly increased apoptosis index (44-100%) in malignant and nonmalignant tumors.³³⁷ A recent study of the ill-defined polymeric black tea polyphenols showed these compounds to significantly increase UVB-induced skin carcinogenesis latency, and decrease UVB-induced skin carcinogenesis multiplicity and incidence.³³⁸

As a potential chemopreventive agent, green tea is an ideal candidate given its worldwide use and favorable side effect profile.³³⁹ Although the mechanism of antineoplastic action of green tea has not been fully elucidated, the current data supporting the efficacy of green tea as an anticarcinogenic and chemopreventive agent is convincing. Thus, further investigation of the potential role of green and black tea as chemopreventive agents against skin cancer is warranted.

Apigenin

Apigenin is a widely distributed plant flavonoid (5,7,4'-trihydroxyflavone) naturally present in numerous fruits³⁴⁰ (apples, cherries, grapes), vegetables³⁴¹ (broccoli, tomatoes), herbs (clove, parsley) and beverages³⁴² (tea, wine). It is a free radical scavenger that has been shown to possess natural antioxidant, antimutagenic, and anticarcinogenic properties.³⁴³⁻³⁴⁸ Several nonskin cancer clinical trials have proven apigenin to be safe in humans.^{349,350}

In a 1990 murine study, topical apigenin was shown to inhibit epidermal ornithine decarboxylase in a dose-dependent fashion, increase TPA/DMBA-induced skin tumor latency by 3 weeks, and decrease TPA/DMBA-induced skin tumor incidence and multiplicity.³⁵¹ In 1997, these results were reconfirmed regarding UV-induced skin carcinogenesis. Treatment of murine skin with apigenin prior to UVB radiation resulted in a 52% reduction of cancer incidence and an increase in tumor-free survival in comparison to control mice ($p < 0.01$).³⁵²

Additionally, apigenin has been shown to inhibit cyclin-dependent kinases leading to cell cycle arrest, accompanied by inhibition of p34/cdk2 kinase protein levels in UV-induced tumorigenesis in mice.³⁵³ Apigenin treatment of mouse keratinocytes resulted in accumulation of p53 tumor suppressor protein and expression of a downstream cdk inhibitor protein p21/WAF1.^{354,355}

A recent in vitro study also showed apigenin to enhance apoptotic tumor cell death and render TC-1 tumor cells more susceptible to cytotoxic T-cells.³⁵⁶ This study furthermore demonstrated apigenin to enhance antitumor DNA vaccine efficacy. Another in vitro study showed apigenin to strongly inhibit the PDGF-dependent increase in vascular endothelial growth factor (VEGF) which is crucial for angiogenesis.³⁵⁷ These mechanisms support the potential chemopreventive effect of apigenin in photocarcinogenesis.

Ginger

Ginger (*Zingiber officinale Roscoe*, *Zingiberaceae*) has long been used in Eastern Medicine for a variety of ailments. Multiple animal and in vitro studies have demonstrated topical ginger extracts to reduce cutaneous tumorigenesis following chemical induction.^{358–364} This activity has been associated with reduced levels of ornithine decarboxylase, NF-KB, COX-2, superoxide, lipoxygenase, and TNF- α , suggesting ginger's chemopreventive properties to be related to its anti-inflammatory properties.^{365–369} A 2004 study showed the ginger extract zerumbone to prevent both tumor initiation and promotion by antioxidant and anti-inflammatory pathways, resulting in a 60% lower incidence and a 80% lower multiplicity.³⁷⁰ A 2005 study also showed topical [6]-gingerol to inhibit angiogenesis of human endothelial cells and cause G1 cell cycle arrest by down-regulating cyclin D1.³⁷¹ Two other in vitro studies have also shown topical ginger extracts to inhibit AP-1.^{372,373} Numerous animal and in vitro studies have furthermore demonstrated topical ginger extracts to induce apoptosis by a variety of mechanisms.^{374–381}

The components of ginger reported to possess cancer chemopreventive properties include vanillyl ketones, [6]-gingerol, and [6]-paradol. These compounds all share a vanilloid structure similar to other natural chemopreventive agents.^{382,383} As a group, Vanilloids have been shown to induce apoptosis.³⁸⁴ Ginger, like green tea, is widely

consumed and has limited side effect profile. Thus, it is also an ideal candidate for continued experimentation as a potential chemopreventive agent for skin cancer.

Curcumin

Another potent vanilloid compound reported to have cancer chemopreventive properties is curcumin (*Curcuma longa Linn*). Curcumin is what makes the widely consumed spice, turmeric, yellow. In 2005, an *in vitro* study of three melanoma cell lines showed curcumin to induce a dose-dependent increase in apoptosis.³⁸⁵ This effect was thought to be caused by down-regulation of NK- κ B and I κ B kinase, which play a central role in cell survival and growth. A 2007 study of murine melanoma cells corroborated these results by demonstrating curcumin to down-regulate constitutive NF-KB activity and induce apoptosis with caspase-3 activation.³⁸⁶ Murine studies have also shown topical curcumin to increase cutaneous glutathione, decrease cutaneous ODC activity, and inhibit DNA adduct formation.^{387–389} Other murine studies have shown curcumin to decrease cutaneous hyperplasia and formation of c-Fos and c-Jun proto-oncoproteins. In one such study, DMBA/TPA-induced tumorigenesis was decreased by 15–59%.³⁹⁰ Curcumin has also been reported to inhibit ERK activity, reduce activating protein-1 (AP-1) levels, and decrease nuclear factor κ B (NF- κ B) activation. These proteins act as transcription factors and are responsible for the upregulation of COX-2 expression.³⁹¹ ERK regulates NF- κ B, which is thought to regulate COX-2 via several mechanisms.³⁹² Curcumin has also been shown to affect the cell cycle by decreasing the number of cells actively synthesizing DNA.³⁹³

A phase I clinical trial has provided preliminary evidence that curcumin is effective in improving the histologic condition of high-risk or premalignant lesions. This study also confirmed that curcumin is nontoxic to humans when administered 8000 mg/day for 3 months.³⁹⁴ A 2004, an *in vitro* study of highly metastatic murine melanoma cells, showed curcumin to significantly inhibit MMP-2 activity, membrane type-1 matrix metalloproteinase (MT1-MMP) expression, and focal adhesion kinase expression for up to 28 days after curcumin withdrawal, potentially explaining curcumin's antimetastasis effects.³⁹⁵ Thus, the preponderance of evidence suggests that curcumin has great potential as an over-the-counter adjunct to skin cancer chemoprevention.

Grape Seed Proanthocyanidins

Grapes (*Vitis vinifera*) are one of the most widely consumed fruits in the world. Grapes are rich in polyphenols 60–70% of grape polyphenols are present in grape seeds.³⁹⁶ These polyphenols are flavan-3-ol derivatives. The term catechin is the combined name for monomers of flavin-3-ol derivatives and the term proanthocyanidin represents dimers and oligomers of flavin-3-ol derivatives.³⁹⁷ Grape seed proanthocyanidins (GSP) have been shown to be more

potent antioxidants and free radical scavengers than ascorbic acid and vitamin E.³⁹⁸ Further, numerous in vitro and in vivo studies have demonstrated the chemoprotective effects of grape seed proanthocyanidins in photocarcinogenesis.³⁹⁹ Mittal et al. provided the first evidence of UV-induced skin cancer prevention with oral GSP in hairless mice. In this study, dietary GSP inhibited photocarcinogenesis in terms of tumor incidence (20–95%), tumor multiplicity (46–95%), and tumor size (29–94%).⁴⁰⁰ Furthermore, dietary GSP was also shown to prevent malignant transformation of UVB-induced papillomas to carcinomas in mice in terms of carcinoma incidence (45%), multiplicity (61%), and size (75%) compared to non-GSP treated mice following UVB-induced skin carcinogenesis.⁴⁰¹ A 2009 study showed oral GSP treatment of mice exposed to TPA/DMBA resulted in significantly lower inflammation, tumor burden ($p < 0.05$), tumor number ($p < 0.01$), total tumor volume per tumor-bearing mouse ($p < 0.01$), and rate of malignant progression from papilloma to carcinoma.⁴⁰²

Grape seed proanthocyanidins is thought to produce these chemopreventive effects by reducing UV-induced oxidative stress, protein kinase activation, nuclear factor-kappa B signaling pathway activation, and immunosuppression.⁴⁰³ A 2005 study suggested GSP to induce p53-dependent apoptosis via activation of Bax, Bcl-2, and caspase 3 pathways in JB6 C141 cells (a well-developed cell culture model for studying tumorigenesis in keratinocytes).⁴⁰⁴ A 2007 study suggested GSP to induce apoptosis in human epidermoid carcinoma A431 cells through alterations in the Cdki-Cdk-cyclin cascade and caspase-3 activation resulting in a loss of mitochondrial membrane potential.⁴⁰⁵ Thus, further investigations into the chemopreventive efficacy and mechanism of GSPs are warranted.

Resveratrol

Resveratrol (trans-3, 5, 4-trihydroxystilbene) is a naturally occurring compound found in grapes, wine, and a variety

of nuts and berries. It is produced by plants in response to injury or fungal infection, however, it does not present any cytotoxic effects in animal models.⁴⁰⁶ Resveratrol has shown remarkable cancer chemopreventive effects in a variety of preclinical studies.^{407–414}

Studies have shown that resveratrol possesses potent antimutagen, antioxidant, antiinflammatory, antiproliferative, induction of phase II drug-metabolizing enzymes and inhibition of COX activity.^{415,416} Resveratrol acts at each of the three phases of carcinogenesis: tumor initiation, promotion and progression phases, and suppression of the final steps, including angiogenesis and metastasis.⁴¹⁷ It has also been shown to activate apoptosis, inhibit kinase pathways, and induce cell cycle arrest in tumor cells.⁴¹⁸ Additionally, it has demonstrated inhibition of reactive oxygen species, COX, NFKB, and AP-1 activity in mammary epithelial cells.⁴¹⁹ A 2005 murine study by Aziz et al. demonstrated that resveratrol imparts significant protection against UVB exposure-mediated skin carcinogenesis in hairless mice via inhibition of survivin.⁴²⁰ Survivin is a biomarker of tumor progression with an established overexpression in several cancers, which is thought to participate in the onset, and progression of SCC, BCC, and melanoma.⁴²¹ In vivo studies by Reagan-Shaw and colleagues showed that treatment with resveratrol inhibited UV-mediated increase in cyclin-dependent kinases (cdk 2, 4, and 6), cyclins (D1 and D2), and the mitogen-activated protein kinase pathway in hairless mice skin.⁴²² A 2009 murine study showed resveratrol treatment of mice exposed to DMBA to result in significantly fewer tumors ($p < 0.001$) when the mice had functioning toll-like receptors. This suggests that toll-like receptors, which function innate and adaptive immune responses, play an important role in resveratrol chemoprevention.⁴²³ Interestingly, another 2009 study showed resveratrol to sensitize A431 human epidermoid carcinoma cells to UVB-induced cell death.⁴²⁴ Several other studies have suggested resveratrol to affect its chemopreventive effects via mitochondrial signaling pathways.^{425,426} Thus, although

What We Know

- In America, skin cancer is more common than all other cancers combined.
- Chemoprevention is defined as a pharmacologic intervention that prevents, arrests, or reverses carcinogenesis.
- Retinoids are promising in the prevention of non-melanoma skin cancers.
- HMG-CoA reductase inhibitors, the cholesterol lowering agents known as statins, may be useful in chemoprevention of melanoma by their effects on the Ras and Rho GTPases. These GTPases are involved in cell cycle progression.
- Selective cyclo-oxygenase 2 (COX-2) inhibitors may prove to be useful in the chemoprevention of nonmelanoma skin cancer but the systemic side effects and risks may outweigh the benefits.
- Melanoma vaccines are promising and the immunomodulating effects of several varieties of these vaccines has proven effective in some clinical trials.
- Botanical ingredients including: tea, apigenin, ginger, curcumin, grape seed proanthocyanidins, and resveratrol affect UV induced carcinogenesis and their anti-oxidative properties hold promise for chemopreventive uses.

its mechanism of action is unclear, resveratrol holds great promise as a chemopreventive agent against UV-induced damage to the skin and further study is warranted.

CONCLUSION

Skin cancer is by far the most common cancer afflicting humans today. Although public health officials have tried to improve patient education regarding sun protection, both melanoma and nonmelanoma skin cancers continue to increase in incidence. As one of the most aggressive cancers, melanoma is associated with very high mortality rates. Although nonmelanoma skin cancers are associated with minimal mortality, patients predisposed to these cancers because of genetic conditions or immunosuppression, often have much higher mortality rates. Furthermore, all patient populations have significant morbidity and costs associated with nonmelanoma skin cancers.

It is subsequently necessary to revisit the issue of skin cancer prevention and possibly revise current recommendations. Many agents show significant chemopreventive effects against skin cancer. However, many of these agents also show significant incidences of serious side effects. Thus, when considering a chemopreventive regimen, the patient and physician must weigh the risks and benefits. Additionally, there are many potentially beneficial chemopreventive agents, which do not have sufficient evidence-based support to advocate their use at this time. Subsequently it is essential that further investigation be pursued.

Treatment of Actinic Keratosis

43

Sean Carlson, D.O., and Jeremy Bordeaux, M.D., M.P.H.

INTRODUCTION

An actinic keratosis (AK) is a dysplastic keratinocytic lesion located in the epidermis.¹ By definition, actinic keratoses (AKs) do not involve the *full thickness* of the epidermis, a characteristic which distinguishes an AK from Bowen's disease (squamous cell carcinoma (SCC) *in situ*).² Also known as solar keratoses, senile keratoses, and actinic cheilitis (when confined to the lips), AKs typically appear as scaly papules on an erythematous base and are normally rough to the touch.³ They are generally distributed over sun-exposed areas on older adults. AKs have the potential to develop into squamous cell carcinomas. Treatment is typically recommended because the natural history of an individual AK is unpredictable.⁴

EPIDEMIOLOGY

The estimated prevalence of AKs in the United States was 39.5 million in 2004,⁵ corresponding to a prevalence of approximately 13% based on census data.⁶ In the U.K., the prevalence of AKs was approximately 15.4% in men and 5.9% in women in a 2000 study.⁷ The risk of AK formation is higher in older patients, patients with childhood freckling, and blue-eyed individuals.⁸

ETIOLOGY

Actinic keratoses are generally felt to result from chronic sun exposure (i.e., chronic UV light exposure), since greater cumulative UVB exposure is associated with a greater risk of AK formation.⁸ Ultraviolet radiation has been shown to induce p53 mutations,⁹ which may serve as the initiating event in the development of an AK.¹⁰ The same p53 mutations found in SCCs are also found in AKs.⁹

DIAGNOSIS

The diagnosis of AKs is typically based on clinical features.¹¹ Biopsies are necessary when the clinical picture is unclear and would help differentiate an AK from an SCC or BCC. Major risk factors associated with progression of

AKs to SCC include induration/inflammation, a diameter >1 cm, rapid enlargement, bleeding, erythema, and ulceration.¹²

SEARCH METHODOLOGY

A PubMed search was performed using the search term "actinic keratosis AND treatment." Only articles available in English were included. Titles and abstracts were reviewed for relevance. References were also gathered from the cited studies reviewed. Case reports or smaller case series studies were not considered unless there was a paucity of information related to a given therapeutic intervention.

Papers were evaluated using the strength of recommendation taxonomy (SORT).¹³ The quality of most *studies* was graded using a 1-3 scale, with 1 representing "good-quality patient-oriented evidence," 2 representing "limited-quality patient-oriented evidence," and 3 representing other evidence based on consensus guidelines, opinion, and usual practice. *Overall recommendations* were graded using the SORT scale of A-C, where A represented a recommendation based on consistent patient-oriented, good-quality evidence, B represented a recommendation based on "inconsistent or limited-quality patient-oriented evidence," and C represented other recommendations, such as those based on consensus, opinion, and/or usual practice.¹³ Unless otherwise stated, recommendations pertain to nonpregnant, immunocompetent individuals.

Research Questions and their Answers

Efficacy, side effects, cost, and duration of therapy are all important factors to consider when deciding upon the optimal treatment for a patient. The thickness, location, and distribution of AK lesions are also important considerations. The purpose of this chapter is to provide the physician with the evidence behind the treatments, so an informed recommendation can be presented to the patient. Financial considerations will not be discussed in this chapter, but the reader is encouraged to gain an understanding of the cost of different therapies.

Is there any way to help prevent AKs?

A number of studies have shown that sunscreen may help prevent new actinic keratoses from forming. In 1993, Thompson et al. compared the effect of sunscreen versus the sunscreen's inactive ingredients (base-cream) on the number of actinic keratoses over a 7-month period and found an average increase of 1.0 ± 0.3 actinic keratoses per participant in the base-cream group compared with an average decrease of 0.6 ± 0.3 actinic keratoses per participant in the group that used sunscreen, concluding that regular sunscreen use prevents the development of actinic keratoses.¹⁴ A randomized-controlled trial by Darlington et al. studied the effects of daily sunscreen use with or without beta carotene supplementation and discretionary sunscreen use with or without beta carotene supplementation, and found that beta carotene supplementation of 30 mg/day had no significant effect on AK counts in the study periods; the daily application of sunscreen resulted in a significant decrease in the mean AK acquisition rate when compared to discretionary sunscreen use during the first 2-year study period, but not in a statistically significant decrease during the second 2-year study period.¹⁵

What will happen if AKs are not treated?

It is generally agreed that AKs have the potential to regress or progress to SCC, although the rates at which AKs regress or progress have been debated. Recent data also suggest that clinically diagnosed AKs may progress to basal cell carcinomas (BCCs).¹

Regression

Most literature favors the concept that an actinic keratosis may regress, but there is speculation on whether this has actually been proven.^{16,17} Several studies report spontaneous remissions of actinic keratoses.^{18–20} In a community-based study in Australia, Frost et al. reported on the regression of 346 (74%) prevalent (present on the first skin examination 12 months prior) actinic keratoses in 35 participants; this was contrasted with a 29% regression of 180 incident lesions (new lesions found during the study).¹⁸ Marks et al. observed 1040 people over 40 years old for 12 months: 616 subjects had actinic keratoses; of these subjects, 224 had at least one actinic keratosis undergo spontaneous remission (for a total of 485 out of the 1873 total lesions, or 25.9%).¹⁹ And finally, a 15% regression rate was reported by Harvey et al. in a South Wales study.²⁰ Thus, the evidence seems to favor the concept that an actinic keratosis may regress, although this does not necessarily indicate that AK lesions should not be treated.

Progression

Despite the rate of spontaneous remission in the aforementioned Marks et al. study, over all there was a 21.8% increase

in the number of actinic keratoses in the study population over the 12-month observation period, and a 0.24% incidence rate of squamous cell carcinoma occurring per actinic keratosis present at the baseline examination.¹⁹ In a subsequent study, Marks et al. mapped AKs to determine whether an SCC arose at the same location; 10/17 SCCs arose in an area that had previously been diagnosed clinically as an actinic keratosis. Since 21,905 actinic keratoses were present on the first visit, the risk of an actinic keratosis transforming into an SCC was estimated to be less than 1/1000.²¹ Prospectively derived data from the Department of Veterans Affairs Topical Tretinoin Chemoprevention Trial indicated the risk of progression of an AK to an SCC (invasive or *in situ* disease) was approximately 0.60% at 1 year, and 2.57% at 4 years, and the risk of progression of an AK to invasive SCC was 0.39% at 1 year and 1.97% at 4 years.¹ Additionally, Mittelbronn et al. reviewed 165 cutaneous SCC cases by light microscopy and found that 82.4% of cases showed AK involvement, and 26.7% of the SCC cases were felt to be arising from a pre-existing AK, providing additional evidence that SCCs develop from pre-existing AKs.²²

Why treat AKs?

Actinic keratoses are typically treated to prevent SCC, although cosmetic or symptomatic reasons may also play a role in the decision to treat AKs.¹ Different treatment modalities have been shown to decrease the incidence of non-melanoma skin cancer (NMSC) when compared with controls.²³ Since the natural history of a given lesion is unpredictable,⁴ treatment is generally recommended.

What has been used to treat AKs?

Table 43-1 summarizes select common and uncommon treatment options that have been used previously in the management of AKs and that will be discussed in this chapter. Investigational therapies, unavailable or discontinued therapies, and therapies only discussed in small case reports or small case series will not be discussed.

What is the evidence behind the use of pharmacologic therapies?

5-Fluorouracil

5-Fluorouracil (5-FU) is by far the most studied pharmacologic therapy for actinic keratoses and was approved for use in the United States in the early 1970s.²⁴ 5-FU interferes with DNA and RNA synthesis by blocking the methylation reaction of deoxyuridylic acid to thymidylic acid and has the most pronounced effect on rapidly dividing cells.²⁵ A number of 5-FU formulations are available in the United States, including 0.5%, 1%, 2%, and 5% creams and solutions (Table 43-2). While all current 5-FU formulations are

TABLE 43-1—Therapeutic Options for Actinic Keratoses

Frequency of use	Pharmacologic	Nonpharmacologic
More Common	<ul style="list-style-type: none"> 5-fluorouracil cream and solutions Imiquimod cream Diclofenac sodium gel 	<ul style="list-style-type: none"> Cryosurgery
Less Common	<ul style="list-style-type: none"> PDT Topical retinoids (tretinoin, adapalene) Chemical peels (trichloroacetic acid, glycolic acid, Jessner's solution) Salicylic acid ointment Oral retinoids (etretinate) 	<ul style="list-style-type: none"> Surgery (curettage and surgical excision) Laser resurfacing (Er:YAG, CO₂) Dermabrasion

PDT, photodynamic therapy.

approved for the treatment of multiple AKs,^{25,26} the 0.5% cream formulation is approved for treating multiple AKs of the face and anterior scalp.²⁷

Variations in dosing schedules, even for a given concentration, are common, although 5-FU is typically applied once to twice daily for 2-6 weeks. For the 2% and 5% formulations, a typical reaction follows when the cream or solution is applied to the AK lesions or subclinical disease; erythema is noted and may be followed by “vesication, desquamation, erosion, and reepithelialization.”²⁵ When 5% 5-FU solution is applied on the face, the erosions typically commence after 7-10 days, and 3-4 weeks of therapy may be sufficient to clear AKs.²⁸ It is recommended that the 2% and 5% cream and solution formulations be used until the erosions begin, at which point therapy should be stopped.²⁵ There has been debate regarding whether intense inflammation is necessary to achieve a clinical response,²⁹ but in general, inflammation has been associated with a greater therapeutic effect.³⁰ Moisturizers, topical antibiotics, and hydrocortisone are often used concomitantly during 5-FU treatment for symptomatic care or management of reactions.³¹

Since 5-FU has been around for several decades, there are numerous studies that support its efficacy. More recent studies generally compare different formulations or

compare 5-FU to other treatment modalities. Table 43-3 lists studies that compare 5-FU cream to a vehicle control and is limited to studies involving 0.5% 5-FU. Table 43-4 lists studies that compare different concentrations of 5-FU. Table 43-5 provides a summary of the major 5-FU treatment schedule variation studies, in which a nontraditional treatment schedule was assessed and/or compared to established treatment protocols. Table 43-6 summarizes 5-FU studies that compared 5-FU to another treatment modality. Table 43-7 reviews 5-FU studies in which 5-FU was combined with another treatment modality.

Comments

Surprisingly, no RCTs were found that compared 5% 5-FU to a control, as was noted by Askew et al. in their systematic review of 5-FU studies.⁴⁴ Despite this, several conclusions can be drawn, because complete clearance rates are reported in several of the studies, and 0.5% 5-FU has been compared to placebo, albeit for a shorter duration.

The only study that compared 0.5% 5-FU to 5% 5-FU found no difference in the percent change in the number of AK lesions after treatment and the proportion of patients with total clearance, noted fewer *patient-reported* side effects with the 0.5% cream even though the incidence of common reactions was the same in both groups, and reported that a significant number of patients preferred the 0.5% formulation.⁴⁵ The study follow-up period was only 4 weeks but demonstrates that the 0.5% formulation is at least as effective as the 5% formulation in the treatment schedule utilized.

5-FU has been included in multiple RCTs and at least two systematic reviews.^{44,45} A 1- to 4-week treatment regimen with 0.5% 5-FU cream applied once daily is supported by a strong body of evidence and has a SORT rating A. A 2- to 4-week course of 5% 5-FU also has a SORT rating A. The use of 5-FU has been shown to be associated with a lower incidence of NMSC based on the Hantash et al. study, which showed a similar effect for a chemical peel and a CO₂ laser.²³ Both the 0.5% and 5% formulations are the most extensively studied, but the effectiveness of other 5-FU concentrations as a therapy for AKs can likely be extrapolated from the data, and randomized-controlled trials evaluating the effectiveness of 1% and 2% formulations are needed. Only one study was found that discussed a 1% 5-FU ointment. In that study, published in 1965, 1%, 2.5%, and 5% ointment formulations were used to treat AKs, and the patients who received the 1% and 2.5% ointment formulations initially showed clearance, but recurrences were noted.⁴⁶

Imiquimod

Imiquimod received initial approval in the United States in 1997 for the treatment of genital warts, but eventually gained approval for the treatment of “nonhyperkeratotic,

TABLE 43-2—Available 5-FU Formulations[25-27]

Concentration	Formulation	Typical treatment schedule
0.5%	cream	Once daily up to 4 weeks ²⁷
1%	cream	Twice daily for 2-6 weeks ²⁶
2%	solution	Twice daily for 2-4 weeks ²⁵
5%	cream, solution	Twice daily for 2-4 weeks ²⁵

TABLE 43–7—Clinical Studies Evaluating 5-FU in Combination with Other Treatment Modalities

Source	Study details	Level of evidence	Intervention	Treatment regimen*	N†	Select outcome measures	F/U	Comments/Conclusions
Jorizzo et al., 2006 ³⁶ (interim analysis in Jorizzo et al., 2004 ³⁵)	Prospective DB, RCT evaluating three cycles of 5-FU + cryotherapy vs 3 cycles of placebo + cryotherapy in the treatment of patients with ≥5 AKs on the face	1	Vehicle	Up to three cycles of the following: vehicle applied once daily for 7 days with cryosurgery 4 weeks post-treatment Up to three cycles of the following: 0.5% 5-FU applied once daily for 7 days with cryosurgery 4 weeks post-treatment	72	Clearance of all AK lesions in all treatment areas: 26.7% % reduction from baseline after cycle 2: 57.8% % reduction from baseline after cycle 3: 64.7% Clearance of all AK lesions in all treatment areas: 36.8% % reduction from baseline after cycle 2: 86.3% % reduction from baseline after cycle 3: 77.8%	4 weeks post-treatment after each cycle	0.5% 5-FU prior to cryotherapy resulted in a significantly greater clearance of all AK lesions and a greater % reduction from baseline compared to cryotherapy alone
Jorizzo et al., 2004 ³⁵ (interim results of Jorizzo et al., 2006 ³⁶)	Prospective DB, RCT evaluating one cycle of 5-FU + cryotherapy vs one cycle of placebo + cryotherapy in the treatment of patients with ≥5 AKs on the face	1	Vehicle followed by cryosurgery	Vehicle cream once daily for 7 days, with residual AKs at 4-week assessment treated with cryosurgery (1 to 2 second single spray, mean thaw time ~10 seconds) 0.5% 5-FU followed by cryotherapy	72	Absolute reduction in AK lesions: 13.1 (SD, 7.6) baseline, 9.1 (SD, 6.1) at 4-week assessment Percentage reduction in AK lesions at 4-week assessment, from baseline: 28.8% Percentage reduction in AK lesions at 6-month assessment, from baseline: 45.6% Absolute reduction in AK lesions: 13.7 (SD, 9.3) baseline, 4.3 (SD, 3.8) at 4-week assessment Percentage reduction in AK lesions at 4-week assessment, from baseline: 62.4% Percentage reduction in AK lesions at 6-month assessment, from baseline: 67.0%	6 months	Compared to cryosurgery alone, patients who received 5-FU for 1 week + cryosurgery had significantly greater reduction in the number and percentage reduction of AK lesions.
Bercovitch, 1987 ⁴³	DB, RCT (with bilateral comparison) evaluating 5-FU + control vs 5-FU + tretinoin in the treatment of patients with multiple AKs on the hands and forearms	1	5-FU + control cream 5-FU + tretinoin	5% 5-FU twice daily + control cream to arm 1 for average of 15.8 days (actual) 5% 5-FU twice daily + 0.05% tretinoin cream nightly to arm 2 for average of 15.8 days (actual)	20	Number of AKs, 15.7 ± 6.1 pretreatment, 3.4 ± 2.6 post-treatment (3 mo) Number of AKs, 15.3 ± 6.9 pretreatment, 4.2 ± 2.5 post-treatment (3 mo)	3 months	Arms treated with 5% 5-FU cream twice daily + 0.05% tretinoin cream nightly were superior to arms treated with 5% 5-FU cream twice daily + a control cream; statistically significant difference in response rates

*Treatment regimen represents the prescribed treatment regimen and may not necessarily represent the actual regimen completed (unless "actual" reported).

†N represents the initial number of participants in each arm of the study and does not necessarily represent the number of participants who completed the study (unless "actual" reported). AK, actinic keratosis; FU, fluorouracil; DB, double-blind; RCT, randomized controlled trial; F/U, follow-up; PDT, photodynamic therapy; SD, standard deviation; TCA, trichloroacetic acid.

nonhypertrophic actinic keratoses (AK) on the face or scalp in immunocompetent adults⁴⁷ although a more recent formulation is indicated for “clinically typical, visible, or palpable actinic keratoses (AK) of the full face or balding scalp in immunocompetent adults.”⁴⁸ Imiquimod is considered a toll-like receptor 7 agonist that activates immune cells.⁴⁸ Although the exact mechanism of action in treating AKs remains unknown,^{47,48} the topical application of imiquimod in animal studies has been shown to result in the production of cytokines, such as TNF and IFN, which may play a role in its efficacy for AK treatment.⁴⁹

Imiquimod is available in 3.75% and 5% creams. The 5% cream is approved for twice weekly application for 16 weeks.⁴⁷ Erythema and scabbing and crusting are the more common reactions; flaking, scaling, dryness, and erosions/ulcerations may also occur;^{11,50} these reactions may or may not limit further treatment. Clearance of lesions is more common in patients who develop local reactions, such as erythema, at the application site.⁵¹ The 3.75% cream is applied once daily before bedtime for 2 weeks, followed by a 2-week no-treatment period, then another 2-week treatment period with once daily application.⁴⁸ Similar types of side effects are expected when using the 3.75% formulation when compared to the 5% formulation.

In addition to the studies comparing 5-FU and imiquimod mentioned previously in this chapter, several double-blind, randomized controlled trials have been published comparing the efficacy of topical 5% imiquimod cream to vehicle controls and have yielded fairly consistent clearance rates. Nevertheless, dosing and treatment duration times have varied. Shorter treatment intervals and twice weekly dosing regimens have also been evaluated (Table 43-8). Two placebo-controlled randomized controlled trials were found evaluating 3.75% imiquimod, as well (Table 43-9).

Three meta-analyses for imiquimod as a treatment for AK were also found.^{51–53} The first, by Falagas, reviewed the efficacy of imiquimod established by earlier trials and showed (with a narrower confidence interval) that imiquimod was significantly greater than placebo for the complete clearance of AKs.⁵¹ Hadley et al. reported a 50% complete clearance rate with imiquimod use, based on 5 trials and 1,293 patients.⁵² Gupta et al. reported higher complete clearance rates based on a small number of studies, which included a case study, and performed a meta-analysis of 5-FU in the same manuscript.⁵³

The use of imiquimod is indicated for immunocompetent persons,⁴⁷ but there are reports of successful use in transplant recipients on continuous systemic immunosuppressive therapy.⁵⁴ At this time, more studies are needed before its use is considered an acceptable first-line choice for immunosuppressed patients.

Comments

Surprisingly, the highest clearance rates reported in the studies reviewed were for treatment schedules <16 weeks in

duration.^{59,63} Nevertheless, more follow-up data are available on the more traditional 16-week regimens.⁶¹ The treatment of facial or scalp AKs in immunocompetent adults with 5% imiquimod cream once daily, 2-3 days per week, for up to 16 weeks has a strength of recommendation rating (SORT) A, based on several randomized controlled trials that demonstrate consistent clearance rates and data on recurrence. Once daily, 3 days/week 5% imiquimod therapy may produce fewer recurrences than 2 days/week therapy.⁶¹ Two 4-week courses with 5% imiquimod have also demonstrated consistent clearance rates comparable to 16-week courses,^{57,59} but two shorter courses of therapy (3-4 weeks each) carry a SORT rating of B because the two randomized controlled trials yielded somewhat inconsistent results (although one evaluated two 3-week courses and the other evaluated two 4-week courses). Good quality evidence is limited on dosing with 5% imiquimod for longer than 16 weeks, and the outcomes with less frequent dosing for longer durations (once weekly for 6 months⁵⁶) are not as robust as more traditional treatment schedules, but still produce improvement. Treatment of facial or scalp AKs with the newer 3.75% imiquimod formulation for two 2-week treatment periods separated by a 2-week no-treatment period also has a SORT rating of A. The role of imiquimod in reducing the overall incidence of NMSC and its associated morbidity and mortality remains to be studied.

Diclofenac gel

Approved in the U.S. in 2000, 3% diclofenac sodium gel (DFS) is indicated for the topical treatment of AKs.⁶⁷ Diclofenac is a nonsteroidal anti-inflammatory drug and, in the topical gel formulation, is in 2.5% hyaluronate sodium;⁶⁸ it is recommended that the gel be applied twice daily for 60–90 days.⁶⁷

In addition to the studies comparing 5-FU and DFS mentioned previously, three randomized, double-blind, placebo-controlled studies that evaluated topical 3.0% diclofenac in 2.5% hyaluronan gel for the treatment of AKs were reviewed, along with one open-label study (Table 43-10). Pirard et al. conducted a meta-analysis of the three RCT studies listed in Table 43-10. For the two RCT studies reporting on a target lesion number score (TLNS), the mean quantity of gel applied was 0.5 g twice daily for an average of 75 days; the meta-analysis showed the diclofenac to be significantly more effective than the hyaluronan gel vehicle in producing a complete resolution of all target lesions in the treatment area (TLNS0), with 39.6% (42/106) having a TLNS0 30 days post-treatment. All three RCTs reported on a cumulative lesion score, as well, which included new lesions. The meta-analysis showed that the diclofenac was significantly more effective than the hyaluronan gel vehicle in producing a complete resolution of all lesions in the treatment area, which included new lesions (cumulative lesion number score, CLNS0). The average duration of treatment was 78 days, with an average of 0.42 g gel applied,

TABLE 43-10—Clinical Studies Evaluating 3.0% Diclofenac in 2.5% Hyaluronan Gel

Source	Study details	Level of evidence	Treatment modality	Treatment regimen	Treatment duration*	N†	Select outcome measures	F/U	Comments/Conclusions
Gebauer et al., 2003 ⁷³	DB, RCT evaluating 3.0% diclofenac in 2.5% hyaluronan gel vs vehicle control in the treatment of patients with solar keratoses on the head, neck, hands, or arms for 5 cm ² area.	1	Hyaluronan gel	0.25 g twice daily	12 weeks	77	Mean lesion count reduction at EOT: 4.7 ± 6.9 Mean lesion count reduction at 16-week post-treatment visit: 2.4 ± 4.3 (23.6%) Complete resolution at EOT: 13% Complete resolution at 16-week post-treatment: 10%	16 weeks from baseline	At 16-weeks post-treatment, diclofenac gel significantly more effective than hyaluronan vehicle in reducing mean lesion count and producing complete resolution.
Rivers et al., 2002 ⁷⁴	DB, RCT evaluating 3.0% diclofenac in 2.5% hyaluronan gel vs vehicle control for the treatment of patients with ≥ 5 AKs within up to three 5 cm ² treatment areas in at least one body area, including the forehead, central face, scalp, and dorsum of hands	1	Hyaluronan gel Hyaluronan gel	0.5 g twice daily topical application 0.5 g twice daily topical application	30 days 60 days	49	See comments. Percentage of patients with complete resolution of all target lesions 30 days after end of treatment: $10\%^{74}$ $\geq 75\%$ clearance of target lesions: $22\%^{69}$ See comments.	30 days after EOT	For all indices measured (target and cumulative lesion scores, lesion total thickness score, investigator and patient global improvement indices), the proportion of patients achieving each outcome measure was greatest in the 60-day treatment arm, followed by the 30-day treatment arm, then the 60-day placebo arm, then the 30-day placebo arm; statistically significant difference was noted between the 60-day placebo and treatment arm, but not between 30-day placebo and treatment arms.
			3.0% diclofenac in 2.5% hyaluronan gel 3.0% diclofenac in 2.5% hyaluronan gel	0.5 g twice daily topical application 0.5 g twice daily topical application	30 days 60 days	49	Percentage of patients with complete resolution of all target lesions 30 days after end of treatment: $33\%^{74}$ $\geq 75\%$ clearance of target lesions: $56\%^{69}$	48	Percentage of patients with complete resolution of all target lesions 30 days after end of treatment: $33\%^{74}$ $\geq 75\%$ clearance of target lesions:

Wolf et al., 2001 ⁷⁵	DB, RCT evaluating 3.0% diclofenac in 2.5% hyaluronan gel vs vehicle control for the treatment of patients with ≥ 5 AKs in up to three 5 cm ² treatment areas (forehead, central face, scalp, arms, hands)	1	Hyaluronan gel	0.5 g twice daily	90 days	59	Percentage of patients with complete resolution of all target lesions 30 days after end of treatment: 20% ⁷⁵ $\geq 75\%$ clearance of target lesions: 48% ⁶⁹	30 days after EOT	When compared with the hyaluronan vehicle, the diclofenac treatment group had a significantly greater percentage of patients with complete resolution of all target lesions and complete resolution of target and new lesions
	Rivers et al., 1997 ⁷⁶	2	Open-label study evaluating 3.0% diclofenac in 2.5% hyaluronan gel in the treatment of patients with ≥ 1 AK on the head, neck, or hands	3.0% diclofenac in 2.5% hyaluronan gel	Up to 180 days	29	Complete response at 30 days post-treatment: 81% (22/27)	30 days after drug stopped	Topical diclofenac is useful for the treatment of AKs; patients with only 1 AK eligible to participate in study

*Treatment regimen represents the prescribed treatment regimen and may not necessarily represent the actual regimen completed (unless "actual" reported)

[†]N represents the initial number of participants in each arm of the study and does not necessarily represent the number of participants who completed the study (unless "actual" reported)
AK, actinic keratosis; DB, double-blind; RCT, randomized controlled trial; F/LJ, follow-up; TLNS, Target Lesion Number Score (number of lesions in a designated area at the initial assessment); CLNS, Cumulative Lesion Number Score (total number of lesions in a designated area, throughout the study); EOT, end-of-treatment.

and 39.1% (70/179) patients treated had a CLNS0 30 days post-treatment.⁶⁸ The authors of the two cited randomized controlled trials re-analyzed their data to assess partial clearance rates as well.⁶⁹

In addition to the placebo-controlled studies, Kose et al. compared the efficacy and tolerability of 3% diclofenac sodium gel to 5% imiquimod in an open-label study involving 49 patients with AKs on the scalp and face. Twenty-four patients were treated with DFS and 25 patients were treated with 5% imiquimod cream three times weekly for 12 weeks. Although the treatment duration for the DFS group is unclear, the authors reported no significant differences in investigator and patient global improvement indices between the treatment groups.⁷⁰ DFS has also been studied in combination with cryotherapy;⁷¹ in that study, complete target lesion clearance was noted in 64% of the patients treated with cryosurgery followed by DFS, and in 32% treated with cryosurgery alone.

Comments

Patients may prefer and experience fewer side effects with diclofenac when compared to 5-FU, but the duration of therapy for DFS is substantially longer than for 5-FU (90 days vs 4 weeks), but comparable to traditional 5% imiquimod schedules (16 weeks), and based on a Smith et al. study, the majority of patients are satisfied with 5-FU treatment despite experiencing more side effects.³⁹ Based on the three RCTs reviewed above, which show consistent results, and the meta-analysis of the RCTs, twice daily application of 3% diclofenac in 2.5% hyaluronan gel for 60-90 days has a SORT rating of A and certainly has a role in the management of AKs. Total treatment durations of less than 60 days (particularly for 30 days only) are not supported by good quality evidence. It should be emphasized that other topical formulations are available for diclofenac, but only the “3% diclofenac in 2.5% hyaluronan gel” should be utilized for the treatment of AKs.⁷²

Photodynamic therapy

Photodynamic therapy involves the use of a photosensitizing agent (typically via topical application) followed by phototherapy. Aminolevulinic acid (ALA) and methyl aminolevulinate (MAL) are common topical agents used for photosensitization; both are not actual photosensitizers, but protoporphyrin IX precursors.⁷⁷⁻⁷⁹ Prior to the application of ALA or MAL, pretreatment of affected areas is typically performed to allow for better absorption of either product. Pretreatment can be accomplished with gentle curettage or a number of different topical products.⁷⁹ In the U.S., ALA was approved for use in 1999 and MAL was approved in 2004.²⁴ ALA is available in the U.S. as an applicator with a 20% ALA solution.⁷⁷ MAL is available in the U.S. as a 16.8% cream,⁷⁸ the same

as MAL 160 mg/g available in parts of Europe.⁸⁰ The application of the topical photosensitizing agent is followed by an incubation period of hours, depending on the specific product. The area is wiped or rinsed off prior to exposure to the light source. A variety of light sources that emit light in the visible spectrum (400-700 nm) can then be used.⁸¹ Blue light sources, red light sources, intense pulsed light, and pulse-dye lasers are more commonly utilized.⁷⁹

Ultimately, PDT creates reactive oxygen intermediates in the tissue, which leads to cell death.⁸² Two PDT sessions are typically necessary to achieve a complete response.⁸² Common side effects include pain,⁸³ erythema, a burning sensation, crusting, and erosions.⁷⁹ Evidence does not support the use of topical anesthetics for pain relief.⁸³ Several randomized controlled trials and open-label trials were found examining ALA-PDT and MAL-PDT. Table 43-11 reviews ALA-PDT trials, Table 43-12 reviews MAL-PDT trials, and Table 43-13 reviews trials comparing PDT to cryotherapy.

Comments

The only randomized, investigator-blinded ALA-PDT trial utilized blue light,⁸⁴ and the four blinded randomized controlled trials investigating MAL-PDT utilized a red light source with several different total doses.^{80,85-87} Although access may be an issue,⁸¹ PDT is an acceptable treatment option that has consistently resulted in high clearance rates. In fact, a study by Sotiriou et al. compared two treatment sessions with ALA-PDT to 5% imiquimod in short treatment courses in an intraindividual comparison study and found similarly high overall response rates at a 6-month follow-up for both therapies (65.32% for PDT, 55.65% for 5% imiquimod cream).⁸⁸ For nonhyperkeratotic lesions, treatment of facial or scalp AKs with 1-2 sessions of MAL-PDT with red light or ALA-PDT with blue light has a SORT rating of A, based on consistent clearance rates and cosmetic outcomes.

Topical retinoids

Retinoid creams investigated for the treatment of AKs include tretinoin and adapalene. Retinoids show antiproliferative effects and have been used in the management of photodamaged skin.⁹⁹ A variety of formulations of retinoids are available, but their use in AKs is off label in the United States.⁹⁹

Tretinoin has been studied alone or in combination with other modalities. As previously mentioned, Bercovitch et al. found that the combination of 5% 5-FU and tretinoin had a significantly greater response rate compared to 5% 5-FU and a control cream.⁴³

Kligman et al. reported on three different studies evaluating the effectiveness of various strengths of

TABLE 43-11—Clinical Studies Evaluating ALA-PDT in the Treatment of AKs

Source	Study details	Level of evidence	Treatment modality	Treatment regimen*	N†	Select outcome measures	F/U	Comments/Conclusions
Tschen et al., 2006 ⁸⁹	Open-label, phase IV study evaluating ALA-PDT for the treatment of patients with 6-12 nonhyperkeratotic AK lesions on the face or scalp	2	ALA-PDT	Application of 20% ALA solution as double coat, incubation period of 14-18 hours, followed by PDT blue light (10 J/cm ²); retreatment of remaining target lesions at month 2	110	Percentage of target lesions cleared after two months (prior to second treatment): 72% (476/661)	12 months	At 12 months from the initial treatment, 39.8% of patients had 100% of the lesions cleared; 78.3% of lesions were clear at 12 months (458/585)
Piacquadio et al., 2004 ⁸⁴	Investigator-blinded, RCT evaluating 20% ALA with blue light vs vehicle with PDT in the treatment of patients with 4-15 nonhyperkeratotic discrete target lesions on the face or scalp	1	Vehicle-PDT	Vehicle applied to lesions twice followed by PDT blue light (10 mW/cm ²) as one treatment, with retreatment of any remaining target lesions at week 8	62	Complete response rates at week 12: 8% (4/52)	12 weeks after first treatment	Treatment with ALA-PDT resulted in a significantly greater complete response rate at week 8 and week 12 evaluations, when compared with the vehicle-PDT control
Alexiades-Armenakas et al., 2003 ⁹⁰	Prospective, randomized study evaluating 20% ALA-PDT with LP PDL compared to LP PDL in the treatment of patients with AKs on the head, extremity, and trunk (including hyperkeratotic lesions)	1	LP PDL	Single treatment with PDL (595 nm, 4-7.5 J/cm ²)	5	Mean % of head lesions cleared at 8 months: no decrease in lesions noted Mean % of extremity lesions cleared at 8 months: no decrease in lesions noted Mean % of trunk lesions cleared at 4 months: no decrease in lesions noted Mean % of head lesions cleared at 8 months: 90.32%	8 months	ALA + LP PDL are effective at reducing lesion counts with good cosmesis; no difference noted between 3-hr and 14-18 hr incubation periods.
			ALA-PDT with LP PDL	Single treatment application of 20% ALA for 3 hours or 14-18 hours followed by PDL (595 nm, 4-7.5 J/cm ²)	36	Mean % of extremity lesions cleared at 8 months: 100% Mean % of trunk lesions cleared at 4 months: 65%

tretinoin creams. The first study was a double-blind study, that followed 138 patients treated with 0.05% tretinoin cream nightly for 3 months and found no change in the number or size of the AKs. The study had an open, uncontrolled extension utilizing the same 0.05% tretinoin cream for durations up to 15 months and showed a greater percentage reduction in lesions at 16 months (approximately 50%) compared to 10 months (approximately 10%), which was a significant decline when compared to baseline. A second study was conducted that was double-blind and evaluated tretinoin 0.05% cream versus a vehicle control in a parallel fashion (266 subjects assigned to tretinoin, 261 assigned to vehicle); creams were applied twice daily. No statistically significant difference was noted between the treatment groups when comparing the mean decrease in the number of lesions. In a third study, the concentration of tretinoin was increased to 0.1%, and again evaluated over 6 months, with the same protocol used from the second study: 203 patients completed 6 months of tretinoin treatment, while 207 patients completed 6 months of vehicle application. A 55% reduction from baseline in the AK count was noted in the tretinoin group, while a 41% reduction was noted in the vehicle group, a difference that was statistically significant.¹⁰⁰

Surprisingly, in the Veterans Affairs Topical Tretinoin Chemoprevention Trial (VATTC) there was an excessive number of deaths in the treatment group that received 0.1% tretinoin cream twice daily to the face and ears (compared to the vehicle control cream). After an extensive discussion regarding potential explanations for the excessive mortality, the authors concluded that it was unlikely that the excess deaths in the tretinoin-treated group are attributable to the medication.¹⁰¹

Comments

The role of topical retinoids in the treatment of AKs is still unclear. The recent VATTC trial data will likely dissuade some practitioners from using 0.1% tretinoin cream for facial AKs, but more evidence is needed to establish any causal relationship to an increase in mortality. For the treatment of AKs, the use of adapalene gel once to twice daily for 9 months has a strength of recommendation of B because only one good-quality randomized controlled trial was found. The role of tretinoin cream in the management of AKs remains unclear.

Salicylic acid ointment

Swinehart studied the use of a methyl salicylate-buffered, croton oil-containing 50% salicylic acid ointment peel in the treatment of actinic damage of the hands and forearms and reported successful results in 11 patients (with removal of ≥90% cutaneous lesions, which may have included seborrheic keratoses, actinic keratoses, and lentigines), but

did not specify the follow-up period¹⁰⁵ and was graded as a level 3 in terms of study quality.

Comments

The use of salicylic acid ointment in the treatment of AKs has a SORT rating of C, because its use is based on a case series for the study of treatment.

Oral retinoids

Two studies were found that addressed the role of the oral retinoid etretinate in the treatment or prevention of actinic keratoses;^{106,107} however, etretinate is no longer available in the U.S. market.²⁴ The first study, by Moriarty et al. reported a complete or partial response in 37/44 patients treated with etretinate and only 2/42 treated with placebo.¹⁰⁶ The second study, authored by Watson in 1986, suggested that etretinate may serve a preventive role in the management of AKs.¹⁰⁷

One study was found that addressed the role of oral isotretinoin in combination with topical 5-FU. That study, conducted by Sander et al. followed 27 patients with widespread AKs who were treated with 5% 5-FU twice daily and oral isotretinoin, 20 mg daily, with a median treatment duration of 21 days, and median follow-up of 12 months: 22/27 subjects had complete regression of palpable AKs. The authors suggested that the treatment regimen was effective at rapidly eliminating thick AKs.¹⁰⁸

Acitretin for the prevention of skin cancer has also been studied in transplantation recipients. McNamara et al. followed five heart transplant recipients on acitretin for the prophylaxis of cutaneous malignancies. Although no specific outcome measures were discussed, it was noted that actinic keratoses were resolving during the treatment period.¹⁰⁹ In a larger double-blind, placebo-controlled study of kidney transplant recipients, Bavinck et al. prescribed acitretin 30 mg daily for 6 months. Nine of the 19 patients receiving placebo developed 18 new skin cancers (15 SCC, 1 SCC in situ, 2 BCC), compared to 2 of 19 patients treated with acitretin who developed SCC; patients treated with acitretin also experienced a reduction in keratotic skin lesions (common warts, flat warts, solar keratoses), although substantial relapses were noted after treatment (Table 43-14).¹¹⁰

Comments

The evidence for the use of oral retinoids approved in the U.S. in the treatment of AKs is based mainly on case reports; more evidence is needed before oral retinoids are recommended on a routine basis, particularly for those individuals who have not undergone any organ transplantation procedures and are not immunosuppressed (and at greater risk of developing cutaneous SCC¹¹¹). Thus, the use of oral retinoids for the treatment of AKs has a C strength

or recommendation rating, as there is limited evidence to support the use of oral retinoids for the management of AK lesions other than in special circumstances (etretinate in organ transplant recipients).

Chemical peels

Glycolic acid, trichloroacetic acid, and Jessner's solution are examples of agents used for chemical peels. Jessner's solution is resorcinol, salicylic acid, and lactic acid.¹¹²

Tse et al. performed a split-face study in which 13 patients with AKs treated the right side of their faces with 70% glycolic acid and 35% trichloroacetic acid (GA-TCA) and the left side of their face with Jessner's solution and 35% TCA (JS-TCA). Patients were treated with 0.05% tretinoin cream for two weeks prior to treatment, and tretinoin was resumed 30 days post-treatment. Three independent evaluators utilized a clinical improvement scale to measure outcomes (0 = no response, 1 = fair, 2 = good, 3 = excellent) for AKs and several other dermatologic conditions, such as actinic lentigines. The clinical response score for AKs treated with GA-TCA was 1.58 (fair to good clinical response), and was slightly higher than the 1.33 score for AKs treated with JS-TCA (fair clinical response). Tse et al. concluded that the GA-TCA peel was an effective medium-depth peel for the treatment of photodamaged skin, not specifically AKs.¹¹² The outcome measures used in this study limit the study conclusions.

Witheiler et al. evaluated the long-term efficacy of JS-TCA compared to 5% 5-FU, also in a split-face study. Fifteen patients applied JS-TCA once to the left side of their face and 5% 5-FU cream twice daily for 3 weeks to the right side of their face, with 8 patients available for follow-up at 32 months. At a 12-month follow-up visit, a 78% and 79% reduction in the number of AKs was noted on the left and right sides of the face, respectively (JS-TCA-treated side and the 5-FU treated side, respectively). However, at the 32-month follow-up visit, a substantial increase in the number of lesions was noted for both treatment groups (with certain patients being affected more than others).¹¹³

Comments

Chemical peels, namely TCA, GA-TCA, and JS-TCA, have all been shown to be effective in reducing AK lesion counts. The use of a 30% trichloroacetic acid peel for the treatment of AKs has a SORT rating of B. The Hantash et al. study mentioned in the 5-FU section deserves further mention because of the more useful outcome measures reported. In that study, a TCA peel was compared with 5-FU and carbon dioxide laser resurfacing, and it resulted in a considerable reduction in the number of AKs at a 3-month follow-up (89.0%) and a reduced incidence of NMSC compared to placebo.²³

What is the evidence behind the use of nonpharmacologic therapies?

Cryotherapy/cryosurgery (liquid nitrogen freezing)

Cryotherapy, or cryosurgery, uses liquid nitrogen to induce tissue injury by a freezing mechanism. The freezing and thawing are both felt to play a role in tissue injury.¹¹⁴ The liquid nitrogen can be applied to the skin lesion or surface using a cotton-tipped applicator or by using a handheld spray device.

Lubritz et al. reported a 98.8% cure rate when cryotherapy was used on 70 patients with 1018 lesions (thaw time ranged from 20 to 45 seconds). Treated lesions had definite borders and were only included if an accurate count could be determined. Follow-up ranged from 1 to 8.5 years, with only 12 recurrences.¹¹⁵ More recent prospective data, though, revealed smaller cure rates^{98,116} and could represent variability in technique and AK lesion characteristics. Szeimies et al. prospectively evaluated the use of cryotherapy compared to PDT and found complete response rates after 3 months of 75.3%.⁹⁸ Thai et al. prospectively evaluated the use of cryotherapy in 90 patients (421 AKs) and reported a 39% complete response rate for freeze times of less than 5 seconds, a 69% complete response rate for freeze times greater than 5 seconds, and an 83% complete response rate for freeze times greater than 20 seconds,¹¹⁶ supporting the notion that variability in the practitioner technique has a substantial influence on the treatment outcomes.

An often cited criticism of cryotherapy is its inability to treat numerous lesions; extensive cryosurgery used for more extensive disease, or cryopeeling, has been cited as having fewer recurrences than 5-FU when measured at a 1-3 year follow-up interval.¹¹⁷ Chiarello (Table 43-15) reported on 373 patients with 34,604 actinic keratoses treated with cryopeeling, in which individual lesions and surrounding areas were treated with cryotherapy. At 6-12 months, a recurrence rate of 9% was noted in 167 patients. At 12-18 months, 12% of the 124 patients examined had new or recurrent lesions. Follow-up ranged from 6 months to 6.5 years.¹¹⁷ Despite the positive outcomes, anecdotally this technique is not widely used and more studies are needed prior to this treatment's being recommended.

TABLE 43-15—Summary of Chiarello Data¹¹⁷

Follow-up interval, months	Number of patients rechecked	New or recurrence rate, %
6-12	167	9
12-18	124	12
18-24	92	16
24-30	71	22
30-36	64	22
36-42	50	40

Comments

The success of cryotherapy will depend on a variety of factors, including freeze time and the extent of the treated field. For localized AK disease, cryotherapy has a strength of recommendation of A. Ease of use, efficacy, and versatility help maintain cryotherapy as an effective treatment choice for AKs.

Surgery (surgical excision or curettage)

Despite their being cited as a mainstay of therapy in the management of AKs¹¹⁸ and a common form of therapy,¹¹⁹ no patient-centered studies were found that evaluated curettage or surgical excision. It is unclear how frequently curettage is actually performed for AKs. Even though “other local excision or destruction of lesion or tissue of skin and subcutaneous tissue” was performed at 75.3% of all visits for AKs from 1993-1994 according to Feldman et al.² it is not clear which specific procedures were used when that term was referenced; the majority of those procedures could have been cryosurgery and not curettage. Furthermore, surgical excision or biopsy is performed when the nature of the lesion is unclear and suspicious for more invasive disease or other NMSCs and is not considered a treatment for an AK.

Comments

Curettage is generally thought to be appropriate for hypertrophic AKs and isolated lesions refractory to other treatments, and it is also helpful when the exact nature of the lesion is in question, because a histologic specimen may be submitted (but it may not be the ideal method for evaluating the histology).¹²⁰ Superficial curettage is also used before other therapies, such as PDT or cryotherapy.⁹⁸ Because the majority of the literature that discusses curettage and excisional surgery is based on opinion and perhaps usual practice, the strength of recommendation rating for curettage in the treatment of actinic keratoses is C.

Lasers

Two RCTs were found, one evaluating the use of a CO₂ laser and the other an Er:YAG laser. Ostertag et al. compared 5-FU to Er:YAG laser resurfacing and found no statistically significant difference in the mean decrease in AK numbers per patient between the two treatment groups; treatment with the Er:YAG laser resulted in a significantly greater difference in the mean percentage of lesions cleared per patient when compared to 5-FU (mean percentage of lesions cleared per patient at 6 months and 12 months post-treatment: 94.4% and 91.1%, respectively).⁴⁰ The efficacy of the Er:YAG laser has been supported by smaller cohort studies as well.^{121,122}

Hantash et al. evaluated the role of carbon dioxide laser resurfacing for AK treatment and skin cancer prophylaxis; patients treated with CO₂ laser resurfacing demonstrated a considerable reduction in the number of AKs at 3-month follow-up (92.0%) and a significantly lower cancer incidence when compared to a control group.²³ Trimas et al. used a CO₂ laser to treat 14 patients with AKs and SCC in situ disease of the face, with a follow-up range of 6-24 months, and noted no clinical evidence of disease post-treatment.¹²³ The long-term efficacy of CO₂ laser resurfacing was evaluated by Sherry et al. who reported on 31 patients with AKs treated with CO₂ laser resurfacing. Fifty-eight percent (18/31) of patients had no evidence of AKs at their follow-up visits. The mean time to recurrence in the 13 patients with recurrent disease was 23.2 months.¹²⁴

Comments

The use of laser resurfacing (Er:YAG or CO₂) for the treatment of AKs has a SORT rating of B, because each modality has at least one RCT supporting its use.

Dermabrasion

Several studies have evaluated the effects of dermabrasion on the prophylaxis and treatment of AKs. Coleman et al. followed patients for 1-5 years after being treated with dermabrasion for refractory AKs.¹²⁵ At a 2-year follow-up, 19/23 (83%) patients had no reappearance of AKs, while at a 5-year follow-up, 7/13 (54%) had no reappearance of any AKs. The study concluded that dermabrasion may play a role in the treatment of patients with severe disease who need frequent treatments. Winton et al. studied dermabrasion for scalp actinic damage in 5 patients and reported complete clearance of actinic keratoses 6 weeks postoperatively, while citing the additional beneficial effects of reduction of dyspigmentation and telangiectasias when compared to a group of patients treated with 5-FU.¹²⁶

Comments

The long-term follow-up data for dermabrasion is promising based on the aforementioned studies, with low recurrence rates noted at 2-year follow-up; dermabrasion was also cited as an effective prophylactic measure.¹²⁵ RCTs are needed to support these smaller studies, and, until then, dermabrasion will likely play a smaller, relatively selective role in the overall management of AKs in typical physician practices. Dermabrasion for the treatment of AKs has a SORT rating of C.

CONCLUSION

The justification to treat AKs for the prevention of NMSC is supported by the current literature. Hantash et al.²³ showed a significantly lower incidence of new NMSC in patients who received either 5% 5-FU, a 30% TCA chemical

peel, or treatment with a CO₂ laser, when compared with placebo. More studies like this are needed to truly define the role of treatment, observation, and follow-up (Table 43-16).

The study by Witheiler et al.¹¹³ while small in numbers, had fairly good long-term follow-up and showed that patients treated with a topical therapy, such as a

chemical peel or 5-FU, will likely present again with additional AKs, supporting the role of follow-up for patients with AKs—especially those with significant disease noted at their visit.

5-FU, imiquimod, diclofenac, cryosurgery, and PDT are all effective at reducing the number of AK lesions and all play a role in AK management. Chemical peels, lasers,

TABLE 43-16—Summary of Actinic Keratosis Treatments and Strength of Recommendations*

Therapy	Recommendation	SORT rating
5-FU		
0.5% 5-FU cream	Once daily topical application for 1-4 weeks for the treatment of multiple actinic keratoses on the face/frontal scalp	A
5% 5-FU cream	Twice daily topical application for 2-4 weeks for the treatment of multiple actinic keratoses	A
Imiquimod		
3.75% imiquimod cream	Once daily for two 2-week treatment periods, separated by a 2-week period without treatment, for the treatment of multiple nonhyperkeratotic, nonhypertrophic actinic keratoses on the face/balding scalp	A
5% imiquimod cream	Once daily, 2-3 d/week, for up to 16 weeks for the treatment of multiple nonhyperkeratotic, nonhypertrophic actinic keratoses on the face/scalp	A
5% imiquimod cream	Once daily, 2-3 d/week for two courses of therapy (3-4 weeks each), for the treatment of nonhyperkeratotic, nonhypertrophic actinic keratoses on the face/scalp	B
3% Diclofenac sodium in 2.5% hyaluronan gel		
3% diclofenac sodium in 2.5% hyaluronan gel	Twice daily application for 60-90 days for the treatment of actinic keratoses on the head, neck, hands, or arms	A
PDT		
ALA-PDT	1-2 sessions 20% ALA-PDT with blue-light source for the treatment of thin to moderately thick, nonhyperkeratotic actinic keratoses on the face or scalp	A
MAL-PDT	1-2 sessions of MAL-PDT with narrowband red-light source for the treatment of thin to moderately thick, nonhyperkeratotic actinic keratoses on the face or scalp	A
Topical retinoids		
adapalene gel	Once to twice daily for 9 months for the treatment of actinic keratoses on the face, ears, scalp, arms and dorsum of hands	B
Salicylic acid		
salicylic acid cream	For the treatment of actinic keratoses on the hands and forearms	C
Oral retinoids		
etretinate	For the prevention of AKs/SCC in transplant patients	C
Chemical peels		
trichloroacetic acid, glycolic acid, or Jessner's solution	For the treatment of actinic keratoses on the face	B
Cryotherapy		
liquid nitrogen	For the localized treatment of actinic keratoses	A
Curettage		
curettage	For the treatment of hypertrophic actinic keratoses	C
Laser		
laser resurfacing (Er:YAG or CO ₂)	For the treatment of actinic keratoses on the face or scalp	B
Dermabrasion		
dermabrasion	For the treatment of refractory actinic keratoses on the face or bald scalp	C

*Unless otherwise stated, recommendations apply to immunocompetent, non-pregnant, otherwise healthy adults.

What We Know

- Some AKs will progress to NMSC and some will regress
 - It is difficult to predict which AKs will progress to NMSC and which will regress
 - Given this difficulty, treatment is generally recommended
 - If treatment is not performed, close clinical follow-up is recommended
- AK therapies with SORT A ratings include select formulations, types, and/or schedules of the following: 5-FU, imiquimod, diclofenac, PDT, cryotherapy
- AK therapies with SORT B ratings include select formulations, types, and/or schedules of the following: adapalene, lasers, and chemical peels
- Sunscreen use prevents AKs from forming and is recommended
- Many factors are considered when choosing AK therapy,¹²⁰ including patient-specific factors (location, number, thickness, patient ability to comply with treatment) and physician-specific factors (experience, training, and ability to utilize a therapy, such as dermabrasion, laser therapy, PDT, or chemical peels)
- AKs resistant to treatment should be biopsied

topical retinoids, and dermabrasion show promise in the management of AKs, but their roles are less well-defined and remain to be elucidated.

For localized or isolated lesions, cryotherapy can be considered first-line therapy. Cryotherapy is easy to perform, has few side effects, and does not depend on patient compliance for efficacy. Curettage should be reserved for thicker hyperkeratotic lesions or may be utilized prior to procedures like PDT. For treatment of widespread and/or subclinical disease (field treatment), consideration should be given to 5-FU, imiquimod, PDT, and 3% diclofenac gel. Factors that may dictate treatment include physician skill, experience, and availability of resources (laser, dermabrasion, PDT, chemical peels), specific patient characteristics (likelihood of patient compliance, patient ability to handle anticipated side effects), and the location of AK disease (periorbital vs scalp). In addition, some patients may respond to one field therapy and fail to respond to another. A biopsy is advisable when patients have failed multiple therapies, or sooner if suspicious lesions are present.

Treatment of Basal Cell Carcinoma

Keyvan Nouri, M.D., Sonal Choudhary, M.D., and Michael Patrick McLeod, B.S., M.S.

INTRODUCTION

EPIDEMIOLOGY

Basal cell carcinoma (BCC) is the most common malignant neoplasm encountered in humans; however; it is difficult to determine the absolute incidence of BCC as it is usually excluded from cancer registry statistics.^{1,2} The average risk for a Caucasian to develop BCC is 30%.³ In dark-skinned races, the incidence of BCC is 19 times less than in Caucasians.⁴ Males are affected by BCC twice as often as females.¹ Older individuals are affected more than younger individuals, as only 20% of BCCs occur in patients younger than 50 years. Rates are highest among elderly males, however, the incidence of BCC is increasing in young women.⁵

In the United States, approximately 800,000 new cases of BCC are diagnosed annually.⁶ The incidence of BCC increases as Caucasians move closer to the equator and is known to be increasing worldwide.^{7,8} Australia has the highest known BCC incidence, at 1-2% of the population per year, which correlates to a rate of 849 per 100,000 in males and 605 per 100,000 in females.^{1,4} According to one model, BCC incidence is predicted to increase in the UK until 2040.⁹

ETIOLOGY

Familial and sporadic cases of BCC occur because multiple components of the Sonic Hedge Hog (SHH) pathway become dysregulated.¹⁰ Inactivation or deletion of PTCH1 (protein patched homologue 1) occurs in approximately 30%-60% of sporadic BCCs.^{11,12} Another 10-20% of sporadic BCC cases are due to mutations in Smoothened (SMO) that cause it to become resistant to PTCH1-mediated inhibition. Therefore, SMO becomes constitutively activated.^{13,14} Together, mutations in PTCH1 or SMO account for about 90% of sporadic BCCs.¹⁰

Protein patched homologue 1 (PTCH1) normally suppresses the seven transmembrane G-protein coupled receptor SMO by keeping it sequestered in intracellular vesicles where it is inactive. Hedgehog interacting protein (HIP) is a transmembrane protein that binds SHH and prevents it from binding to PTCH1.¹⁰ When secreted

SHH protein binds to PTCH1, PTCH1 undergoes endocytosis and becomes degraded, thus losing its ability to inhibit SMO. When SHH binds to PTCH1, SMO becomes phosphorylated. SMO phosphorylation may be catalyzed by several kinases, including protein kinase A (PKA), G protein coupled receptor kinase 2 (GRK2), and casein kinase 1.^{10,15-18} SMO then translocates to the cell surface and becomes active, leading to increased GLI transcription factor family activation via freeing GLI from the fused (Fu)-suppressor of fused complex (sFu).^{10,19} Nearly 50% of BCCs are known to overexpress SHH and therefore overwhelm HIP, thus enabling more SHH to bind to PTCH1.^{20,21} Ninety percent of BCCs are known to overexpress GLI1.²¹ GLI3 can act as either a transcriptional activator or repressor, while GLI1 and GLI2 are thought to act as only transcriptional activators.¹⁹ It is believed that the Hedgehog pathway is inactive in adults, and its reactivation in the interfollicular basaloid keratinocytes, hair follicles, and sebaceous glands is what leads to the cutaneous findings of BCC.^{10,22}

Fifty percent of the sporadic cases of BCC are known to be caused by mutations in the p53 tumor suppressor gene.² UVB radiation from 290 to 320 nm is known to cause CC→TT and C→T transition mutations at dipyrimidines.² Acute intermittent sun exposure that leads to sunburns is thought to be a major risk factor for developing BCC. People with skin phototypes I and II, albinos, those exposed to x-ray therapy for acne, those with high UVR exposure as a child, and people who have ingested arsenic are at increased risk of developing BCC.²³

Nevoid basal cell carcinoma syndrome (NBCCS) is inherited in an autosomal dominant fashion.¹ The NBCCS gene is located on chromosome 9q22.3-q31. Eighty percent of NBCCS cases involve PTCH mutations leading to a shortened PTCH protein that is deficient in its ability to suppress SMO.¹⁰ Therefore, in this pathologic state, the SHH pathway becomes constitutively active, leading to increases in downstream pathway products of GLI1 and GLI2.

DIAGNOSIS

The diagnosis of BCC is made clinically and confirmed with a biopsy and by studying the histology under the microscope.

FIGURE 44-1 Clinical picture of basal cell carcinoma-1.

There are primarily five clinical types of BCC: nodular, sclerosing, superficial, pigmented, and cystic¹ (Figures 44-1 and 44-2). The most common form of BCC is the nodular subtype. It is characterized by a papule/nodule that appears translucent or “pearly” with telangiectasia.²³ The center may ulcerate or erode and can lead to crust and scale as well as bleeding.¹ This ulceration is responsible for what was formerly termed a “rodent ulcer.” Poor cohesive forces can be noted upon biopsy of a nodular BCC; and can be fully appreciated with a curette.¹ Sclerosing BCC is also known as morpheaform and tends to be white to pale yellow in color with a waxy appearance.¹ It can be flat or mildly raised, and can be mistaken for localized scleroderma.¹ Superficial BCC is clinically characterized by being round to oval shaped, with erythema and scaling often present, allowing for confusion between eczema, psoriasis, extramammary Paget’s disease, or Bowen’s disease.¹ It is less aggressive than the other clinical subtypes of BCC, and is often found on the trunk and extremities.¹ The

FIGURE 44-2 Clinical picture of basal cell carcinoma-2.

pigmented subtype of BCC contains areas of melanin that can yield a brown, blue, or black color. The lesion typically exhibits a translucent, pearly border.¹ Histologically, pigmented BCCs most commonly have a nodular pattern. Cystic BCCs are considered a variant of nodular BCCs and present as a round, smooth, cystic mass.¹

Nevoid basal cell carcinoma syndrome presents with multiple BCCs, as well as medulloblastomas, odontogenic cysts, meningiomas, ovarian fibromas, fibrosarcomas, cardiac fibromas, and rhabdomyosarcomas.¹⁰ In 50-75% of NBCCS cases, multiple small pits on the soles and palms are present.¹ Seventy-five percent of NBCCS cases have partial or complete bridging of the sella turcica.¹ There is variability in how the BCCs in NBCCS can present, with the median age of first BCC being 25¹⁰ and the median number of BCCs being eight.¹ Additionally, patients can have no BCCs, or even more than 1000.^{1,10}

Histologically, BCC consists of a solid tumor with large, oval, deep-blue staining atypical basal cells.²³ There is a peripheral palisading arrangement, with little amounts of anaplasia, small numbers of mitoses, and variable quantities of mucinous stroma.²³ There are five major histologic patterns: nodular, superficial, micronodular, infiltrative, and morpheaform. Nodular accounts for 21% of BCC histologic patterns and is typically well developed and well defined, with peripheral palisading and consisting of a rounded neoplastic mass of cells.¹ The superficial BCC accounts for approximately 21% of BCC histologic patterns. It extends from the basal layer of the epidermis with atypical buds of basal cells. The micronodular type of BCC makes up about 15% of BCC histologic patterns and is characterized by hair bulb-sized rounded tumor nodules that are well demarcated and exhibit peripheral palisading. Infiltrative BCC accounts for approximately 7% of BCC patterns. It is characterized by a jagged configuration of variably sized tumor islands. The morpheaform histologic type of BCC constitutes 1% of BCC patterns and usually demonstrates a fibrous stroma with small elongated islands that appear as strands.

RESEARCH QUESTIONS

Various aspects of basal cell carcinoma are discussed in the chapter ahead and have been summarized as an evidence-based table (Table 44-1) for an overview.

How does histology help to determine treatment type in BCC?

The choice of treatment modality for BCCs should depend on the site and size of the tumor and whether the BCC shows indolent (superficial or nodular BCC) or aggressive growth (infiltrative BCC or basosquamous carcinoma).^{24,25} The treatment of BCCs with mixed histology is based on the most aggressive variety present in the tumor.²⁴ Although

TABLE 44-1—Evidence-Based Table Summarizing Various Research Questions Related to Basal Cell Carcinomas

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
How does histology help to determine treatment type in BCC?				
Smeets NW, et al., 2004 ²⁵	To evaluate the efficiency of Mohs micrographic surgery for facial BCC	Retrospective study measuring recurrence rates	1. 5-year recurrence rate for primary BCC=3.2%, recurrent BCC=6.7% 2. Factors associated with recurrence were aggressive histology, more than 4 Mohs stages, a large defect size, and recurrent BCC	2B
Bath-Hextall FJ, et al., 2007 ²⁶	Assess treatment effects of BCC	1. Search of Cochrane Central Registry of Controlled Trials, Cochrane Database of Systematic Reviews, MEDLINE (2004 to January 2006), EMBASE (2005 to January 2006), the metaRegister of Controlled Trials (February 2006) 2. Inclusion criteria: adults with one or more histologically proven, primary BCC. The primary outcome was recurrence from 3 to 5 years. The secondary outcome was early treatment failure within 6 months, measured histologically.	1. Surgery and radiotherapy are the most effective treatments 2. Surgery had the lowest failure rate 3. Cosmetic outcomes good with PDT	2A
Batra RS, et al. ³⁷	Identify the most predictive risk factors for extensive subclinical tumor spread	Retrospective analysis of 1131 Mohs micrographic surgical cases	1. Highest risk tumors were basosquamous and morphaeform on the cheek, preoperative size greater than 10 mm 2. Age<35 years old was associated with a lower risk	2A
Hendrix JD, et al. ⁴⁰	Demonstrate that infiltrative BCC have both wider and deeper tumor extensions than nodular BCC of a similar size	Retrospective analysis involving 139 cases of infiltrative BCC and 139 cases of nodular BCC treated with MMS	Infiltrative BCC is more difficult to detect and successfully remove than nodular BCC. The number of stages, tumor width, and depth of defect were all greater with infiltrative BCC in comparison to nodular BCC	3A
Ratner D, et al. ⁴¹	To determine if perineural spread of BCC is more common than 1%	Prospective evaluation of 434 patients with BCC treated by MMS	3.8% of the 434 cases demonstrated perineural invasion	2C
Whitaker IS, et al. ⁴²	Improving treatment efficacy of BCC with CO ₂ laser and photodynamic therapy	12 patients with 13 nodular BCCs involving an uncontrolled trial using both PDT with methyl aminolevulinate and Aktilite 16 LED lamp and CO ₂ laser	No recurrences during a mean follow-up period of 18.1 months	4

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
Smucler R, et al. ⁴³	Measure the effectiveness of tumor mass reduction using Er:YAG laser	Three methods: 1. PDT with ALA 2. Er:YAG laser 3. Er:YAG to reduce tumor below 2 mm then ALA PDT All 286 subjects underwent all 3 methods of treatment. Patients were interviewed and followed at 3, 6, and 12 months	Combination therapy was the most effective at 98.97%, PDT alone was 94.85%, and Er:YAG yielded only 91.75%	2B
Martin RC 2 nd ⁴⁴	Review cases of basosquamous carcinoma from 1985 to 1988 at university institution to identify prognostic factors	Prognostic factors were analyzed using a Cox regression and log rank test	Predictive factors for recurrence included male gender, positive surgical resection margins, lymphatic invasion, and perineural invasion, at $p < .01$	4
Staibano S ⁴⁷	Determine if the angiogenic rate in cutaneous BCC correlates with biologic behavior	Blood vessels were highlighted by immunocytochemical staining for FVIII-related antigen in 2201 BCCs and compared between BCC1 (more benign pathologic morphology) and BCC2 (more aggressive appearing pathologic morphology)	All BCC2 samples of this series showed a significantly higher microvessel count than did BCC1	3A
Orengo IF, et al. ⁴⁸	Determine if subtypes of BCC require more Mohs stages to achieve tumor-free margins	Retrospective study of 342 primary BCCs treated by MMS measuring histologic subtype and number of MMS stages	A higher number of Mohs stages were required for infiltrative, morpheaform, micronodular, and mixed histologic subtypes of BCC	2B
Sexton M, et al., 1990 ⁵⁰	To define histologic patterns involving 1039 cases of BCC with correlation to adequacy of surgical margins	Retrospective analysis of archives at university institution from 1987 to 1988	93.6% of nodular and 96.4% of superficial BCC can be removed via simple surgical excision. Micronodular, infiltrative, and morpheic BCC have a higher rate of positive tumor margins after excision, at 18.6%, 26.5%, and 33.3%, respectively	2B
What is the literature on metastatic BCC?				
Tavin E, et al., 1995 ⁵¹				
Snow, et al., 1995 ⁵⁴	[Implied] To add to the body of evidence demonstrating that metastatic BCC originates from large primary tumors	Case report of 5 patients with metastatic BCC	Mean diameter of primary BCC lesion was 8.7 cm. 75% of the T2-T4 tumors accounted for the metastasis	4
Martin RC 2 nd , et al., 2000 ⁵⁷	To identify prognostic factors influencing recurrence	Medical records reviewed between 1985-1988	Positive predictors of recurrence included male gender, positive surgical resection margin, lymphatic invasion, and perineural invasion ($p < .01$)	4

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
Do higher levels of 25-hydroxyvitamin D lead to an increased risk of developing BCC?	No RCTs or CCTs in the literature			
What is the role of dermoscopy and confocal microscopy in the diagnosis of BCC?				
Menzies SW, et al., 2000 ⁷⁷	To describe a simple diagnostic method for pigmented BCC cutaneous surface microscopy	142 pigmented BCCs, 142 invasive melanomas, and 142 benign pigmented lesions were photographed, excised, and histologically analyzed. A training set of images was created to develop a model and tested on an independent test set of images	A sensitivity of 97% for pigmented BCC, 93% specificity for invasive melanoma, and 92% specificity for benign pigmented skin lesions	2C
Giacomel J, et al. ⁸³	To examine the dermoscopic features of superficial BCC	Twenty-four histologically proven cases of superficial BCC. The lesions were evaluated for vascular pattern, ulceration, and "additional dermoscopic features"	All superficial BCC cases had a shiny white to red appearance and 91.7% of lesions had irregularly dispersed, short, fine telangiectasias. 70.8% of superficial BCC demonstrated multiple small surface ulcerations with red to brown to black structureless areas	2C
Scalvenzi M, et al., 2008 ⁸⁴	To improve superficial BCC diagnostic criteria for dermoscopy	Forty-two dermoscopic images were photographed and subsequently analyzed	100% of the lesions had shiny white to red areas 78.6% had erosions 66.6% had short fine telangiectasias (SFT) 16.6% had leaf-like areas 14.3% had arborizing telangiectasias 14.3% had blue-gray globules 4.7% had large blue-gray ovoid nests	2C
Demirtasoglu M, et al., 2006 ⁸⁷	To analyze dermoscopic features of BCC along with its corresponding histology and evaluate the correlation to pigmented BCCs	Thirty-two pigmented BCCs were dermoscopically evaluated and then histologically analyzed	Large gray-blue ovoid nests, multiple gray-blue globules, maple leaf arborizing telangiectasia, yellow-brown, whitish-yellow, and black-dark brown color were significantly correlated to their histologic counterparts ($p<0.05$)	2C
Maloney ME, et al., 1992 ⁸⁸	To identify the histologic subtypes of BCC that were most often associated with pigment and to determine whether this correlated with outcome after excision	1039 nonpigmented and pigmented BCCs were divided into their histologic subtypes and compared	Of the 1039 lesions, 6.7% contained pigment. 12.4% of nodular/micronodular BCCs had pigment, 7.7% of the nodular, 7.2% of the superficial, 4.0% of the micronodular, and 3.4% of the nodular/micronodular/infiltrative	2C

(Continued)**

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
Peris K, et al. ⁹¹	To evaluate agreement using a recently proposed method	Fifty-six images of pigmented BCCs analyzed by 5 observers	Absence of a pigment network had full agreement ($k=1$). Spoke-and-wheel areas had very good agreement ($k=.85$) and arborizing vessels ($k=0.72$). Good agreement was demonstrated for ulceration ($k=0.49$) as well as multiple blue-gray globules ($k=0.41$). No agreement was determined on large blue-gray ovoid nests ($k=0.28$) and leaflike areas ($k=0.26$)	2C
Astner S, et al. ⁹²	To evaluate the clinical applicability of a fluorescent confocal laser scanning microscope (FLSM)	Forty patients, 10 controls, 30 patients with suspected nonmelanoma skin cancers	AK and BCC had common FLSM characteristics, including nuclear pleomorphism in the granular and spinous layers and increased vascularity in the superficial dermal compartment. More typical features of BCC included nesting of atypical basal cells, increased tortuosity of blood vessels, and nuclear polarization	3B
Garaeu DS, et al. ⁹⁵	To evaluate confocal fluorescence mosaics for presence or absence of BCC	45 confocal fluorescence mosaics were blindly evaluated by an experienced Mohs surgeon and an inexperienced Mohs surgeon and compared to histologic findings	BCCs were detected with a sensitivity of 96.6% and specificity of 89.2%, a positive predictive value of 93.0%, and a negative predictive value of 94.7%	2C
What is the role of Hedge Hog inhibitors in the treatment of BCC?				
Von Hoff DD, et al. ²²	Phase 1 clinical trial to determine safety and pharmacokinetics of GDC-0449	Thirty-three patients with metastatic or advanced BCC received 3 different doses	18/33 patients had an objective response	2B
Can NSAIDS be used to prevent BCC?				
Sørenson HT, et al. ¹⁰⁴	To determine if a correlation exists between NSAID use and the incidence of cancer	Data from North Jutland Prescription Database and Danish Cancer Registry, included 172,057 patients over 9-year period	1093 cases of nonmelanoma skin cancer with SIR=1.1, 05% CI=1.0-1.2	2C
Clouser MC, et al. ¹⁰⁵	To determine if a correlation exists between NSAID use and the incidence of nonmelanoma skin cancer	Cox proportional hazard models were used to analyze the time to first SCC or BCC	A protective effect was observed for patients who reported NSAID use less than the study duration (HR=.43, 95% CI=0.25-0.73).	2C

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
What is the current role of imiquimod versus fluorouracil in treatment of BCC?				
Love WE, et al., 2009 ¹¹²	To determine rates of clearance as well as adverse effects of imiquimod or fluorouracil in BCC and SCC	Medline, CANCERLIT, and Cochrane database searches for prospective, retrospective, and case studies	Imiquimod=43-100% clearance for superficial BCC, 42%-100% for nodular BCC, 56-63% for infiltrative BCC Fluorouracil=90% for superficial BCC 100% of patients using imiquimod experienced at least 1 adverse event 97% of patients using fluorouracil experienced at least 1 adverse event	2C
Gross K, et al., 2009 ¹¹³	To evaluate the efficacy, tolerability, cosmetic outcome, and patient satisfaction with 5% 5-FU for superficial BCC treatment	31 biopsy-proven superficial BCC were treated with 5% 5-FU cream 2 times per day for 12 weeks. The BCC was excised 3 weeks after the end of treatment to evaluation for histologic cure.	28/31 (90%) of the lesions were clear, with a mean time to clearance of 10.5 weeks	2C
Geisse J, et al., 2004 ¹¹⁴	To determine the efficacy and safety of 5% imiquimod cream in comparison to placebo vehicle	Phase III trial, patients received imiquimod or vehicle cream once per day 5-7 times per week. The lesion was histologically examined 12 weeks after treatment	Clearance for imiquimod 5 times per week was 75%. Clearance for imiquimod 7 times per week was 73%. Histologic clearance for 5 times per week was 82%, while for 7 times per week was 29%.	1B
Schulze HJ, et al., 2005 ¹¹⁵	To analyze the safety and clinical efficacy of imiquimod 5% cream for superficial BCC	Multicenter, randomized, parallel, vehicle-controlled, double-blind, phase III clinical trial involving 26 centers in Europe. 166 subjects with histologically confirmed superficial BCC randomly assigned to apply imiquimod or a placebo cream, once daily for 7 times per week.	Clearance was achieved in 77% of imiquimod group versus 6% in the placebo group. Histologic clearance was achieved in 80% of the imiquimod group versus 6% of the placebo group.	1B
Gollnick H, et al., 2005 ¹¹⁶	Evaluate the long-term clinical efficacy and safety of 5% imiquimod cream in the treatment of superficial BCC	Phase III open-label study. Imiquimod was applied 5 times per week for 6 weeks (182 subjects)	12-week clearance rate was 90%. 2-year clearance rate was 79.4%.	2C
Quirk C, et al., 2006 ¹¹⁷	Evaluate the long-term clinical efficacy and safety of 5% imiquimod cream in the treatment of superficial BCC	Phase III open-label study involving 169 patients. If BCC was clear at 12 weeks, subjects were then evaluated at 3, 6, 12, and 24 month follow-up	12-week clearance was 94.1% 2-year clearance rate was 82.0%	2C

**TABLE 44-1—Evidence-Based Table Summarizing Various Research Questions Related to Basal Cell Carcinomas
(Continued)**

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
What is the role of cryogen in management of BCCs?				
Mallon E, et al., 1996	To determine if one freeze-thaw cycle or two freeze-thaw cycles are more effective in the treatment of superficial truncal basal cell carcinomas	Subjects were randomly assigned to either one of the two treatment groups. One group received a single 30-second freeze-thaw cycle, while the other group received a double 30-second freeze-thaw cycle	The group with the double freeze-thaw cycle attained a 95.3% cure rate. The group with the single freeze-thaw cycle attained a 79.4% cure rate.	2C
How are lasers placed in the management of BCCs?				
Campolmi P, et al., 2008 ¹³¹	Evaluate the efficacy of dye laser for superficial BCC	Twenty patients with superficial BCC were treated 5 times every 20 days	Complete response in 16/20 patients. Three recurrences were reported, with a follow-up range of 12–24 months	2C
Shah SM, et al., 2009 ¹³³	To determine the effectiveness of repeated PDL treatments on superficial and nodular types of BCC	Twenty histologically proven BCCs were treated 4 times with the 595 nm PDL at 2-week intervals. The area was biopsied and analyzed for residual tumor in comparison to controls. The diameter was also measured.	(11/12) BCCs less than 1.5 cm in diameter had complete responses, compared to 16.7% of controls (2/12), $p<0.0003$	3B
What is the role of photodynamic therapy with aminolevulinic acid or methylaminolevulinate in treatment of BCC?				
Thissen MR, et al., 2000 ¹³⁹	To determine the efficacy of PDT with delta-aminolevulinic acid for nodular basal cell carcinomas using a prior debulking technique	Twenty-four nodular BCCs were treated one time with delta-aminolevulinic acid 3 weeks after a prior debulking. Three months after treatment with PDT, all BCCs were excised and histologically analyzed.	92% of the nodular BCCs showed complete response with respect to both the clinical appearance and histologic evaluation	2C
Wang, et al., 2001 ¹⁴¹	To compare the efficacy of ALA-PDT versus cryotherapy for BCC	88 lesions of superficial and nodular BCCs randomized to receive either ALA-PDT or cryosurgery using two freeze-thaw cycles	11/44 (25%) of the patients who received ALA-PDT had recurrences, while 6/39(15%) of the patients who received cryosurgery had recurrences. 30% of the PDT patients required additional treatments	2C
Haller JC, et al., 2000 ¹⁴²	To determine if a second treatment at 7 days can improve the clearance rates	Two treatments using ALA-PDT involving 26 superficial BCCs	100% of the patients had a complete response 1 month after treatment. One lesion relapsed 16 months after treatment. Median follow-up of 27 months.	2C

Investigators	Objective	Methods	Results/Conclusions	Level of evidence
Soler AM, et al., 2000 ¹⁴³	To compare the clinical as well as cosmetic outcome of superficial BCC using a laser or PDT with ALA	245 superficial BCCs. One group received PDT-ALA and the other group received laser treatment	86% of the lesions in the laser group had a complete response. 82% of the lesions in the BL group had a complete response 6 months after treatment. There was no statistical difference	2C
Oseroff AR, et al., 2005 ¹⁵⁴	To report use of wide area 5-aminolevulinic acid PDT to treat BCCs and basaloid follicular hamartomas (BFHs)	Case report, individual areas received 1-3 treatments	85%-98% clearance was achieved	4
Foley P, et al., 2005 ¹⁶²	To investigate the histologic response, tolerability, and cosmetic outcome with MAL PDT for primary nodular BCC	Multicenter, randomized, double-blind, using MAL cream or placebo cream with broad-spectrum red light and repeated 1 week later. Lesions that partially responded at 3 months were retreated. Lesions were excised at 3 and 6 months for histologic analysis	73% (55/75) of the lesions treated with MAL PDT completely responded, while 27% or 20/75 of the placebo PDT completely responded.	1B
Is Candida antigen an effective treatment for BCC?				
Aftergut et al., 2005 ¹⁶⁴	To determine the efficacy and safety of intralesional Candida antigen for treating nodular BCC	Twenty-one patients were enrolled for the randomized, open-label, placebo-controlled trial; patients had histologically proven nodular or superficial BCC with size under 2.25cm ² . Candida antigen was injected weekly for 6 weeks. The control group received saline. 4–6 weeks after the last injection, the tumor was excised and histologically analyzed	10/17 (56%) patients in the Candida group had complete clearing of their tumor. 0/3 patients in the control group had complete clearing of their BCC. The results were not statistically significant	1B
Is there an association between statin use and BCC?				
Asgari et al., 2009 ¹⁸⁶	To determine if an association exists between statin use and BCC	Using a large, integrated, health care system, 12,123 patients with a histological diagnosis of BCC were included. From pharmacy records, exposure to statins was recorded. A Cox regression was used to determine if an independent association existed between statin therapy and risk of subsequent BCC	Statin therapy was found not to be statistically significantly associated with risk of BCC	2B

surgical excision remains the preferred treatment for most BCCs because of its ease and high treatment rates, newer noninvasive therapies have emerged for selected low-risk BCC, such as photodynamic therapy (PDT), 5-fluorouracil (5-FU), and imiquimod 5% cream. These modalities have shown great cosmetic results.²⁶

Twenty-six histologic subtypes of BCCs have been described, but for practical purposes, a clustering of these subtypes is used.^{27,28} Nodular and superficial BCC are the prototypical varieties of BCC and tend to be less aggressive. Superficial BCCs (sBCC) are generally larger, appear on the trunk, and are considered a less aggressive subtype.²⁹ Morpheaform, infiltrating, and basosquamous subtypes of BCC have distinct histologic features and are often more extensive, with higher clinical risk.^{30,38} Morpheaform BCC has been associated with greater subclinical depth of extension.³¹ Also, morpheaform and infiltrating BCCs are associated with a greater rate of recurrence.^{32,33} The clinical factors contributing to an aggressive BCC have been characterized as large size, facial location, neglect/long-standing tumor, incomplete excision, histologic variants, and perineural or perivascular invasion.³⁴⁻⁴¹

In a review of literature for randomized controlled trials, the efficacy of investigated treatments was studied. The conclusions that could be drawn from these RCTs were as follows:

- Surgical excision is the gold standard of BCC treatment.
- Mohs micrographic surgery (MMS) is preferable for recurrent facial BCC or BCC with an aggressive histologic subtype.
- Surgical treatment, although commonly used for sBCC, leads to scarring and keloid formation, because the trunk is a more susceptible location for these complications. Thus, a major role for PDT, imiquimod, 5-FU, etc., can be foreseen, although more trials need to be conducted to compare the efficacies of these modalities in treatment of sBCC.
- In nodular BCC (nBCC) at low-risk anatomic sites, cryosurgery, curettage, surgical excision (SE) and radiotherapy have been tried, but more research is needed to determine if noninvasive methods should be applied in recurrent tumors. Photodynamic therapy (PDT) combined with lasers has also been tried for nodular BCCs and will be discussed subsequently.^{42,43} In the few cases where surgery is impossible or undesirable, it may be advantageous to treat a patient with a less-invasive method that may be less effective.

Tumors with perineural spread are difficult to manage because skip areas tend to complicate margin assessment.⁴⁴⁻⁴⁶ Achieving complete clearance is often unsuccessful and may result in focal neurologic deficits.

In addition, increased tumor vascularity can be correlated with aggressive cases of BCC. The increased vascularity can be assessed by a factor VIII immunohistochemical stain.⁴⁷ Perivascular invasion may lead to tumor extension

by increasing blood supply to the tumor mass and creating channels for local and distant spread.

The aggressive histologic subtypes of BCC have been found to require more Mohs surgery stages to achieve tumor-free margins, with 37% requiring three or more stages,⁴⁸ compared to an average of 1.6 stages in a large sample of histologically low-risk BCC cases.⁴⁹ Aggressive subtypes are also frequently associated with residual positive margins (21.8% of 239 cases).⁵⁰

CONCLUSION

Surgical excision is the standard of care for BCC. MMS is the best option for the treatment of aggressive BCCs, BCCs on the face, and recurrent BCCs. Nodular BCCs can be managed with SE, radiotherapy, combined ablative lasers with PDT, and cryosurgery. PDT is a useful modality for sBCC.

What is the literature on metastatic BCC?

Metastatic BCC (MBCC) is defined as primary cutaneous BCC that spreads to anatomically distant sites as histologically similar deposits of BCC. Metastasis of BCC is rare: the incidence ranges between 0.003 and 0.55%.^{51,52} Less than 300 cases of MBCC have been reported in the literature.⁵³ Metastases occur in males and females in a 2:1 ratio.^{54,55} The majority of MBCCs are from primary BCC in the head and neck region.⁵³ The most frequent site of BCC metastasis is regional lymph nodes, followed by bone, lung, and liver.⁵⁶⁻⁵⁸ Involvement of salivary glands has been reported in several patients, although it may be difficult to distinguish direct extension of tumor from true metastasis at this site.^{52,59,60}

The risk factors associated with MBCC are actinic damage, fair complexion, history of excessive sun exposure, family history of skin cancer,⁶¹⁻⁶³ middle age, male sex,⁵³ large ($>10 \text{ cm}^2$) solitary tumor,^{64,65} and a long-standing lesion.⁶⁶ The histologic patterns that are aggressive, such as basosquamous, metatypical, morpheaform, and adenocystic BCC, may determine the ability of BCC to create its own specialized stroma at the distant metastatic site.⁶⁷⁻⁶⁹ These risk factors, when present, are an indication for more aggressive initial treatment to prevent recurrence and further progression of BCC infiltration and metastasis.

In a case report by Ting et al. two cases of metastatic BCC were presented.⁶⁴ These patients were managed by local radiation therapy and palliative methods only. Patient 1 died 7 years after, and patient 2 died 2 years after, the documentation of metastases, despite aggressive treatment.

The prognosis for MBCC is poor. Estimated median survival after metastases ranges from 8 to 14 months; the longest known survival is 25 years.^{53,54}

CONCLUSION

Metastatic BCC, although a rare condition, should be considered when dealing with aggressive histology, large

solitary BCCs, prolonged photodamage, and a positive family history, especially in fair complexioned populations.

Do higher levels of 25-hydroxyvitamin D lead to an increased risk of developing BCC?

BCCs are known to express the 1,25(OH)₂D₃ vitamin D receptor (VDR). UVB radiation has the dual effect on the skin of producing both CC→TT and C→T transition mutations at dypyridines as well as increasing the synthesis of 25-OH vitamin D. Additionally, the transcription factors GLI1 and GLI2 are known to have VDR consensus sequences, which may allow for vitamin D regulation of the Sonic Hedgehog pathway.⁷⁰ 1,25(OH)₂D₃ may also play a role in assisting cells in DNA damage repair, as it has been noted that skin cells treated with 1,25(OH)₂D₃, demonstrate more photoproduct excision in both human and mouse cells as well as increased expression of XPC and DDB2/XPE.^{68,71,72} *In vitro* studies have demonstrated that vitamin D may actually inhibit BCC cell growth. More specifically and recently, Xiao et al. have shown that 5–10 µM vitamin D reduces the expression of GLI1 by a factor of 4 and therefore exhibits an effect similar to that of 10 µM cyclopamine.⁷³

Despite this evidence, there are few epidemiologic studies linking serum vitamin D levels to either promoting or inhibiting BCC formation. Certainly, the mode of attaining vitamin D plays a significant factor in the development of cutaneous carcinogenesis. At least one nested case-control study has attempted to show a link between BCC and pre-diagnostic serum vitamin D levels.⁷⁴ In fact, the investigators found that for every 1 ng mL⁻¹ rise in serum 25-OH vitamin D, there was a 3% increased risk of developing BCC.⁷² However, the authors may not have adequately controlled for acute intermittent UV exposures.⁷² In addition, and subjects who reported higher occupational UV exposure had lower serum levels of 25(OH)D.⁷²

Future studies are needed to explore the association between serum vitamin D levels and risk of BCC, with careful attention to controlling for UV radiation exposure and comparing oral supplementation of vitamin D versus UV radiation exposure.

CONCLUSION

More epidemiologic evidence will need to be gathered to affirm or refute the link between vitamin D levels and risk of developing BCC, with special attention paid to the route by which the vitamin D is attained.

What is the role of dermoscopy and confocal microscopy in diagnosis of BCC?

The early detection of BCC is helpful in guiding curative treatments, avoiding destructive growth, preventing

local spread, and eventually preventing metastases. The early clinical detection of BCCs was made more feasible and convenient with the introduction of dermoscopy and confocal microscopy.

Dermoscopy

Dermoscopy has the highest clinical impact among all noninvasive diagnostic procedures available for differentiating malignant from benign skin lesions at an early stage.^{75,76} Dermoscopy is a noninvasive diagnostic technique that permits the visualization of morphologic features that are not visible to the naked eye, thus representing a link between macroscopic clinical dermatology and microscopic dermatopathology. The dermoscopic model for the diagnosis of the pigmented variant of BCC is based on the absence of a pigmented network and the presence of at least one positive feature, including: (1) ulceration (not associated with a recent history of trauma); (2) multiple blue/gray globules; (3) leaflike areas; (4) large blue/gray ovoid nests; (5) spoke-wheel areas; and (6) arborizing (treelike) telangiectasia.⁷⁷ Yet, a wide range of clinical and dermoscopic characteristics may be presented by BCCs along with a fairly large variety of histologic patterns.^{75,78} These have been discussed in several case reports.^{79–84}

Altamura et al. conducted a retrospective analysis of 609 BCCs and 200 melanocytic and nonmelanocytic lesions and assessed inter-rater reliability of dermoscopic BCC criteria.⁸⁵ They found that classic BCC patterns, including arborizing telangiectasia, blue/gray ovoid nests, ulceration, multiple blue/gray globules, leaflike areas, and spoke-wheel areas, were significantly increased in pigmented BCCs compared with nonpigmented and heavily pigmented BCCs. Among nonclassic BCC patterns, short, fine, superficial telangiectasias and multiple small erosions were detected. Two new patterns, named “concentric structures” and “multiple in-focus blue/gray dots,” were described. Dermoscopic features suggestive of melanocytic lesions (e.g., multiple brown to black dots/globules, blue/white veil-like structures, and nonarborizing vessels) were observed in 40.6% of BCCs and were significantly increased in heavily pigmented BCCs. Expert observers provided an accurate (sensitivity: 97%) and reliable (K: 87%) dermoscopic diagnosis of BCC, although a significant difference in terms of specificity ($P = .0002$) and positive predictive value ($P = .0004$) was found. Arborizing telangiectasia, leaflike areas, and large blue/gray ovoid nests represented reliable and robust diagnostic parameters.

On the other hand, Scalvenzi et al. in their investigation on dermoscopic patterns in 42 superficial BCCs, demonstrated the presence of shiny white to red areas, short fine telangiectasias, and erosions as the chief dermoscopic criteria of superficial BCC. Scalvenzi et al. also concluded that other findings were not as strongly associated with superficial BCCs but did help in differential diagnosis from other pigmented and nonpigmented skin lesions.⁸⁶

Because of the clinical similarities between pigmented basal cell carcinomas and other melanocytic pigmented lesions, especially melanoma, dermoscopy proves to be a useful tool for the diagnosis of pigmented BCCs. There are special dermoscopic features described for pigmented BCCs, of which ulceration, large gray-blue ovoid nests, multiple gray-blue globules, maple-leaflike areas and arborizing telangiectasias were found to correlate with their histopathologic counterparts.⁸⁷ In pigmented BCCs, melanin can be found in the tumor mass or surrounding dermis histopathologically. In the tumor mass, melanin can be seen in hyperplastic melanocytes or may be taken up by surrounding tumor cells. However, in the dermis, melanin can either be found in melanophages or lie free. Melanin might also be found in hyperplastic epidermal melanocytes in the overlying epidermis.^{88–90}

Interobserver agreement is of great importance in surface microscopy. Peris et al. evaluated observers' global agreement and interobserver agreement on each dermoscopic parameter for 56 pigmented BCCs.⁹¹ Five observers, classified on the basis of their expertise, conducted this study, and the results suggested that dermoscopy is a reproducible method for ulceration, spoke-wheel areas, and arborizing telangiectasias. No agreement was reached for large blue-gray ovoid nests and leaflike areas.

Confocal Microscopy

Another noninvasive modality very useful for detecting, evaluating, and monitoring a number of cutaneous lesions is confocal microscopy. It offers high-resolution real-time imaging of human skin with a confocal microscope either *in vivo* or in freshly excised tissue *ex vivo*. Similar to conventional histology, nuclear and cellular morphology is observed in thin optical sections. Use of contrast agents, such as acridine orange in fluorescence and acetic acid in reflectance, help enhance contrast. Although histology remains the gold standard for microscopic evaluation of the skin, confocal microscopy has the advantages of being rapid and noninvasive and allows for repeated dynamic evaluations over time; it also does not cause any tissue damage or alteration by processing or staining.

In a study by Astner et al. fluorescent confocal laser scanning microscopy (FLSM) was used for diagnosis and therapeutic monitoring of nonmelanoma skin cancers (NMSCs).⁹² The BCCs showed comparable epidermal pleomorphism and characteristic nesting of atypical basal cells, and they demonstrated increased blood vessel tortuosity. FLSM was able to detect the morphologic characteristics of BCC that correlated with routine histology. To allow the noninvasive monitoring of treatment response to imiquimod, all corresponding FLSM features for superficial BCC were evaluated at baseline and variable time points during and after therapy. The preliminary observations showed an initial increase of inflammatory cells

relating to local immune response, and these findings subsided with cessation of therapy. The vascular dilatation or increased vascularization of treatment sites was observed after a course of 6 weeks of topical treatment and persisted at the 12-week follow-up, relating to the induction of neovascularization following imiquimod therapy. With FLSM, timing of the evaluation remains an important aspect, because the distribution of fluorescein follows a characteristic dynamic in live skin. Reflectance confocal microscopy (RCM) allows an evaluation without exogenous contrast agents.

Besides its use in detection and monitoring of NMSCs, confocal microscopy has been shown to be a tool to expedite Mohs surgery.^{93,94} The preparation of frozen histology is slow, requiring 20 to 45 min per excision. Confocal reflectance mosaicing may enable rapid detection of BCCs directly in surgical excisions, with minimal need for frozen histology. Soaking the excisions in acetic acid rapidly brightens nuclei and enhances BCC-to-dermis contrast, known as "acetowhitening." Mosaics created displayed up to 12 × 12 mm of tissue in Mohs surgical excisions, which corresponded to the view with twofold magnification that is routinely used by Mohs surgeons when examining frozen histology with a standard light microscope. These mosaics were created in less than 9 min, whereas preparation of frozen histology requires 20 to 45 min per excision. This suggests that large-area mosaicing may offer a means for rapid examination of BCCs directly in fresh excisions while minimizing labor and costs.

In one study, 45 confocal mosaics were blindly evaluated for the presence (or absence) of BCC tumor and the blinded evaluation was compared to the gold standard of frozen histopathology.⁹⁵ BCCs were detected with an overall sensitivity of 96.6%, specificity of 89.2%, positive predictive value of 93.0%, and negative predictive value of 94.7%, demonstrating the potential utility of confocal microscopy for rapid surgical pathology at the bedside to expedite and guide surgery.

CONCLUSION

BCCs show a large spectrum of global and local dermoscopic features; heavily pigmented BCCs show the most challenging combinations of dermoscopic features.

Confocal microscopy has emerged as a very useful modality for diagnosing and monitoring BCCs and to expedite Mohs surgery.

What is the role of Hedge Hog inhibitors in the treatment of BCC?

Several Hedge Hog inhibitors are being explored as possible therapeutic agents in the treatment of BCC. One such agent and perhaps the most well known, cyclopamine, is derived from the lily plant *Veratrum californicum*.

It binds directly to SMO's transmembrane helices and inhibits its action.⁹⁶ It is theorized that cyclopamine induces a conformation change in SMO or affects the localization of SMO, thereby inactivating it.⁹⁴ Cyclopamine has also been shown to upregulate Fas expression leading to Fas/Fas ligand interaction and caspase 8-mediated apoptosis in murine BCC cells.⁹⁷ A topical preparation of cyclopamine was studied in a Phase I clinical trial, however, the trial was discontinued because of poor transepidermal drug penetration.⁹⁸ Despite the poor transepidermal penetration, histologic clearing was noted in some patients.^{10,95} Unfortunately, cyclopamine probably should not be used in pregnant patients because it is known to cause cyclopia in the lambs of ewes that eat *Veratrum californicum*.^{10,99}

GDC-0449 is another HH inhibitor that has recently been used in a Phase I clinical trial. GDC-0449 inhibits signal transduction in the hedgehog pathway by directly binding to SMO, rendering it unable to activate downstream target genes.²² It was discovered by high-throughput screening of a small molecule library.²² GDC-0449 has been shown to be effective against other hedgehog-dependent neoplasias, such as medulloblastoma, colorectal cancer, and pancreatic carcinoma.²² One trial showed a response to GDC-0449 in 18 of 33 patients with locally advanced or metastatic BCC.²² At doses of 150 mg, 270 mg, or 540 mg per day, there were no reported dose-limiting toxic side effects or grade 5 adverse events. One patient did exhibit a grade 4 adverse event. It was noted that out of the four patients with progressive BCC (unresponsive to GDC-0449), two had increased hedgehog signaling pathway activity, suggesting an unknown mechanism behind their lack of response.²²

Other small-molecule inhibitors of SMO include SANT1-4 and G-024856. At least one phase I trial of G-024856 (formerly known as CUR61414) is ongoing.¹⁰ Williams et al. demonstrated that G-024856 decreases HH signaling involving oncogenic PTCH1 mutations.^{97,100} Chen et al. suggest that the SANT1-4 molecules may interact differently than cyclopamine with SMO, and therefore may be useful in the future to clinically target cyclopamine nonresponders.¹⁰¹ Future research will need to determine the possible clinical utility of these small molecules as well as to develop a more detailed understanding of the HH signaling pathway.

CONCLUSION

At least two Phase I clinical trials with HH inhibitors have demonstrated histologic response. The results of the trials demonstrate proof of principle from basic science to clinical trials. Further research will need to be carried out to better understand BCC at the molecular level and to account for patients who do not respond to a particular HH therapy.

Can NSAIDs be used to prevent BCC?

NSAIDs have been theorized to prevent the occurrence of NMSCs. Recent evidence demonstrating that NSAIDs may reduce the incidence of colorectal polyps and esophageal, stomach, ovarian, and breast cancers, but increase the risk of kidney, lung, and prostate cancer has stimulated research into animal model and human tumors.^{102–104} One of the most recent studies found a protective effect of non-ASA NSAIDs on the development of a first BCC.¹⁰⁵ The protective effect was only statistically significant for subjects who reported short-term use (i.e., less than the study duration, with a HR of 0.43, 95% CI 0.25–0.73).¹⁰³ In addition, the study found that more recent NSAID use was more protective than long-term use for risk of developing a first BCC.¹⁰³ The investigators suggest that this effect may be caused by receptor overexpression with alternative signaling pathways becoming more active.¹⁰³ The results of this study also suggest that NSAIDs likely block different pathways of BCCs and SCCs en route to carcinogenesis.¹⁰³ Unfortunately, as of this date, there have been no randomized prospective clinical trials examining this issue.¹⁰¹

It is hypothesized that chronic inflammation, largely through UV radiation^{106,107} exposure, leads to the release of arachidonic acid. Arachidonic acid then leads to prostaglandin synthesis, which is believed to release free oxygen radicals causing tissue damage. Prostaglandins may prevent apoptosis of UV-damaged cells, therefore leading to promotion of a possible neoplastic process.¹⁰⁸ There are three known classes of COX inhibitors. COX-1 has been found throughout human and mouse epidermis, whereas COX-2 is found predominantly in the suprabasilar keratinocytes.¹⁰⁹ Paradoxically, BCC is known to express little quantities of COX-1 or COX-2 isoenzymes.¹⁰⁷

Future studies may be aimed at the basic science level to determine possible alternative pathways via which NSAIDs may alter the pathway to carcinogenesis. In addition, more controlled prospective studies will be needed to cement the link between NSAIDs in the chemoprevention of BCC, if one actually exists.

CONCLUSION

NSAIDs have been shown to protect against BCC with short-term use. More basic science studies will need to be carried out to determine the mechanism behind this finding.

What is the current role of imiquimod versus fluorouracil in treatment of BCC?

Imiquimod is a nucleoside analogue of the imidazoquinoline family and functions as an immune response modifier that specifically acts as a toll-like receptor 7 and

8 agonist.¹¹⁰ This agonist stimulates the innate immune system to produce interferon, thereby augmenting the TH₁ immune response and hence antitumor/antiviral activity.¹¹⁰ Fluorouracil is a pyrimidine analog that inhibits DNA synthesis by blocking the methylation reaction converting deoxyuridylic acid to thymidylic acid. Therefore, thymine is not produced or is produced at lower levels, resulting in unbalanced cell growth and eventually cell death.¹¹¹ Imiquimod and fluorouracil are used in topical format for treating superficial BCCs. A recent meta-analysis reviewed different dosing regimens and long-term follow-up for treating BCC with imiquimod and fluorouracil.¹¹² When imiquimod was used daily at least 5 days per week for 6 to 12 weeks to treat superficial BCC, 81% of the patients demonstrated histologic cure at 6 or 12 weeks.¹¹⁰ One long-term study from that group showed that at 5 years after the 6-week treatment period consisting of 5 days per week of application, 69% of the patients were clinically asymptomatic.¹¹⁰ When imiquimod was used in the treatment of nodular BCC, applied daily for 12 weeks, 76% histologic clearance was observed at 6 weeks.¹¹⁰ When imiquimod was applied two times per day for 3 days per week, 42% histologic clearance was observed at 6 weeks.¹¹⁰ Imiquimod application was also explored in infiltrative BCC, yielding 5-year histologic clearance rates of 63% and 56%.¹¹⁰ Fluorouracil was applied twice daily for superficial BCC for an average of 11 weeks, with 90% histologic clearance 3 weeks after treatment.^{110,113} Unfortunately, 5-year follow-up did not occur in that study.

Imiquimod and fluorouracil exhibit a number of side effects. More specifically, application of topical 5% imiquimod cream has been shown to result in hypopigmentation (9-67% of subjects), erythema (63-100%), pruritus (16-67%), burning (6-35%), pain (3-35%), erosion (36-53%), ulceration (25-27%), flu-like symptoms (9%), scarring (15%), and crusting, scabbing, and scaling (52-65%).¹¹⁰ Interestingly, a higher level of inflammatory response predicts a higher rate of tumor clearance.¹¹⁴ The inflammatory response tends to be most intense from weeks 2 to 6 to after initiating imiquimod and is known to last up to 12 weeks, with possible scaling and erythema lasting up to 2 years.^{110,115-117} Fluorouracil is associated with erythema (33-97%), pain (33-50%), dermatitis (20%), pruritus (17%), scarring (9-16%), scabbing, crusting (13%), burning (7%), ulceration (4-9%), erosion (6%), and hyperpigmentation (3%)^{112,110}. It was noted that 97% of subjects using fluorouracil experienced at least one adverse effect.¹¹¹ Unlike imiquimod, a robust inflammatory response is not associated with higher levels of tumor clearance.¹¹⁰

Cost is another important issue when considering treatment modalities involving BCC. Assuming 1 cm superficial BCC located on the trunk, Murphy et al. calculated that topical imiquimod 5% cream for 6 weeks cost \$814.08, topical fluorouracil for 8 weeks cost \$499.96, Mohs

microsurgery cost \$535.45 for a single stage, curettage with electrodesiccation cost \$128.84, and surgical excision with intermediate layered closure cost \$415.40.¹¹⁸

Since cure rates for conventional BCC treatment modalities range from 90-99%,¹¹⁹ imiquimod and fluorouracil should remain alternatives for patients in whom conventional therapies are contraindicated or in patients with superficial BCC, given its less aggressive nature. In addition, topical fluorouracil and imiquimod are associated with a number of cutaneous side effects and may actually cost more than conventional therapy.

CONCLUSIONS

Since cure rates for conventional BCC treatment modalities range from 90 to 99%,¹²⁰ imiquimod and fluorouracil should remain alternatives for patients in whom conventional therapies are contraindicated or in patients with superficial BCC, given its less aggressive nature. In addition, topical fluorouracil and imiquimod are associated with a number of cutaneous side effects and may actually cost more than conventional therapy.

What is the role of cryogen in management of BCCs?

Cryotherapy or cold-induced destruction of nonmelanoma skin cancer can be achieved with liquid nitrogen cryosurgery. Variations in spray technique and duration and number of freeze/thaw cycles have been tried to improve results.¹²¹ This technique is most suited for treatment of low-risk primary basal cell and squamous cell carcinomas.^{122,123} In one study, the recurrence rates were similar for cryosurgery and surgical excision, and results of another study showed a higher recurrence rate for basal cell carcinoma treated with cryosurgery (39%) than for carcinoma treated with radiotherapy (4%) at 2-year follow-up.^{124,125}

Cosmetic results were similar for cryosurgery and radiotherapy, whereas results of surgical excision were better than those of cryosurgery.

CONCLUSION

With close monitoring, cryotherapy is an option used conventionally for management of less aggressive and superficial BCC.

How are lasers placed in the management of BCCs?

Due to commonly arising adverse events and complications with medical and surgical therapies, lasers have emerged as a possible and potential modality for treatment of skin cancers. Imiquimod is associated with erythema, edema,

weeping, pruritus, permanent hypopigmentation, crusting/scabbing/scaling, erosion, burning, and pain.¹¹⁰ 5-FU may cause erythema, pain, irritant dermatitis, and pruritus.¹¹⁰ Procedures like cryosurgery and curettage and electrodesiccation often lead to hyperpigmentation and atrophic scarring.¹²⁶ Surgery and radiotherapy also lead to visible scarring. Thus, lasers could offer a cosmetically good outcome for BCCs. Good candidates for lasers would be those having multiple BCCs or those who cannot tolerate surgery or the inflammation associated with topical medications. The pulsed dye laser (PDL) has been tried for BCC and works on the principle of selective photothermolysis. This indicates that the laser targets a particular chromophore within the lesion while preserving the surrounding tissue. The rationale for using PDL for BCCs is that BCCs often have telangiectasias. These may be a basket-like capillary plexus interwoven throughout the tumor bed, with many abnormal blood vessels with luminal diameters of 20 µm. By specifically targeting the tumor vasculature, BCC burden may be decreased or even eliminated with less damage to the surrounding skin and structures.

Lasers can be used in the treatment and prophylaxis of skin cancers by:

- Nonspecific ablation of dermis
- Coherent light sources in PDT
- PDL alone

The ablative approach suggests elimination of premalignant cells in the cancerization field. Studies have focused on the CO₂ and Er:YAG lasers, the role of which is discussed in the next research question.

The pulsed dye laser has been used to selectively target tumor vasculature, with success in treating glottal dysplasia and squamous cell carcinomas *in situ* using 585 nm PDL.^{127,128} Depending on fluence, 595 nm PDL can penetrate skin to thicknesses ranging from 0.75 to 1.25 mm (encompassing most BCCs).¹²⁹ Allison et al. conducted single treatment of 585 nm PDL on seven BCCs, which resulted in histologic clearance of only one tumor.¹³⁰ Campolmi et al. conducted two studies on superficial BCCs with the 595 nm PDL which demonstrated no clinical recurrences at a minimum follow-up of 1 year in 16 out of 20 BCCs.^{131,132} Repeated PDL treatments on BCCs of superficial and nodular subtypes and of varying diameters revealed that tumor histologic types among the complete responders included superficial, nodular, micronodular, and keratinizing. Incompletely responding BCCs showed a significant reduction in tumor burden after PDL treatment, with residual histologic tumor burden ranging from <1% to 29% of the original clinical tumor diameter, compared to 13–68% residual tumor burden for the corresponding controls.¹³³

In a study by Moskalik et al. on 3461 patients with 3624 facial skin cancer lesions, it was reported that Nd:YAG laser irradiation can be used for basal cell cancers of the

face, particularly if the tumors are located in the periocular region or on the eyelids.¹³⁴

Photodynamic therapy for BCCs may utilize a laser as the light source. Studies have been done with diode laser, in one of which 15 basal cell carcinoma (BCC) lesions and 19 Bowen's disease were submitted to 6-h topical and occlusive 20% 5-ALA plus DMSO and EDTA, and later were exposed to 630 nm diode laser, 100 or 300 J/cm² dose.¹³⁵ At 3 months, tumor-free rate was 91.2%, whereas at 60 months, it was 57.7% (15/26), and slightly higher in BCC (63.6%; 7/11). The relation between the reduction of the clinical response and the increase of tumor dimension observed at 18 months was lost at 60 months. The sBCC recurrence was earlier compared to the nBCC one.

CONCLUSION

Lasers have a multifaceted role in BCC treatment. They can be used alone (PDL), as the noncoherent light source for PDT, as ablative therapy managing the field of cancerization, or as an adjuvant in debulking of the tumor (as will be discussed in the next research question).

What is the role of photodynamic therapy with aminolevulinic acid or methylaminolevulinate in treatment of BCC?

Photodynamic therapy (PDT) refers to the procedure wherein a photosensitizer is first used on the skin, followed by an incubation period, allowing the uptake of the photosensitizer by the neoplastic cells, and finally is exposed to a light source (coherent or noncoherent), triggering a reaction in the cancer cells and damaging them. The photosensitizers used in the clinical trials for treating BCCs are aminolevulinic acid (ALA) and methyl-aminolevulinic acid (MAL). The photosensitizers taken up by the cells are metabolized into phototoxic compounds like protoporphyrin IX (PpIX).¹³⁶ Various light sources have been tried, including blue light, red light, and lasers.

Several studies have investigated the use of ALA-PDT for the management of BCCs with a large number of patients and the clearance rates ranged from 66–100%.^{137–141} From the many studies conducted to examine ALA-PDT for the treatment of BCCs, it may be concluded that multiple treatments most likely lead to a higher clearance rates than a single treatment.^{142,143} One of the studies involved long-term follow-up of 47 patients with 95 sBCC. The reported response rate was 44% at 36 months after therapy.¹⁴⁴ In addition, ALA-PDT may be superior to both electrosurgery for large superficial BCCs and to excision in patients with multiple BCCs.¹⁴⁵

Besides being a noninvasive treatment, the main advantages of ALA-PDT are significantly shorter healing times and excellent cosmetic results. In addition, PDT used as

field treatment instead of spot treatment, helps to treat the entire field of cancer. The concept of “field cancerization” refers to a process ‘whereby the whole neighborhood is affected’.^{146–149} It was first described by Slaughter et al. in 1953 and has been expanded to include areas that are clinically occult but have multifocal (pre)neoplastic changes and microsatellite alterations, showing genetic mutations that precede the development of second primary tumors and local recurrences.¹⁵⁰ So, treating severely photodamaged skin, which has a risk of developing more BCCs, can help treat many lesions that may not be clinically evident at present but may manifest as BCC in future.

Increased incidence of nonmelanoma skin cancers (NMSC) is known in patients with immunosuppression, such as AIDS patients,^{151,152} transplant patients, patients on immunosuppressive drugs, etc. Immunosuppression in organ transplant patients strongly contributes to the increase in skin cancer incidence—being 65–250 times more frequent than in the general population. Often these patients suffer from a second and third lesion and the severity of the tumors is linked to their number.¹⁵³ PDT has been suggested as a management tool in such patients because of destruction of subclinical lesions, induction of an antitumor response that suppresses development of new carcinomas, or both.¹⁵⁴ Given the role of innate and adaptive immunity in PDT, it is not surprising that ALA-PDT is less effective in immunosuppressed transplant recipients. Besides, there is also increasing evidence that PDT induces antitumor responses and generates tumor vaccines.^{155,156} Existing protein antigens and neoantigens produced by oxidation or by the crosslinking of adjacent membrane or cytoplasmic proteins can be bound and subsequently presented by PDT-induced stress protein chaperones, such as HSP-70.¹⁵⁷

On the other hand, one of the studies brought out the limitations of using coherent and incoherent light sources for the ALA-PDT treatment of large or multiple BCCs, namely, unacceptably long treatment of large or multiple lesions and high costs. Moreover, repetitive treatments, debulking,¹⁵⁸ and the use of penetration enhancers such as DMSO (dimethyl sulfoxide)^{159,160} have made ALA-PDT a popular treatment for superficial BCCs. Combining PDT with CO₂ or Er:YAG lasers has also been tried in nodular BCCs to achieve ablation or reducing the tumor to a depth less than 2 mm and then eradicating the remaining tumor (if any) with PDT.^{42,43} Also, greater saturation of the pathologic tissue with ALA can be achieved after surface treatment with such lasers, as it enhances the penetration of ALA.¹⁵⁶

MAL-PDT was investigated by Foley et al. in two randomized studies.¹⁶¹ They evaluated the histologic response, tolerability, and cosmetic outcome with MAL-PDT for primary nodular BCC (≤ 5 mm in depth). Two multicenter, randomized, double-blind studies with similar design and procedures were conducted. Histologically verified lesion complete response rates were higher with MAL-PDT than with placebo (73% vs. 27%). Treatment was most effective

for facial lesions. Cosmetic outcome was good or excellent in 98% of evaluable, completely responding lesions treated with MAL-PDT. MAL (Metvix in Canada and Metvixia in the U.S., Galderma) is available as a cream, while ALA is available in a stick form (Levulan Kerastick, Dusa Pharmaceuticals Inc., Wilmington, MA).

CONCLUSIONS

PDT with ALA or MAL is a great option for management of BCCs, especially multiple BCCs and superficial BCCs, and can be combined with debulking procedures, such as curettage, or ablative lasers or penetration enhancers to improve their efficacy. PDT has the advantages of treating the entire field of cancerization, good cosmesis, and noninvasiveness.

Is *Candida* antigen an effective treatment for BCC?

Candida antigen is known to induce a delayed-type hypersensitivity (Type IV) reaction mediated primarily by the TH₁ immune response. Intralesional injections of IL-2 and interferon alpha have previously been shown to cause BCC regression.^{162,163} In addition, lymphocytes infiltrating BCC tumors are known to produce IL-2 and IFN-γ, therefore stimulating the TH₁ immune response.¹⁶⁴ BCCs attempt to combat the TH₁ response by producing IL-10, which is known to inhibit both TH₁ and TH₂ immune responses.¹⁶⁵ In theory, injecting intralesional *Candida* antigen induces a type IV delayed hypersensitivity reaction, ultimately leading to regression of the tumor via cell-mediated immunity.^{166–169}

Intralesional injection of 0.4 mg *Candida* antigen every 6 weeks into nodular or superficial BCC demonstrated that 10 out of the 17 patients had complete histologic clearing of their tumor.¹⁶⁴ Unfortunately, this was only a pilot study, with four people in the control group in whom normal saline was injected intralesionally with no BCC regression at the end of the trial. A Fisher exact test was used and only revealed a p value of 0.105 between experimental and control groups.¹⁶⁴ Perhaps the BCC tumor regression would have been higher in the experimental group if there were more frequent intralesional *Candida* injections, as the delayed-type hypersensitivity reaction lasted only approximately 48–72 hours and was noticeably not active 1 week later when the patient returned for the next injection.¹⁶⁴ Future studies may focus on using an antigen that creates a longer hypersensitivity reaction¹⁶⁴ as well as an antigen that actually causes specific targeting of the tumor, as has been recently accomplished in melanoma,¹⁷⁰ vulvar intraepithelial neoplasia,¹⁷¹ and in murine models of NBCCS.⁹⁷ Out of the 17 subjects assigned to the *Candida* intralesional injection group, 55% experienced pain, 78% experienced pruritus, 21% reported flu-like symptoms, and 12% experienced bleeding.¹⁶⁴

CONCLUSION

Although delayed-type hypersensitivity reaction against the Candida antigen may aid in clearing BCCs, more focused antigenic reactions against certain proteins within a BCC lesion, as has been carried out in other fields, may yield more efficacious results.

Is there an association between statin use and BCC?

Statins are 3-hydroxy-3-methylglutaryl (HMG) coenzyme A reductase inhibitors that target low-density lipoprotein. They are the most commonly prescribed medication in the U.S.¹⁷² Various laboratory studies have demonstrated that statins may play a role in the prevention of BCC. In particular, statins have been shown to act as inhibitors in the sonic hedgehog pathway.^{173,174} *In vitro* and animal model studies have shown statins to inhibit cancer cells' growth.^{175,176} Statins have also been shown to deplete cholesterol and promote apoptosis in keratinocytes.¹⁷⁷ One study demonstrated that statins may increase UV phototoxicity in human cutaneous cell lines, and the effect was shown to be reversible with cholesterol supplementation.¹⁷⁸ Additionally, some statins, such as atorvastatin, are associated with UVB phototoxicity.¹⁷⁹ Another possible mechanism of cutaneous carcinogenesis lies in the theory that statins, specifically simvastatin, may inhibit certain lymphocyte functions, thereby decreasing tumor surveillance.¹⁸⁰ Along those lines, statins have been shown to be carcinogenic in rodents.¹⁸¹ Several noncutaneous neoplasm clinical studies have demonstrated inconsistent results.¹⁸²⁻¹⁸⁵ One recent longitudinal cohort study

examined the relationship between statin therapy and risk for subsequent BCC using data from Kaiser Permanente of Northern California during 1997.¹⁸⁶ Asgari et al. did not find an association between the risk of subsequent BCC and statin use after adjustment. However, before adjusting for age, sex, and health care use, the investigators did observe a higher risk with increasing duration of statin therapy and any use of statin therapy.¹⁸⁶ Remarkably, the study had a 10-year follow-up, and therefore examined the long-term effects of statins on BCC recurrence.¹⁸⁶ The results of this study are consistent with previous large randomized controlled trials that were primarily designed to measure cardiovascular endpoints and that observed a mildly increased risk of nonmelanoma skin cancer that did not quite meet statistical significance.¹⁸⁷⁻¹⁹⁰ One article that reviewed three statin trials did not observe any increased risk for skin cancer; not even a statistically insignificant risk.¹⁹¹ It should be noted that those trials were probably not powered appropriately to detect a relationship between statin use and skin cancer.¹⁸⁶

Further research may be useful to delineate a possible risk of specific statins for BCC. Given that statins are the most commonly prescribed drugs in the U.S., and BCC is the most common cancer, future studies will have a high relevance for public health.¹⁸⁶

CONCLUSION

In vitro studies have demonstrated reasons for and against a possible statin-mediated role in the development of BCCs. After statistical adjustment, Asgari et al. did not observe a statistically significant association between statin use and BCC recurrence.

What We Know

- Basal cell carcinoma (BCC) is the most common malignant neoplasm encountered in humans.
- The average risk for a Caucasian to develop BCC is 30%. In dark-skinned races, the incidence of BCC is 19 times less than in Caucasians.
- Older individuals are affected more than younger individuals.
- Familial and sporadic cases of BCC occur as a result of multiple components of the Sonic Hedge Hog (SHH) pathway becoming dysregulated.
- There are primarily 5 clinical types of BCC: nodular, sclerosing, superficial, pigmented, and cystic.
- There are 5 major histological patterns of BCC: nodular, superficial, micronodular, infiltrative, and morpheaform.
- Surgical excision is the standard of care for BCCs. MMS is the best option for the treatment of aggressive

- BCCs, BCCs on the face, and recurrent BCCs. Nodular BCCs can be managed with SE, radiotherapy, combined ablative lasers with PDT and cryosurgery. PDT is a useful modality for sBCC.
- Metastatic BCC, though a rare condition, should be considered when dealing with aggressive histology, large solitary BCCs, prolonged photodamage, and a positive family history, especially in fair-complexioned population.
- BCCs show a large spectrum of global and local dermoscopic features; heavily pigmented BCCs show the most challenging combinations of dermoscopic features.
- Confocal microscopy has emerged as a very useful modality for diagnosing and monitoring BCCs as well as for expediting Mohs surgery.

(Continued)

(Continued)

- With close monitoring, cryotherapy is an option used for conventional management of less-aggressive and superficial BCC.
- Lasers have a multifaceted role in BCC treatment. They can be used alone (PDL), as the non-coherent light source for PDT, as ablative therapy for managing the field of cancerization, or as an adjuvant in debulking of the tumor.
- PDT with ALA or MAL is an efficacious option for management of BCCs, especially multiple BCCs and superficial BCCs, and can be combined with debulking procedures, such as curettage, or ablative lasers or penetration enhancers, to improve their efficacy. PDT has the advantages of treating the entire field of cancerization, good cosmesis, and noninvasiveness.

The levels of evidence are as outlined by Sackett and colleagues in *Evidence-Based Medicine: How to Practice and teach EBM*:

1A	Systematic review of randomized controlled trials
1B	Randomized controlled trial with narrow confidence interval
1C	All-or-none case series
2A	Systematic review of cohort studies
2B	Cohort study/low-quality randomized controlled trial
2C	Outcomes research
3A	Systematic review of case-controlled studies
3B	Case-controlled study
4	Case series, poor cohort case-controlled
5	Expert opinion

Treatment of Cutaneous Squamous Cell Carcinoma

Jennifer D. Bahner, M.D., and Jeremy Bordeaux, M.D., M.P.H.

INTRODUCTION

Nonmelanoma skin cancers (NMSC) are the most common malignancies in the United States, with an annual incidence of over 1 million cases. The vast majority are basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), with a BCC:SCC incidence ratio of 4:1.¹ Unlike almost all BCC, cutaneous SCC is associated with a substantial risk of metastasis, and a small number of patients die from metastatic SCC annually. Risk factors for SCC include childhood sun exposure, ionizing radiation, male gender, light skin, freckling, and treatment with oral psoralen and ultraviolet A (PUVA).²⁻⁵ Incidence of SCC increases with high levels of ultraviolet B exposure⁶ and is highest in lower latitudes, such as Australia and the southern United States. There has been a documented sharp increase in incidence during the past two decades.^{7,8} It is important to identify those lesions (Table 45-1) that have an increased risk (>5%)

of developing metastases to regional lymph nodes. Most cutaneous SCC, however, is low risk and able to be cured with local therapy.

TREATMENT

The aim of treating cutaneous SCC is to completely remove or destroy the tumor while limiting functional and cosmetic impairment. The primary treatment modalities for primary cutaneous SCC are surgical excision, electrodesiccation and curettage (EDC), cryotherapy, Mohs micrographic surgery (MMS), topical agents [i.e., 5-fluorouracil (5-FU), photodynamic therapy (PDT), imiquimod], and radiotherapy (RT). Cryotherapy, EDC, and topical agents are typically reserved for superficial and *in situ* lesions. Excision and MMS are more time-consuming but allow for evaluation of the surgical margins to ensure the lesion has been completely removed.

In selecting the appropriate therapy for SCC, the morbidity of the procedure must be evaluated on a case-by-case basis. The National Comprehensive Cancer Network (www.nccn.org) has published clinical practice guidelines for the treatment of SCC,⁹ although there is a paucity of data from multicenter randomized controlled trials evaluating and comparing treatments for SCC.

SEARCH METHODOLOGY

Reports in the literature were reviewed to identify studies pertaining to treatment of cutaneous squamous cell carcinoma. Articles were retrieved from PubMed by searching for “squamous cell,” “skin” or “cutaneous,” and “cancer” or “carcinoma” concurrently with the name of each therapy. The references from review papers and meta-analyses were also reviewed for relevance. The individual studies were graded using Strength of Recommendation Taxonomy (SORT) criteria¹¹: a Level 1 study contains good quality patient-oriented evidence; a Level 2 study contains limited quality patient-oriented evidence; and Level 3 is other evidence. The strength of each recommendation was then determined based on the body of evidence, again using the SORT criteria: an A strength of recommendation is based on patient-oriented evidence, including consistent findings

TABLE 45-1—Risk Factors for Recurrence, Nodal Metastases of Cutaneous Squamous Cell Carcinoma^{9,10}

History
Recurrent tumor
Rapidly growing tumor
Site of prior radiotherapy or chronic inflammatory process
Neurologic symptoms
Physical examination
Size >2 cm
Location on/around the ear/lower lip
Poorly defined borders
Pathology
Thick and invasive (>4 mm)
Incomplete excision
Moderately or poorly differentiated
Adenoid, adenosquamous, or desmoplastic subtype
Perineural or vascular involvement

from at least two quality studies; a B recommendation is based on patient-oriented evidence but may not include consistent findings from two quality studies; and a C recommendation is not based on patient-oriented evidence and/or is based on opinion, bench research, consensus guidelines, usual practice, clinical experience, or case series.

RESEARCH QUESTIONS

What are the relative efficacies of common modalities in the treatment of cutaneous SCC (Table 45-2)?

TABLE 45-2—Cutaneous Squamous Cell Carcinoma Recurrence Rates Following Treatment

Modality	Location	Follow-up	Rate of recurrence/metastases
Surgical excision	Lip	5-year 3-year All	45/452 (10%) 23/159 (14.5%) 24/237 (10%)
	All (excluding lip-only papers)	5-year 3-year All	39/285 (13.7%) 9/84 (10.7%) 147/1939 (7.6%)
Electrosurgery	All	5-year <5-year Total	7/357 (2%) 27/896 (3%) 34/1253 (2.7%)
Mohs		5-year <5-year Total	9/308 (2.9%) 51/935 (5.5%) 60/1243 (4.8%)
Radiotherapy	Lip	5-year 3-year All	520/3420 (15.2%) 141/755 (18.7%) 666/4237 (15.7%)
	All (excluding lip-only papers)	5-year 3-year All	24.5/362 (6.8%) 13/228 (5.7%) 30/292 (10.3%)
Cryotherapy	All	All	6/171 (3.5%)

What is the efficacy of surgical excision in the treatment of cutaneous SCC?

Incomplete excision, defined as the presence of cancer cells at the margins of the excision base, is a major risk factor for recurrence. There are data on the recommended surgical margins,¹² risk factors for incomplete excision,¹³ and recurrence of SCC following incomplete excision.¹⁴ The papers in the following table, however, primarily address outcomes following complete excision (i.e., with “clear” or “negative” margins) of primary lesions (Table 45-3).

What is the efficacy of electrosurgery in the treatment of cutaneous SCC?

Although electrosurgery using the combination of electrodesiccation and curettage (EDC) has been used to treat

SCC since the early 20th century, it is currently utilized less frequently than other standard therapies. It is still useful for small, well-defined SCC in low-risk sites. Unlike surgical techniques, it is difficult to standardize and lacks histologic control (Table 45-4).

What is the efficacy of Mohs micrographic surgery in the treatment of cutaneous SCC?

For high-risk NMSC, MMS offers advantages over other treatment modalities, including improved functional and cosmetic outcomes. MMS also allows for the evaluation of 100% of the tissue margins, leading to superior cure rates.⁴⁸ It is, however, time-intensive and requires specialized training (Table 45-5).

What is the efficacy of radiotherapy in the treatment of cutaneous SCC?

Advances in surgical and reconstructive techniques have led to a decline in the use of radiotherapy. RT is still used as adjuvant therapy, particularly for lesions on the head and neck, inoperable lesions, lesions with evidence of perineural invasion, and for patient preference and/or cosmesis (Table 45-6).

CRYOTHERAPY

Cryotherapy destroys malignant cells via freezing and thawing, most commonly using liquid nitrogen. It is fast and cost-effective but does not permit histologic confirmation of the adequacy of treatment margins. In the following studies, multiple techniques were employed, ranging from double liquid nitrogen freeze-thaw technique to using the microthermocouple to freeze to -30°C, thaw to 0°C, and then immediately repeat the cycle (Table 45-7).

OTHER

Topical imiquimod and 5-fluorouracil (5-FU) are both approved by the United States Food and Drug Administration (FDA) for the treatment of actinic keratoses. They are widely used in the treatment of Bowen's disease and SCC in situ, though they are not FDA-approved for these indications and there are limited studies of their efficacy. There are no randomized controlled trials of 5-FU treatment for invasive SCC.⁶⁸ There are a number of case reports or small case series reporting successful use of imiquimod treatment for SCC (Table 45-8), but there is a need for well-designed long-term studies.

Laser and light sources alone and in conjunction with photodynamic therapy (PDT) have been used in the treatment of NMSC; however, the evidence in support of these therapies for invasive cutaneous SCC is limited.⁷⁵ 5-Aminolevulinic acid PDT (ALA-PDT) is highly efficacious in Bowen's disease and actinic keratoses and has demonstrated efficacy in small studies of superficial SCC⁷⁶;

TABLE 45-8—Efficacy of Topical Imiquimod for Cutaneous SCC

Paper	Study design	N	Outcome	Follow-up
Peris 2006 ⁶⁹	• Invasive SCC treated w/imiquimod 5% cream	7	• Complete clearance: 71% • Partial clearance: 29% • No recurrences	Mean 31 months
Tillman 2007 ⁷⁰	• Elderly subjects who were not candidates for surgical excision • Treated with imiquimod for 6 weeks	22	• Biopsy 3 months after therapy: 1 residual tumor • One additional recurrence	Median 26 weeks
Goh 2006 ⁷¹	• Invasive SCC treated with topical imiquimod	2	• Clinical response: 1/2 (50%)	
Oster-Schmidt 2004 ⁷²	• 2 elderly females, multiple comorbidities • Biopsy-proven invasive highly differentiated SCC • Imiquimod 5% cream daily 5 days/week x2 weeks	2	• Case 1: negative biopsy at 3 months, no recurrence 21 months later. • Case 2: negative biopsy at 3 months, no recurrence 8 months later.	8-21 months
Nouri 2003 ⁷³	• Invasive SCC • Imiquimod 5% cream daily for 6 weeks	1	• Negative biopsy at 4 weeks post-treatment	1 month
Martin-Garcia 2005 ⁷⁴	• 43-year-old man with biopsy-proven invasive SCC; refused Mohs • Imiquimod 5% cream daily x 2 weeks then 5 days/week x 10 weeks	1	• Negative biopsy at 2 weeks post-treatment • No recurrence 1 year later	12 months

SCC, squamous cell carcinoma.

however, with recurrence rates up to 69%,⁷⁷ it cannot currently be recommended in the treatment of invasive SCC. In one trial, 225 patients with SCC *in situ* were randomized to receive PDT with methyl aminolevulinate PDT using placebo, cryotherapy, or topical 5-FU.⁷⁸ Twelve months after treatment, the lesion recurrence rates were similar: 15% for MLA-PDT, 21% for cryotherapy, and 17% for 5-FU. Harth et al.⁷⁹ report a modified topical regimen of PDT which achieved complete response in 4/5 (80%) superficial SCC treated. In a randomized intra-patient study, Perrett et al. compared topical 5-FU versus topical MLA-PDT in organ transplant recipients with multiple actinic keratoses and/or carcinoma *in situ*.⁸⁰ In these 8 subjects, PDT proved more effective than 5-FU in achieving complete lesion resolution (complete

resolution rate with PDT: 89%, vs. 5-FU: 11%), as well as superior lesional area reduction, cosmetic outcome, and patient preference.

For advanced cutaneous SCC, there are case reports evaluating the efficacy of various chemotherapy regimens. In one series, four subjects were treated with oral capecitabine and subcutaneous interferon-alpha. Two subjects achieved complete remission, and two achieved partial response; however, the final outcome was complete remission in two, progressive disease, and death from unknown etiology in the fourth.⁸¹ A phase III trial by Brewster et al. demonstrated no decrease in time to recurrence or incidence of second primary tumors following 6 months of adjuvant 13-cis-retinoic acid plus interferon-alfa following surgery and/or radiation for aggressive SCC.⁸² Another

paper reported partial regression of one case of recurrent, locoregionally metastatic SCC following combination therapy with cetuximab, a monoclonal antibody against EGFR, and the COX-2 inhibitor celecoxib.⁸³ Kim et al.⁸⁴ presented a case of a 92-year-old man with history of cutaneous SCC who presented with rapidly growing (>7 cm in 1 month) neck metastasis involving the right carotid artery. This patient was treated with primary cetuximab because of age, comorbidities, and small contralateral lymph node involvement. Seven months after a 3-month regimen of cetuximab, the patient continues to have complete response.

CONCLUSIONS

Although there are many papers reporting the rates of recurrence of cutaneous squamous cell carcinoma following various therapies, there is a paucity of randomized-controlled trials comparing therapies. The methodology and follow-up are also not standardized, making it difficult to compare data between case series. Large-scale well-designed studies with long-term follow-up are needed to reach reliable and meaningful conclusions. Based on the data available (see Table 45-2), there appear to be higher rates of recurrence following surgical excision and radiation than following electrosurgery, Mohs micrographic surgery, and cryotherapy. This may, however, simply be a product of the patient population selected for each treatment type.

The National Comprehensive Cancer Network (NCCN) publishes guidelines for care of nonmelanoma skin cancers.⁸⁵ Although these guidelines are based on author consensus and are a work in progress, they are currently the best algorithm for making treatment decisions for cutaneous SCC. They include guidelines for local lesions as well as those with either palpable regional lymph nodes or palpable intraparotid mass. Local lesions are then considered to be at either high or low risk of recurrence based on such clinical factors as location, size, and rapidity of growth, as well as such pathologic characteristics as degree of differentiation and Clark level or thickness. Based on these and other factors, such as age of patient and location of lesion, the guidelines give recommendations for treatment.

Treatment of Cutaneous Melanoma

Andrea L. Suárez, M.D., Ph.D., Gregory J. Wing, B.S.,
Robert P. Dellavalle, M.D., Ph.D., M.S.P.H., and Rene Gonzalez, M.D.

METHODS

PubMed's MEDLINE database and the Melanoma Molecular Map Project's interactive multidatabase¹ were searched for full-text articles using the following key words: "Melanoma," "Melanoma treatment," "Surgical treatment of melanoma," and "Melanoma lymph node evaluation." The most relevant randomized controlled trials with best supporting evidence for current treatment guidelines were selected from the search results to be used as references in this chapter.

SURGICAL TREATMENT OF MELANOMA

Once the diagnosis of melanoma has been established, the tumor is carefully examined to determine how deeply it has penetrated into the skin. This degree of skin invasion is known as the "tumor microstage." The microstage has significant bearing upon type of treatment, prognosis, and survival, and is most often described in terms of Clark's level and Breslow thickness.

The definitive surgical treatment for primary cutaneous melanoma is a wide local excision (WLE) down to the deep fascia. The recommended surgical margins are based on the depth of the tumor (Breslow measurement). Multiple large clinical trials have examined the impact of the surgical margin on the local recurrence rate (Table 46-1).

Melanoma In Situ

For patients with in situ melanomas, there are no data from randomized trials to define the optimal extent of surgical resection. However, retrospective data support the routine use of 0.5 cm margins.^{11,12}

Invasive Melanomas

For melanomas up to 1 mm in depth, a surgical margin of 1 cm is recommended.¹¹ For melanomas 1-4 mm in depth, randomized prospective studies show that 2-cm margins are appropriate, although 1-cm margins have been proven effective for tumors of 1- to 2-mm thickness.^{3,9} A well-conducted retrospective study of high-risk primary

melanomas (>4 mm thickness, median depth 6 mm) showed that excisional margins greater than 2 cm have no effect on local recurrence, disease-free survival (DFS), or overall survival (OS) rates; therefore, a 2-cm margin is likely appropriate in this subgroup.¹³

SENTINEL LYMPH NODE BIOPSY

Sentinel lymph node biopsy (SLNB) has replaced elective regional nodal dissection for the evaluation of regional nodal status. Sentinel lymph node (SLN) status (positive or negative) is the most important prognostic factor for recurrence and is the most powerful predictor of survival in melanoma patients. In a study of 612 patients with cutaneous melanoma (stage I/II), negative results from SLNB were associated with a nearly 60% increase in 3-year disease-free survival compared with positive SLNB results.¹⁴

In the fall of 2006, the results of the third of five planned interim analyses of the Multicenter Selective Lymphadenectomy Trial-1 (MSLT-1) were published.¹⁵ This trial was performed to compare the outcomes of patients with newly diagnosed cutaneous melanoma treated with either WLE plus observation of the regional nodes, followed by regional lymphadenectomy if nodal metastases became clinically apparent (the observation group), or WLE plus SLNB (the SLN group) and: (1) immediate regional lymphadenectomy if a SLN was positive (i.e., selective lymphadenectomy), or (2) observation if the SLN was negative. The primary goal was to assess the survival impact of SLNB. The trial also addressed several other questions regarding the use of SLNB in the initial management of patients with melanoma.

This interim analysis of the MSLT-1 confirms previous reports that SLN status is the most powerful independent predictor of survival, but it does not provide a definitive answer on whether SLN biopsy provides a survival advantage. With a median follow-up of 5 years, this analysis showed a 3%, nonsignificant survival advantage for patients in the SLN group.

A secondary analysis from the MSLT-1 trial compared the patients who had positive SLNs and underwent immediate lymphadenectomy versus the patients in the

TABLE 46-1—Trials Investigating Surgical Margin Width for Melanoma Resection

observation group who later developed palpable nodal disease. The results from this analysis are particularly important to note: there was a significant progression to more advanced nodal disease in the nodal observation group, and there was a significant survival advantage (20%) for the SLN-positive patients who underwent immediate lymphadenectomy.¹⁶ However, this remains highly controversial, as discussed by Sondak et al.¹⁷

In general, SLN biopsy is indicated for melanomas >1.0 mm and for tumors 1 mm or less when histologic ulceration is present and/or classified as Clark level 4 or higher. Patients with clinically enlarged lymph nodes and no evidence of distant disease should undergo a complete regional lymph node dissection.

Standard of care is to perform a complete lymph node dissection (CLND) in melanoma patients with positive SLNs. However, less than 20% will have metastases in non-SLNs. The S classification was described in an attempt to predict the non-SLN status, hoping to identify a subset of patients who can be spared the CLND. This classification is based on the progression of melanoma metastasis from the outside of the lymph node through afferent vessels to the subcapsular lymphatic sinuses through intracapsular lymphatic channels.¹⁸ From there, they reach in a centripetal fashion the deeper part of the node. The occurrence of non-SLN metastasis is significantly related to this S classification ($P = 0.010$), and it has a high prognostic correlation.¹⁹ Studies aimed at assessing the feasibility and usefulness of this method suggest that the S classification predicts the status of non-SLNs.^{20,21} No patient with status was found to have additional non-SLN positive nodes.²¹ Thus larger-scale trials are necessary to confirm these results, as they offer the potential for sparing patients the morbidity of CLND with a positive SLN.

FOLLOW-UP FOR PRIMARY MELANOMA

Patients should be monitored regularly after a diagnosis of cutaneous melanoma, particularly in the setting of

TABLE 46-2—Follow-Up Guidelines²¹

Stage	History and physical examination	Chest radiograph (CXR)/laboratory studies*
Stage IA	6 months × 2 years 12 months thereafter	No
Stage I/II Breslow depth = 1.0–4.0 mm	4–6 months × 3 years 12 months thereafter	Initial: CXR, optional CBC, LFT Follow-up: Yearly CXR, optional CBC, LDH
Stage I/II Breslow depth >4.0 mm	4–6 months × 3 years 12 months thereafter	Initial: CXR, optional CBC, LFT Follow-up: Yearly CXR, optional CBC, LDH
Stage III/IV	3–4 months × 5 years 12 months thereafter	Initial: CXR and CT scans Initial: CBC, LFTs, LDH (for staging) Follow-up: q 6–12 mo CXR, LFT

*LFT are LDH, AST, ALT, and Alk Phos. LDH is lactate dehydrogenase.

thicker tumors, because most metastases occur in the first 1–3 years after treatment of the primary tumor. Annual skin examinations are recommended for life because an estimated 4–8% of patients with a history of melanoma develop new primary melanoma, generally within the first 3–5 years following diagnosis (Table 46-2).²²

RADIATION THERAPY FOR CUTANEOUS MELANOMA

Melanoma cell lines possess a marked ability to repair damaged intracellular contents and recover from radiation-induced damage compared to other cell lines.^{23–26} While melanoma is generally considered a radio-resistant tumor, radiation therapy has proved to be effective treatment for lentigo maligna melanoma (LMM) and lentigo maligna. These melanomas are slow growing, have low metastatic

potential, and were confined to either the epidermis or dermis; attributes which make them responsive to RT alone.^{27,28} In a series of 95 cases in which high radiation doses of 100-110 Gy were delivered in 6 Gy fractions, a 68% 5-year survival rate was obtained, similar to that obtained with local-wide excision.²⁹ However, RT has often been employed nihilistically in patients with a relatively low probability of achieving long-term control because of presentations of large, unresectable, or incompletely resectable locoregional disease.^{30,31} To this end, it has often been administered in palliative settings, in cases of localized (usually unresectable) metastatic disease.^{32,33} In 2006, a prospective Phase II study by the Trans-Tasman Radiation Oncology Group (TROG) treated two hundred and thirty-four patients with melanoma involving lymph nodes with 48 Gy in 20 fractions to the high-risk nodal regions. In contrast to the suggestion that melanoma is unresponsive to RT, regional in-field relapses occurred in only 16/234 patients (6.8%). The progression-free survival and regional control rates were 27% and 91%, respectively, at 5 years, with the major problem being distant metastasis.^{34,35} A randomized Phase III study is underway to confirm the efficacy of local-regional radiation for patients with head and neck melanoma.³⁶

ADJUVANT TREATMENT OF REGIONAL MELANOMA

High-dose interferon α 2b (IFN) is approved as postsurgical adjuvant immunotherapy in patients with resected stage IIB-III melanoma. Based primarily on three Eastern Cooperative Oncology Group (ECOG) trials (E1684, E1690 & E1694), which showed a statistically significant improvement in RFS and OS. Wheatly et al. reported a meta-analysis of 13 randomized trials that demonstrated significant benefit of IFN for OS odds ratio 0.9 ($p=.008$), although the impact on survival appears to be small. The European Organization for Research and Treatment of Cancers (EORTC) has evaluated PEG-IFN α 2b for 5 years versus observation (EORTC 18991). The primary endpoint was distant metastasis-free survival, and at 3.8 years median follow-up there was a nonsignificant benefit in favor of PEG-IFN α 2b. In summary, IFN seems to provide benefit in terms of RFS, but its impact on OS is modest and further studies are underway to identify subsets most likely to derive benefit.

MELANOMA-SPECIFIC VACCINES

Numerous approaches to the development of melanoma-specific vaccines have been disappointing. A vaccine prepared from three allogeneic melanoma cell lines using BCG as an adjuvant (Canvaxin) was studied in two phase III trials in patients with resected stage III and resected stage IV melanoma. In 2005, the Data Safety Monitoring Board overseeing these two studies determined that the trials were sufficiently unlikely to result in a determination

of vaccine efficacy, and each trial was ended and all protocol treatments were discontinued. The Southwest Oncology Group conducted a randomized phase III trial of an allogeneic melanoma vaccine (Melaccine) versus observation in patients with intermediate-thickness, clinically or pathologically node-negative melanoma. Six hundred eighty-nine patients were accrued. After a median follow-up of 5.6 years, the vaccine was not associated with a statistically significant benefit in disease-free or overall survival.³⁷

Melanoma-defined antigen vaccines include targets such as gangliosides and antigens recognized by T cells infiltrating melanoma lesions. Gangliosides are attractive targets for immunotherapy because of their ability to induce antibody responses. GM2 administered with BCG or in combination with the keyhole limpet hemocyanin (KLH) hapten are effective modes of inducing GM2-specific antibodies.³⁸⁻⁴⁰ Despite this, two large phase III trials have demonstrated no evidence of a survival benefit when a vaccine using GM2-KLH was used and also suggested that vaccination may have a negative effect on survival. Numerous T cell antigens identified in patients with melanoma also are the basis for ongoing efforts in vaccine development. Specifically, MAGE-3 protein, which contains both HLA-A1 and HLA-2.1 restricted CTL epitopes, is able to induce both a specific antibody response and a cellular immune response in patients with advanced melanoma.⁴¹ Gene expression profiling studies can demonstrate specific markers that are associated with improved clinical response to the MAGE-3 vaccine, such as the MAGE-A3 gene signature.^{42,43} Currently, an international phase III trial is underway to evaluate the MAGE-A3 vaccine in patients with completely resected stage III melanoma and the MAGE-A3 expression profile in their resected lymph node (NCT00796445).

SYSTEMIC TREATMENT OF ADVANCED MELANOMA

Interleukin-2 is an approved treatment in metastatic melanoma, because a small number of patients can achieve a durable complete response and may in fact be “cured.” The toxicity is manageable and IL-2 is a reasonable option for some patients, although there are no phase III data.

Chemotherapy is ineffective in metastatic melanoma. Dacarbazine is often the standard-of-care arm in phase III trials but it has no impact on survival and the time to progression is generally 6-8 weeks. It may be useful for palliation in some patients.

Korn et al. reported a meta-analysis of phase II trials performed in the cooperative group setting from 1975 to 2005. Seventy trial arms were analyzed and parameters are defined to evaluate and plan future phase III trials.

BIOCHEMOTHERAPY

In an effort to enhance response rates, chemotherapy agents are often combined with other chemotherapeutic

or biologic agents. Regimens consisting of combinations of IL-2 or IFN- α , or both, administered with chemotherapy produced high response rates in the treatment of MM in phase 2 trials. Unfortunately, all failed to demonstrate a statistically significant benefit in overall survival compared to chemotherapy regimens.^{44–49}

The combination of cisplatin, vinblastine, and dacarbazine (CVD) with IL-2 and IFN- α is an extensively used biochemotherapy regimen that yields the highest overall response rate.^{44,45,47,50,51} A large phase III trial compared CVD with CVD plus IFN- α and IL-2 administered concurrently and demonstrated no significant difference between the biochemotherapy and chemotherapy arms in response rates and survival.⁵²

Despite the apparent high response rates from biochemotherapy, no overall survival advantage is conveyed when compared to chemotherapy alone.

ANTI-CTLA-4 MONOCLONAL ANTIBODIES

T cells recognize intracellular protein peptide fragments displayed on the surface of antigen presenting cells (APCs). This recognition is a critical event in the activation of cellular immunity. The interaction of T cells with APCs requires the presence of the co-stimulatory molecule B7. Subsequent activation results in upregulation of cytotoxic T-lymphocyte antigen 4 (CTLA-4). CTLA-4 then competes for binding with B7 and negatively inhibits T cell activation. Therefore, monoclonal antibodies (MAbs) targeting CTLA-4 have the potential to promote immune responses in melanoma patients, where such responses are associated with disease regression.

Ipilimumab and tremelimumab are two CTLA-4 MAbs currently being evaluated in melanoma patients. Several studies demonstrate significant and lasting responses to ipilimumab in a subset of patients with unresectable or metastatic melanoma. A delayed response of weeks to months is sometimes observed.⁵³ There is also an associated potential for autoimmune toxicity, including enterocolitis and hypophysitis.⁵⁴ In a phase II trial of 72 chemotherapy-naïve patients with advanced melanoma randomly assigned to ipilimumab with or without dacarbazine, the disease control rate was increased with the combined treatment (31 versus 22 percent with ipilimumab alone).⁵⁵ Tremilimumab showed similar activity in phase I and II clinical studies in previously treated patients.⁵⁶ Preliminary results of a phase III clinical trial comparing tremilimumab to chemotherapy (either temozolamide or dacarbazine) in 655 previously untreated patients with metastatic melanoma⁵⁷ showed no statistical difference in the objective response rate for overall survival (American Society of Clinical Oncology meeting, 2008). Longer follow-up is required to determine if tremilimumab yields more lasting responses than cytotoxic chemotherapy.

A recently published phase III study of ipilimumab randomized 676 patients with unresectable stage III or IV melanoma, whose disease had progressed while receiving therapy for metastatic disease, in a 3:1:1 ratio to receive ipilimumab plus gp100 (a peptide vaccine), ipilimumab alone, or gp100 alone, administered every 3 weeks for up to four treatments.⁵⁸ The median overall survival was statistically higher among patients receiving ipilimumab plus gp100 compared to patients receiving gp100 alone (10.0 months vs 6.4 months), whereas there was no difference in overall survival between the ipilimumab groups with or without gp100. These data suggest that ipilimumab, with or without gp100, improves overall survival in patients previously treated with metastatic melanoma. Until now, no randomized studies had ever shown a clear survival benefit with any agent or combination of agents.

MOLECULARLY TARGETED THERAPY

Recent advances in the molecular biology of melanoma tumorigenesis have enhanced our understanding of features critical for effective melanoma cell death and resistance mechanisms. Gain-of-function KIT mutations were reported in 21% of mucosal melanomas, 11% of acral melanomas, and 16.7% of melanomas arising in chronically sun-damaged skin,⁵⁹ while 15% of anal melanomas harbored a KIT oncogenic mutation⁶⁰ and in other cases showed increased KIT copy number or amplification. Most mutations affect the juxtamembrane region of the KIT protein, which predicts responsiveness to imatinib mesylate.⁶¹ In *in vitro* assays, mucosal melanoma cells exhibited imatinib sensitivity, which correlated with KIT mutational status.⁶² In these studies, imatinib dramatically decreased proliferation and was cytotoxic to a KIT mutated and amplified cell culture, suggesting that these mutations may serve as mediators and/or biomarkers of *in vivo* treatment efficacy. Preliminary findings from trials of imatinib or other c-KIT inhibitors in melanoma patients demonstrate a 50% response rate with imatinib in metastatic melanoma patients with a c-KIT mutation in their tumor.⁶³ Investigators are actively working to identify the optimal inhibitors to use for the most common c-KIT mutations found in melanoma.^{64,65}

The RAS-RAF-MAPK signaling pathway is an important signaling pathway that mediates a number of cellular responses to growth signals. Activating mutations of RAS and BRAF result in a constant activation of the MAP kinase cascade and eventually contribute to proliferation and dedifferentiation of cancer cells. Activating mutations of BRAF have been observed in approximately 50% of malignant melanomas. The V600E mutant accounting for over 90% of these mutations leads to a continuous stimulation of the MAP kinase pathway, resulting in uncontrolled cancer cell growth.^{66,67} While numerous amino acids within

the BRAF protein are targets for mutation in melanoma,⁶⁷ valine at position 600 (BRAF^{V600E}) is the most predominately targeted residue, comprising 95% of all BRAF mutations in melanoma.^{67–69} Not only is this mutation present in primary tumors and metastases, but it is also found in benign nevi,^{70,71} suggesting that while activating BRAF mutations portend a growth advantage to melanocytic cells, these mutations are not sufficient to fully transform normal human melanocytes. Various small-molecule inhibitors with improved RAF kinase selectivity, such as Raf265 (Novartis), XL281 (Exelixis/Bristol Myers Squibb), AZ628 (AstraZeneca), SB-59088 (GlaxoSmithKline) and PLX-4032 (Plexxikon/Roche), hold promise for evaluating BRAF mutations as therapeutic targets in clinical studies.

PLX-4032 is highly selective for BRAF, exhibits tenfold greater potency for BRAF^{V600E} over wild-type BRAF, has excellent oral bioavailability, and has a relatively low toxicity profile.⁷² This agent is currently under investigation as a form of treatment in advanced melanoma (www.clinicaltrials.gov), and results of a phase I trial have been reported recently.⁷³ In the beginning stage of the phase I trial, cohorts of patients with advanced solid tumors were treated with increasing doses of PLX4032 (200 to 1,600 micrograms), administered twice daily as oral capsules. During the dose-escalation stage of the phase I trial, 21 patients with metastatic melanoma, 16 with, and 5 without, BRAF mutations, were treated at doses that achieved AUC_{0–24} >300 μMh. Tumor dimensions were measured by computed tomography (CT). Ten patients with BRAF-mutant melanoma achieved a partial response with tumor regression and one patient had a complete response; none of the patients with melanomas who were wild-type for BRAF achieved tumor regression. In a follow-up study of 32 participants, tumor size decreased in 24 and disappeared entirely in two

patients with BRAF mutations. There is the potential for patients with metastatic melanoma to undergo screening before the initiation of therapy for the presence of mutations in BRAF, KIT, and probably other key genes.

Melanoma, like many other cancers, displays epigenetic abnormalities, such as global losses and local gains in methylation patterns, which likely portend a tumor survival advantage through silencing of tumor suppressor genes.^{74–77} With advanced molecular biologic techniques, researchers can use methylated DNA immunoprecipitation and promoter array hybridization to determine relative methylation in normal human melanocyte and melanoma cells, allowing for identification of unique tumor-specific methylation markers.⁷⁸ CpG methylation represents a reversible event, thus silenced tumor suppressor genes represent potential anticancer therapy targets. Decitabine is a cytosine analog that induces genome hypomethylation and is an agent with potential to upregulate silenced genes.⁷⁹ Recent studies aimed at classifying gene upregulation based on promoter methylation and CpG content underscore that understanding patterns of decitabine action could facilitate predicting the likelihood of upregulating silenced tumor suppressor genes.⁸⁰

RNA interference (RNAi) is a technique for turning off specific genes, but until recently, its translation into clinical cancer therapy has been a struggle, given the challenge of delivering the short sequences of interfering RNA to cellular targets.^{81,82} Recent phase I clinical trials, however, demonstrate RNAi-mediated reduction of ribonucleotide reductase subunit M2 expression from melanoma biopsies of patients who received intravenous infusions with small interfering RNAs (siRNA).⁸³ Therefore, anticancer therapies that target RNAs seem to be one step closer to a new class of targeted melanoma therapy.

What We Know: Therapeutic Management of Melanoma

- The definitive surgical treatment for primary cutaneous melanoma is a wide local excision (WLE) down to the deep fascia.
- Sentinel node status (positive or negative) is the most important prognostic factor for recurrence and is the most powerful predictor of survival in melanoma patients.
- Standard of care is to perform a complete lymph node dissection (CLND) in melanoma patients with positive SLNs.
- Annual skin examinations are recommended for life because an estimated 4-8% of patients with a history of melanoma develop new primary melanoma, generally within the first 3-5 years following diagnosis.
- Melanoma is generally a radio-resistant tumor, and radiation therapy is reserved for specific cases of lentigo maligna and lentigo maligna melanoma (LMM), and in the palliative setting.
- Ipilimumab (MAb targeting CTLA-4) has the potential to promote immune responses in melanoma patients, where such responses are associated with disease regression. Ipilimumab has demonstrated a survival advantage in a randomized-controlled trial.
- Melanoma cells frequently display gain-of-function c-KIT mutations, activating BRAF, and epigenetic abnormalities, such as global losses and local gains in methylation patterns, all of which likely translate into tumor cell growth and survival advantages. These are important and promising areas of ongoing research.

Treatment of Mycosis Fungoides and Sézary Syndrome

Farah R. Abdulla, M.D., Cameron Harrison, M.D., and Youn H. Kim, M.D.

INTRODUCTION

Cutaneous T cell lymphomas (CTCL) are T cell non-Hodgkin lymphomas (NHL) with primary cutaneous involvement. Mycosis fungoides (MF) and Sézary syndrome (SS) are subsets of CTCL.¹ The diagnosis and work-up for MF and SS are outlined in the National Comprehensive Cancer Network (NCCN) practice guidelines.²

Mycosis fungoides is the most common type of CTCL with a unique clinical-pathologic presentation. The initial cutaneous presentation of MF can be as patches or plaques that may subsequently evolve into tumors or generalized erythroderma.³ Patches or plaques in MF are often localized, typically affecting flexural areas and the buttocks, although any area of the body can be involved. However, the skin involvement can be much more extensive and sometimes may progress to tumors or generalized erythroderma involving the entire skin surface. In the more generalized presentations, keratoderma may develop, nails may become dystrophic, and scalp involvement can result in alopecia.¹

Sézary syndrome (SS) is a distinct subtype of CTCL, which is characterized by erythroderma, lymphadenopathy, and neoplastic T cells (or Sézary cells) in the peripheral blood that meet criteria of significance either by morphology, flow cytometry, or molecular analysis.^{4,5} Patients may present initially with all components of SS or with only one component (e.g., generalized erythroderma), and subsequently progress to develop other clinical features of SS.

Accurate staging is important because therapeutic approaches in MF are largely based on the clinical stage of the disease. The standard clinical staging system for MF and SS is based on the extent and type of skin involvement (T classification), the presence of lymph node (N classification) or visceral disease (M classification), and the detection of abnormal (Sézary) cells in the peripheral blood (B classification).⁴

The risk of extracutaneous disease tends to correlate with the extent and type of skin involvement.^{6,7} The extent and type of skin involvement are defined in the T-classification in the revised staging system.⁴ T1 disease is defined as less than 10% of the skin surface involved with patches or plaques while T2 disease is defined as greater than 10% but less than 80% of the skin surface involved with patches or plaques. T3 disease is defined as

tumor (nodular) disease, and T4 disease is erythroderma with at least 80% of the skin surface diffusely involved. Extracutaneous involvement at presentation is exceedingly rare in patients with T1 disease, infrequent in patients with T2 disease (2%), and (more) likely in patients with T3 (13%) or T4 (24%) disease.^{7,8} Patients who present with limited cutaneous involvement (T1) may never progress to more advanced T classification, especially when appropriate treatment is administered.^{6,9,10} Although MF may be a systemic disease from the outset, the clinical behavior is such that progression of skin disease precedes onset of clinical symptoms at extracutaneous sites. Any visceral site can be involved with MF, the most common of which are the lungs, bone marrow, gastrointestinal tract, liver, and central nervous system.¹¹

EPIDEMIOLOGY AND ETIOLOGY

Although MF and SS are uncommon forms of NHL, they are the most common lymphomas with primary involvement of the skin. The annual incidence in the United States is estimated at 0.96 cases per 100,000 with approximately 3,000 new cases per year in the United States.¹² While MF and SS occur in children and young adults, the median age at diagnosis is between 55 and 60 years.¹³ There is 2:1 male predominance, and black patients have a two-fold greater risk for developing MF/SS than white.

The etiology of MF and SS remains undetermined. Various studies and case reports have suggested an association with genetic factors, environmental exposure, or an infectious etiology, but none has confirmed a causal association. The immunopathogenesis has been a focus of much research in the last decade. The malignant lymphocytes in mycosis fungoides are CD4⁺T cells that express the skin-homing receptors CLA and CCR4. The malignant cells are associated with increased T helper type 2 and reduced T helper type 1 cytokine production.³ The trigger of T cell activation and subsequent clonal expansion of the malignant T cells in the skin remains unclear.

METHODOLOGY

While there are multiple therapeutic options for MF and SS, there is a lack of well-designed, prospective, controlled

clinical trials comparing the efficacy and safety of various therapies. There are also no standardized response criteria. Many studies use skin response as the primary endpoint only while others used composite or global responses as the primary endpoint. As a result, caution is needed when interpreting efficacy data such as duration of response and time to response. The most important factor in designing a treatment plan is the clinical stage. Selection of a specific treatment plan is based on the clinical stage, additional prognostic factors (e.g., folliculotropism or large cell transformation), toxicities associated with the treatment options, the patient's age, and other social and medical problems (Figures 47-1 thru 47-5). The NCCN as well as the European Organisation for the Research and Treatment of Cancer (EORTC) outline the treatment guidelines for MF and SS according to stage of disease.^{2,14} In considering all possible therapeutic options for a given stage of disease, retrospective cohort as well prospective studies were reviewed. Subsequently, the studies were evaluated using the U.S. Preventive Services Task Force: Hierarchy of Evidence (Table 47-1).¹⁵

In general, the treatment options in MF/SS are categorized into skin-directed treatments, systemic biologic/noncytotoxic therapies, and systemic cytotoxic chemotherapies. For patients with T1 and T2 disease without extracutaneous involvement, stages IA-IIA, the primary treatment plan will usually be limited to skin-directed therapies (Tables 47-2 thru 47-5). However, if these fail or there is histologic evidence of either large cell transformation or folliculotropism, a more intensive regimen is usually indicated (Tables 47-6 thru 47-7). With respect to tumor

disease, stage IIB, the treatment plan depends on the extent of the tumor lesions. If the tumor lesions are few in number, the skin directed treatment options for stage IA-IIA are indicated, and the tumor lesions should be treated with local radiation (Table 47-8). In cases with extensive tumor involvement, total skin electron beam therapy or systemic therapies are considered (Tables 47-9 and 47-10). The affected skin in patients with erythroderma (T4) is very sensitive and cannot tolerate skin-directed treatment. Hence, primary therapy for patients with erythroderma consists of the use of systemic biologic response modifiers (e.g., photopheresis, and oral retinoids/rexinoids, interferons), histone deacetylase inhibitors (HDAC-i), denileukin diftitox (fusion toxin), or low-dose methotrexate monotherapy or in combination (Tables 47-11 thru 47-15). When biologic therapies fail in patients with refractory stage IIB to IV disease, single-agent chemotherapy such as gemcitabine, or liposomal doxorubicin are considered (Table 47-9).

Effective supportive care is critical in the management of patients with T4 disease. Increased susceptibility to bacterial and viral infection is a considerable source of morbidity and mortality. Patients with this type of compromise to the skin barrier should have diligent surveillance for skin infections, especially *Staphylococcus aureus* and herpes simplex virus. There is a low threshold for beginning systemic and skin-directed antibacterial agents with the appropriate susceptibilities.

Mycosis fungoides and Sézary syndrome are associated with severe pruritus, which can be a serious detriment to patient quality of life. The measurement of this very subjective symptom is important to assess improvements in

itching. It is important to attempt to quantify the severity of pruritus using a tool such as a visual analog scale). The Visual Analog Scale is a line with the numbers one (representing minimal itch) through ten (representing the worst itch), and it is the most common assessment tool utilized

in the assessment of pruritus in clinical trials. However, a more rigorous validated tool is needed for clinical trials. The effective symptomatic treatment of pruritus is of utmost importance, especially in Sézary syndrome. Most often, occlusive medium potency topical steroids and oral

TABLE 47-1—U.S. Preventive Services Task Force: Hierarchy of Evidence¹⁵**Hierarchy of Research Design**

I	Evidence obtained from at least one properly randomized controlled trial.
II-1	Evidence obtained from well-designed controlled trials without randomization.
II-2	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
II-3	Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence.
III	Opinions of respected authorities, based on clinical experience, descriptive studies and case reports, or reports of expert committees.

anti-itch measures such as gabapentin and mirtazapine are used.¹⁶

Combination chemotherapy is generally reserved for patients with lymph node or visceral disease. Patients with advanced disease in whom primary treatment fails are candidates for potential allogeneic stem cell transplantation. There is no evidence that early aggressive systemic therapy is better than conservative therapy in the management of limited disease. There is a definite need for more reliably effective therapies, especially in advanced cases of the disease. As a result, participation in clinical trials is critical for patients with advanced disease who have failed primary systemic therapies. It is important to consider allogenic stem cell transplant in patients with advanced disease as this may offer a long lasting remission or possible cure.

SKIN-DIRECTED THERAPIES

Despite advances in treatment for MF and SS, traditional skin-directed therapies are still used as the primary therapeutic modality in the majority of patients with stage I-IIA

disease (Tables 47-2 thru 47-5). In patients where initial skin-directed therapy has failed or in those with severely symptomatic disease, skin-directed therapies can be combined with systemic treatments, or the patients may be referred for experimental therapy.

TOPICAL CORTICOSTEROID THERAPY

Topical steroids can be used either as primary treatment in patients with limited patch or thin plaque disease, or they can be combined with other skin-directed treatments for added symptomatic control.² The rationale for use of corticosteroids in MF is that they inhibit lymphocyte binding to endothelium and intercellular adhesion.¹⁷ In addition, they also induce apoptosis of neoplastic lymphoid cells.¹⁸

For patients with very limited skin involvement, topical corticosteroids can be a very cost-effective option for disease control. Application of topical steroids as treatment is generally performed once to twice a day to affected areas¹⁹ (Table 47-3). The efficacy of topical steroids is not

diminished over time and can be used again in the event of disease relapse. The benefit is that topical steroids can be used again for relapse of disease. However, long-term use of topical corticosteroids in any disease may lead to epidermal atrophy, striae, dyspigmentation, and steroid addiction. In particular, clinical morphologic subsets of MF, such as the poikilodermatous MF, may make it difficult to interpret resolution of disease when topical steroids are used. In this variant, the clinical findings of telangiectasias and atrophy are the same as the side effects induced by prolonged use of topical corticosteroids. Hence, caution should be used in interpretation of disease versus side effect of therapy.

TOPICAL CHEMOTHERAPY

Topical nitrogen mustard (mechllorethamine hydrochloride) is the major form of topical chemotherapy used for MF and SS.²⁰ Topical carmustine (BCNU) has also been used (Table 47-3).²¹

Nitrogen mustard is the most widely utilized topical chemotherapeutic agent for MF because of its well-demonstrated efficacy, safety, and ease of application. The mechanism of action of nitrogen mustard in MF is unclear but may be mediated by immune mechanisms (e.g.,

immune stimulation) or by interaction with the epidermal Langerhans cell.²⁰

Topical nitrogen mustard preparation is applied to the skin once daily as initial therapy. If the disease is localized, the application field may be limited to the regional area of involvement or to the entire skin surface for those patients with generalized skin involvement. The initial concentration used is usually 20 mg%. If there is no response or a suboptimal response after several months of treatment, the concentration can either be increased to 30 or 40 mg% or the frequency of application may be increased to twice a day. Once complete skin clearance is achieved with topical nitrogen mustard, a maintenance regimen of some kind is usually instituted, but there is no evidence that more prolonged maintenance is beneficial.²⁰

Both acute and chronic complications have been associated with topical nitrogen mustard therapy. The most frequent acute complication is an immediate or delayed cutaneous hypersensitivity reaction. It occurs in less than 10% of patients treated with the ointment-based preparation of nitrogen mustard. However, patients can be desensitized with a variety of topical or systemic desensitizing regimens.^{20,22}

Chronic use of topical nitrogen mustard is not associated with increased risk of secondary cutaneous malignancies.²⁰ However, in patients who have used topical

nitrogen mustard in combination or sequentially with other skin-damaging therapies (e.g., ultraviolet [UV] phototherapy, radiation therapy), there is an increased risk for nonmelanoma skin cancers.^{23,24} Application of nitrogen mustard in the genital areas should be strictly avoided since genital application has been linked with development

of secondary skin cancers. Topical HN2 can be used safely in pediatric patients, and studies have not shown worse adverse effects in children.²⁰ There is no evidence of significant systemic absorption of the medication.

BCNU can be used in solution or ointment form.^{21,25} Similar to nitrogen mustard, it can be applied to regional

areas for localized disease or to the entire skin surface for generalized disease. Contact should be avoided with the eyes or orifices.²⁶ There are both cutaneous and hematologic side effects. The majority of patients experience a degree of erythema accompanied by a burning sensation. This tends to localize to the intertriginous areas. It usually subsides with the use of topical corticosteroids and cool compresses. More severe erythematous reactions can lead to the development of telangiectasias that can persist for several years. With respect to hematologic parameters, 5% of patients treating the general body surface had mild leukopenia. Other adverse hematologic side effects have not been observed.²⁶

Topical corticosteroids, nitrogen mustard, and BCNU are indicated as initial primary therapy for patients with stage IA or IB disease. Topical chemotherapy should be considered as an alternative for those patients who are candidates for phototherapy but prefer the convenience of home application or already have a significant amount of photodamage.

PHOTOTHERAPY

Phototherapy involves using UV radiation in the form of UVA or UVB wavelengths. It can be used alone or in

combination with psoralen, a photosensitizing agent. Psoralen used with UVA (PUVA) is also referred to as photochemotherapy. PUVA therapy is widely used in dermatology for various dermatoses such as psoriasis. Psoralens intercalate between pyrimidines within DNA and, upon exposure to UVA, form photoadducts and DNA crosslinks.²⁷ This process results in cytotoxic, antiproliferative, and immunomodulatory effects. The long-wave UVA has an advantage over UVB because of its greater depth of penetration. This is useful in that while MF is defined as an epidermotropic process, a considerable amount of neoplastic infiltrate is still in the dermis.

Phototherapy used with UVA is indicated as primary therapy in generalized plaque and erythrodermic MF without evidence of extracutaneous disease (Table 47-4). It is also used as palliative therapy in combination with another treatment in patients with advanced disease. Initially, PUVA treatments are given 2-3 times per week, with a minimum of 48 hours between treatments to monitor the delayed erythema reaction.²⁸ The initial dose of UVA and the rate at which the dose is increased are generally dependent upon the skin type. Erythrodermic patients tend to require very low starting doses with very small dose increments. After maximal response, the frequency of PUVA treatments is decreased.

Both acute and chronic adverse effects have been observed with PUVA therapy.²⁸ Nausea from psoralen ingestion is observed in 10-20% of patients and can be managed by ingesting the drug with food or milk, or with appropriate antiemetics.²⁷ Phototoxic reactions can range from erythema to the development of bullae. Ultraviolet-opaque goggles must be worn during the UVA irradiation. Long-term PUVA therapy with high cumulative doses has been linked to an increased risk for the development of squamous cell carcinomas,^{29, 30} pigmented macules,³¹ and cataract formation.²⁷ Up to one-third of patients treated with PUVA develop signs of chronic photodamage and secondary cutaneous malignancies. After each PUVA treatment, appropriate photoprotection, including application of sunscreens, protective clothing, and UV-shielding glasses, should be used for a minimum of 24 hours.

Ultraviolet B (UVB) therapy is a widely used alternative to PUVA. While broadband has been used, it has been supplanted with light limited to the 311 nm wavelength known as narrowband UVB (NBUVB). The use of NBUVB does not require the ingestion of psoralen prior to therapy, which is advantageous in patients that have problems tolerating the medication. Similar to PUVA, it is performed 2-3x per week with 24 hours between treatments. NBUVB is considered to have less toxicity than broadband UVB or PUVA because the penetration of UVB is reduced. Although several published studies using NBUVB in MF have shown clinical efficacy superior to that of broadband UVB, PUVA has been shown to be more effective than either³² (Table 47-4).

TOPICAL RETINOID AND REXINOID THERAPY

Retinoids modulate gene expression by activating nuclear retinoic acid receptors (RARs) and retinoid X receptors (RXRs). This leads to alterations in cell differentiation, proliferation, and apoptosis.³³ These properties have prompted investigation into their use as antineoplastic agents. Broad-spectrum retinoids have an affinity for RARs but exhibit poor tissue specificity and low activity. There is a derivative category of agents, known as rexinoids, which specifically activate the RXR receptors and have a lower affinity for RAR receptors. A rexinoid agent commonly used in MF is bexarotene. Although the molecular basis of bexarotene has not been clearly elucidated, it has been shown to induce apoptosis in CTCL lines.³⁴

Bexarotene 1% gel, a rexinoid, is the most commonly used topical retinoid for treating MF. The medication is typically applied as a thin film to the patches or plaques. It is most effective and best tolerated when used twice daily³⁵ (Table 47-3). Because of the irritant effect of the rexinoids, it is only feasible to use this agent when there is limited number of patches or plaques. It is not intended for generalized application. The most common toxicity of bexarotene gel is irritation at the sites of application and occurs in

the majority of patients.³⁵ The irritation commonly occurs in flexural areas affected by MF. Because of the erythema from the irritant reaction, it may be necessary to withhold therapy for a few weeks to assess disease activity.

Tazarotene 0.1% gel, a RAR agonist, has also been evaluated in a pilot study³⁶ (Table 47-6). The gel was applied daily to discrete lesions only. Use of the gel to lesions resulted in a 35% clearance rate.³⁶ Mild to moderate local irritation was the most common adverse event in the majority of patients (84%). Any associated irritation was relieved by decreasing the frequency to every other day application or the use of a mid-potency steroid.³⁶

Imiquimod

Imiquimod is a topical immunomodulator that has been approved by the Food and Drug Administration (FDA) for the treatment of genital warts. The drug is believed to function in part through the induction of local interferon (IFN) production.³⁷ Because systemic IFN is effective in the treatment of MF, it has been hypothesized that topical imiquimod might also be effective while sparing patients the systemic side effects of IFN treatment. An open-label, pilot study used 5% imiquimod cream to localized patches and plaques of MF (Table 47-6). Imiquimod was generally well tolerated, and skin irritation was limited to lesions, which ultimately cleared with treatment.

RADIATION THERAPY

Mycosis fungoides is an extremely radiosensitive neoplasm. Individual plaques or tumors can be treated with local electron beam therapy (EBT) to total doses of 24-36 Gy, with a high complete response rates.

Total skin electron beam therapy (TSEBT) has been developed to treat patients with extensive cutaneous disease.³⁸ Radiation is administered four times a week to a total dose of 30-36 Gy. The treatment course is 8-10 weeks in duration. During each treatment session, patients assume multiple positions to ensure that the entire skin surface is irradiated. Supplementary treatment is required for the soles of the feet, perineum, and inframammary areas. The eyes are shielded routinely, but other areas may be protected over the course of the treatment to help control localized skin reactions.

Short-term side effects associated with TSEBT include acute erythema, desquamation, temporary nail and hair loss, and an impaired ability to perspire properly for up to 12 months. Long-term, there is an increased risk of secondary squamous cell and basal cell carcinomas of the skin. The risk of secondary malignancies is greatest in those who have received long courses of therapy with other skin-damaging therapies such as phototherapy.²³

The use of TSEBT is indicated as primary or secondary management in patients with generalized plaque or tumor involvement (Tables 47-5 and 47-8). TSEBT can provide

important palliative benefit in patients with extensive or severely symptomatic disease. Although the therapy is effective with nearly 100% response rates, it is not curative, and disease usually recurs. Up to two courses of TSEBT may be administered over the course of a lifetime, which can limit its use in long-term management of the disease.³⁹

SYSTEMIC THERAPIES

Systemic therapies are indicated when skin-directed primary therapies fail or in aggressive or advanced MF cases. Patients with significant numbers of circulating Sézary cells should also be placed on a systemic therapy as part of their treatment regimen. Therapeutic efforts are focused on targeted biologic agents that promote apoptosis and manipulate the host immune response. Either the combination of a biologic agent with a skin directed therapy or the combination of multiple biologic agents results in improved disease control by acting in a synergistic manner. Toxicity can also be reduced in combination regimens, as lower doses are required for each therapeutic modality.

BIOLOGIC THERAPIES

Extracorporeal Photopheresis (ECP)

ECP is considered first line therapy for patients with Sézary cell blood involvement (Table 47-14). ECP delivers psoralen and UVA radiation systemically by utilizing an extracorporeal technique.⁴⁰ White blood cells are collected in a clear container (leukapheresis) and exposed to psoralen. The cells are then irradiated with UVA (PUVA). The irradiated cells are returned to the patient in a closed system. The ECP instrument performs the leukapheresis and delivers the UVA. The mechanism of action of ECP involves induction of malignant T cell apoptosis with PUVA, which is accompanied by the enhancement of a tumor-specific immune response. Extracorporeal photopheresis also induces monocytes to differentiate into dendritic cells capable of phagocytosing and processing the apoptotic tumor cell antigens.^{3,41}

A standard complete ECP regimen for CTCL consists of 2 consecutive days of therapy repeated at 2-4-week intervals. The frequency of administration is adjusted according to disease severity and/or clinical response. After a maximal, stable response has been achieved, the frequency of treatments is gradually decreased, and then stopped completely, unless the disease relapses or flares during the weaning process, or when maintenance therapy is given. Maintenance therapy is given every 4-6 weeks; a repeat attempt at weaning can be made later. If an adequate response is not attained with ECP monotherapy, or if patients have a significant level of circulating Sézary cells, additional biologic agents should be added. These can include interferon or systemic retinoid. A minimum of 4-6

months of treatment should be given before ECP is considered a failure.

An advantage of ECP is its limited side effect profile. One of the greatest advantages of ECP is that the adverse effects are minimal.⁴⁰ Common side effects include mild fatigue associated with leukapheresis and fluid shifts. Peripheral intravenous access for treatment is preferable to central access to minimize complications. There are no significant side effects in terms of laboratory parameters. Patients receive psoralen, and need to protect their eyes and skin from UV exposure for 24 hours after treatment. Extracorporeal photopheresis (ECP) has been shown to be most effective in patients with blood involvement, particularly those with SS^{42,43} (Table 47-14).

Interferon-alpha

Interferon (IFN) therapy is indicated for refractory or advanced disease and is often combined with other skin-directed or systemic therapies. IFN was originally discovered by Isaacs and Lindenmann in 1957.⁴⁴ It is a protein expressing virus nonspecific antiviral activity.⁴⁵ Based on antigenic proteins, IFNs are divided into three main groups: IFN-alpha, IFN-beta, and IFN-gamma. IFN-alpha and beta bind to IFN type I receptor while IFN-gamma binds to the IFN type II receptor. IFN-alpha preparations are primarily used in the treatment of CTCL.⁴⁶ IFN-gamma has been used rarely as an alternative in patients who have developed resistance to IFN-alpha.⁴⁶

IFN-alpha induces a variety of immunologic effects that may lead to clinical response.³ It directly enhances cell-mediated cytotoxicity by CD8⁺ T cells and NK cells, which augments the antitumor response. It also suppresses TH2 cytokine production by malignant T cells, which can lead to enhanced immunomodulation.

Interferons are administered intramuscularly or subcutaneously with a maximum plasma concentration 6 to 8 hours after administration.⁴⁶ There are multiple regimens used. Traditionally, interferon-alpha is started at lower doses, such as 1-3MU three times per week subcutaneously and titrated up as tolerated. However, because of the numerous associated side effects, it is typically not used as monotherapy. Rather, it is used in combination with ECP, systemic retinoids, methotrexate, and phototherapy in an effort to limit side effects. When used in combination, it is a first line therapy for advanced MF and SS.²

The adverse effects of interferon can prohibit its use in some patient populations such as the elderly. The most common side effects include fevers, chills, tachycardia, malaise, myalgias, and headaches that are part of the general flu-like syndrome.⁴⁷ The flu-like syndrome seems to decrease in intensity with time.⁴⁶ However, in patients on low-dose intermittent therapy, acetaminophen is able to control the symptoms. Hematologic side effects primarily involve leukocytes, platelets and erythrocytes. Leukopenia occurs within hours of exposure, and often stabilizes around

40–60% of the normal leukocyte count. The recovery of granulocyte and lymphocyte counts is rather rapid after discontinuation of IFN therapy.⁴⁷ Prolonged IFN therapy often results in normocytic normochromic anemia, which in contrast to the IFN-induced leukopenia, has a slow recovery. Thrombocytopenia is also a common side effect especially in patients with hematologic malignancies.⁴⁷

Retinoids

Systemic retinoids are indicated primarily in patients with advanced disease and can be used as monotherapy or as part of combination regimens with skin-directed or other biologic therapies (Tables 47-7, 47-8, 47-9, 47-11, 47-13). They are also used in early stage, refractory disease (Table 47-6).

The most commonly used systemic retinoid is a retinoid X receptor (RXR) agonist, bexarotene; however, retinoic acid receptor (RAR) agonists, such as isotretinoin, acitretin, or all-trans retinoic acid, are available as alternative agents.⁴⁸ Much of the molecular basis of the mechanism of action of bexarotene is unknown. However, it has been shown to induce apoptosis in CTCL lines and T lymphocytes from Sézary patients.^{34,49} In addition, patients who have responded to bexarotene had higher CD8+ cell counts after therapy.⁵⁰ The initial dose of oral bexarotene is 300 mg/m²/day, which can be adjusted according to the clinical response and the severity of adverse effects.

There is a common toxicity profile for the different forms of retinoids, and many of these adverse effects are dose dependent. Most commonly, patients experience photosensitivity and dryness of the skin and mucous membranes. Other adverse effects include myalgia, arthralgia, and fatigue, and less commonly, headaches. On rare occasions, headaches can be caused by pseudotumor cerebri. The well-known teratogenic effects of retinoids must be carefully addressed in female patients of childbearing age. Potential long-term, cumulative toxicity of retinoids includes the development of bony changes such as hyperostosis. Bexarotene also has unique effects on the pituitary-thyroid axis, which results in hypothyroidism with low free thyroxine (FT4) and low thyroid-stimulating hormone (TSH) levels.

Bexarotene is a selective agonist for RXR receptors. The receptors can form homodimers and heterodimers with RARs, as well as with other nuclear receptors such as vitamin D receptors and thyroid receptors. Due to the formation of heterodimers, the use of bexarotene affects the thyroid receptors leading to central hypothyroidism. Because of their potential hepatotoxic and hyperlipidemic effects, liver function and serum lipid levels (triglycerides/cholesterol) should be monitored during treatment. Bexarotene also has more profound effects on serum lipid levels, especially triglycerides, than any other retinoid. Thus, it is conventional to have patients on lipid-lowering agents and thyroid supplements during bexarotene therapy.

These are ideally started in the week prior to beginning bexarotene therapy. Gemfibrozil is contraindicated with bexarotene because of increased plasma levels of bexarotene and higher triglyceride levels. In addition, several patients were known to develop pancreatitis in early clinical trials.⁵¹ The preferred lipid-lowering drugs are of the statin or fenofibrate class of agents.⁵² Toxicities associated with systemic retinoids are usually reversible upon cessation of therapy.

Retinoids can be combined with a skin-directed therapy such as PUVA or with other systemic agents including IFN-alpha, ECP, or denileukin diftitox therapy. Combination therapies often have better efficacy and safety profiles when compared to the use of individual biologic agents alone.³

Recombinant Fusion Proteins

Denileukin diftitox is a recombinant cytotoxic fusion protein that targets the IL-2 receptor on T-cells. It is indicated for use in patients with advanced, persistent and recurrent MF and SS.^{53–55} This recombinant fusion protein combines the receptor-binding domain of IL-2 with diphtheria toxin. Once the molecule is bound to the IL-2 receptor, it is taken up by endocytosis, and the diphtheria toxin is cleaved. This leads to inhibition of protein synthesis and results in killing of defined neoplastic cell populations.⁵⁶

Denileukin diftitox is administered intravenously for 5 consecutive days and repeated every three weeks at daily doses of 9 or 18 ug/kg over 1 hour. Toxicities include fever, chills, nausea, a ‘capillary leak’ syndrome, which may be ameliorated by pre- and post-treatment hydration, and a hypersensitivity reaction, which can be countered with premedication with corticosteroids.^{55, 56}

Bexarotene upregulates IL-2 receptors expression on T-cells. Hence, the use of bexarotene may lead to more enhanced binding of denileukin diftitox and greater effectiveness.⁵⁷

Histone Deacetylase Inhibitors

Histone deacetylase inhibitors (HDAC-i) are a novel class of agents. HDAC inhibition results in acetylation of histone and nonhistone proteins leading to a transcriptionally active chromatin and activation of gene expression.⁵⁸ Defective histone-acetylation enzymes have been identified in malignant cells^{59,60}; hence, HDAC-I may have anticancer properties through the restoration of normal acetylation.

There are two HDAC-i used in advanced, refractory, and relapsed MF and SS. The first is vorinostat. It is generally used as monotherapy, but it can be used in combination with other skin directed and systemic agents. However, there is no data for the use of combination therapy involving HDAC-i, and caution is needed with regards

to safety and efficacy. Vorinostat is an oral agent that is dosed orally at 400 mg daily. The most common side effects are gastrointestinal (nausea, vomiting, diarrhea), constitutional, hematologic, and taste disorders.⁶¹ As a result of the gastrointestinal effects, electrolyte abnormalities, particularly in magnesium and potassium, can occur and potentially lead to QT prolongation on EKG. This is more common in patients with a history of heart disease. Other serious side effects to monitor include thromboembolic events, gastrointestinal hemorrhage, ischemic stroke, and thrombocytopenia.⁶¹

A second HDAC-i, romidepsin, is FDA- approved for use in CTCL. It is an intravenous drug used which is primarily used as monotherapy. It is given on days 1, 8, and 15 of a 28-day cycle at a dose of 14 mg/kg/m². Toxicities are similar to those seen in vorinostat.⁶² The same monitoring recommendations are applicable to vorinostat and romidepsin. A clinically meaningful response is seen in up to one-third of patients. In advanced disease, global response rates were higher with romidepsin than vorinostat.^{61,63,64}

MONOCLONAL ANTIBODY THERAPY

One of the most effective monoclonal antibodies used in the treatment of advanced disease such as erythrodermic (T4) MF and SS is alemtuzumab. It is reserved for those patients with advanced disease in whom other traditional therapies have failed. It is a humanized IgG antibody directed against CD52.⁵⁶ CD52 is expressed on T-lymphocytes, B-lymphocytes, natural killer cells, monocyte, and malignant T-cells in CTCL.^{65,66} The mechanism through which alemtuzumab exerts its clinical effect is not well known, but likely includes apoptosis,⁶⁷ antibody-dependent cellular cytotoxicity,^{68,69} and complement mediated cell lysis.^{70,71}

In the standard therapeutic schedule used in other lymphomas, such as chronic lymphocytic leukemia, T-cell prolymphocytic leukemia, and peripheral T-cell lymphoma, escalating doses from 3 to 10 mg and then to 30 mg are administered on alternating days followed by 30 mg three times per week for 12 weeks.⁷²⁻⁷⁵ However, evidence suggests that low dose intermittent alemtuzumab (3 mg on day 1 with 10 mg on days administered subcutaneously thereafter), has equal efficacy and durable remissions with less toxicity.⁷⁶ Alemtuzumab is more efficacious in patients with Sézary syndrome. One of the goals of therapy is to keep the Sézary cell count <1,000 mm³.

Complications of alemtuzumab include serious infections such as cytomegalovirus, generalized herpes simplex virus, fatal, fungal, and mycobacterial infections. Thus, prophylactic regimen of antivirals, antifungals, and antibacterials are typically utilized with alemtuzumab therapy.⁷⁷ In addition, other hematologic toxicities occur, such as severe neutropenia, thrombocytopenia, and anemia.⁷⁷

SYSTEMIC CYTOTOXIC THERAPY (CHEMOTHERAPY)

Systemic chemotherapy is appropriate for patients with large cell transformed stage IIB MF and stage IV MF with extracutaneous involvement. Most chemotherapeutic regimens, however, result in only temporary palliative responses. Multiple single-agent and combination chemotherapies have been tried in advanced MF and SS. For single-agent chemotherapy, no particular drug has been shown to be superior and no large, randomized studies comparing agents have been reported. Single agent chemotherapy is more widely utilized in MF/SS. Combination regimens are largely reserved as salvage after single agent therapy has failed or if there is solid organ involvement.

While typically used in advanced MF and SS, methotrexate has been used in lower doses for extensive stage IB disease (refer to Table 47.6 for I-IIA). Methotrexate inhibits dihydrofolate reductase (DHFR), leading to the subsequent inhibition of DNA synthesis.⁷⁸ Multiple dose ranges and schedules have been used as therapy in erythrodermic MF (T4) and SS. No clear benefit has been demonstrated for higher doses compared to lower doses of methotrexate. Side effects observed with the use of methotrexate include elevated serum aminotransferase levels (which are usually reversible after dose reduction or withdrawal), oral mucositis, pharyngeal mucositis, gastrointestinal complications such as nausea and diarrhea, interstitial pulmonary fibrosis, and uncommonly, reversible leucopenia.⁷⁹

Gemcitabine, a novel nucleoside analog, is activated by deoxycytidine kinase to its triphosphate form, gemcitabine triphosphate, which is then incorporated into RNA and DNA. The latter causes chain termination and inhibition of DNA repair, which is responsible for antitumor effect of the medication. Response rates as high as 70% have been reported, but the complete remission rate is low with a median duration of complete remission of 10 months (range 4-22 months).⁸⁰ Recently this agent has been used as front-line therapy for patients in whom control is needed of massive lymph node disease (see Table 47.15). Gemcitabine is generally well tolerated, even in the elderly population. Myelosuppression with resulting anemia, thrombocytopenia, or leukopenia are the most common adverse events.⁸⁰ Cutaneous adverse events include flares of lesional erythema within 1 week of treatment, as well as generalized hyperpigmentation.⁸⁰ Serious adverse events are rare.

Doxorubicin is an anthracycline agent used in advanced stages of MF and SS. Pegylated liposomal doxorubicin is a formulation of doxorubicin that is encapsulated into liposomes. The liposomes serve as stable, long-circulating carriers useful for delivering doxorubicin to tumor sites with a lower toxicity than the free drug. The most frequent side effects are mild anemia and lymphopenia. Another significant toxicity with this class of drugs is palmoplantar erythrodysthesia.⁸¹

A new cytotoxic agent is temozolomide, which has shown encouraging activity in advanced MF. It is an imidazotetrazine derivative and oral alkylating agent that has excellent oral bioavailability.⁸² Its mechanism of action is similar to that of other alkylating agents, which induce DNA damage by cross-linking. Resistance has been associated with high levels of the scavenger protein O6-alkylguanine-DNA alkyltransferase in tumor cells. Response rates of 30% have been reported in stage IIB and III patients. In a phase II study, the most frequent adverse effects were nausea, vomiting, neutropenia, and thrombocytopenia.⁸²

In addition, other mechanisms to inhibit growth and encourage apoptosis of tumor cells are being developed. Bortezomib, which inhibits the proteasome, leads to the down-regulation of NF-KB activation and induction of CTCL cell apoptosis.⁸³ In a phase II trial, the response rate was 67% in all stages; however, the complete response rate was much lower at 10%.⁸⁴ With regard to hematologic adverse effects, neutropenia and thrombocytopenia were observed. The most significant nonhematologic toxicity was sensory neuropathy.⁸⁴

The purine analogs are a class of drugs that have demonstrated activity in MF and a variety of other non-Hodgkin lymphomas. T-cells have a high level of adenosine deaminase (ADA), a key enzyme in the purine degradation pathway. The purine analogs pentostatin, fludarabine, and 2-chloro-deoxyadenosine are a group of structurally similar agents, which were developed to target ADA. They have different interactions with ADA, but all result in DNA damage. Hematologic toxicity and opportunistic infections are the most common complications associated with this class of drugs. Prophylactic antibiotics against *Pneumocystis carinii* and antivirals to prevent herpes virus infection are routinely indicated.⁸⁵

Most of the patients treated with combination chemotherapy have failed single agent chemotherapy or have solid organ involvement (IIB to IV). There are no randomized trials comparing combination chemotherapy to single-agent regimens. The largest experience is with combinations such as cyclophosphamide, vincristine, and prednisone, with or without doxorubicin.^{86,87} Complete response rates are generally about 25% (range 11-57%) and response duration is 3-20 months.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

There has been recent interest in using hematopoietic stem cell transplantation in MF. Given the small number of patients treated thus far, there are no well-defined prognostic factors to identify patients suitable for this therapy.

Bigler and associates reported that five of six patients achieved a complete response with an autologous

transplant.⁸⁸ In another study, eight of nine patients achieved a complete response.⁸⁹ However, all of the patients in these studies ultimately relapsed, suggesting that autologous transplantation is not a curative approach.

The concept of allogeneic hematopoietic stem cell transplantation (HSCT) is promising. Even in the absence of a complete response, an allogeneic graft-versus-tumor effect may provide an immune mechanism to control the malignant T-cell process associated with mycosis fungoides. Molina and associates reported a complete response in all eight patients transplanted for refractory MF or SS. With a median follow-up of 56 months, six patients remained alive and without evidence of lymphoma.⁹⁰ Mild acute and chronic GVHD developed in all patients who survived. A non-myeloablative approach has also been reported in which all three patients who achieved a durable complete response.⁹¹

It appears that compared to autologous HSCT, allogeneic HSCT may result in durable long-term remissions.⁹² With better understanding of the disease biology, it may be possible to develop prognostic factors so that these aggressive approaches can be offered to suitable patients. Larger studies will be required to identify the best conditioning regimen, efficacy, safety, and impact on quality of life.

Treatment of Kaposi's Sarcoma

Carrie Kovarik, M.D.

INTRODUCTION

Kaposi's sarcoma (KS) was originally described in 1872 by Moritz Kaposi, a Hungarian dermatologist, as multifocal pigmented sarcoma of the skin in five European men.¹ KS has since been categorized into four types, including classic, endemic, iatrogenic immunosuppression-associated, and epidemic, or AIDS-associated, KS. Kaposi's sarcoma-associated herpesvirus (KSHV), or human herpesvirus 8 (HHV8), is a primary factor for the development of all types of KS and the histologic features are indistinguishable; however, the clinical variants have a distinct epidemiology and clinical course.

EPIDEMIOLOGY AND CLINICAL PRESENTATIONS

Classic, or Mediterranean KS, occurs primarily in elderly men of Mediterranean or Eastern European descent. Classic KS typically presents as slowly progressing violaceous to red-brown nodules or plaques that begin on the hands and feet and progress to more widespread involvement over years. Lymphedema may be present and visceral or mucosal involvement develops in approximately 10% of patients.² Endemic African KS occurs in non-HIV-infected patients in Africa and has a variety of clinical manifestations, including slow-growing nodular cutaneous disease in young adults, aggressive invasive localized cutaneous disease, florid mucocutaneous and visceral disease, and fulminant lymphadenopathic disease that rapidly progresses and most often occurs in young children.³

The incidence of KS rose dramatically with the HIV epidemic. Epidemic, or AIDS-associated, KS occurs more commonly with decreasing CD4 counts and has a variety of clinical manifestations, ranging from localized or diffuse cutaneous disease (Figure 48-1) to aggressive and rapidly progressive oral, mucocutaneous, or visceral disease. Mucocutaneous lesions may appear as violaceous to hyperpigmented patches, papules, plaques, nodules, or tumors and may be associated with lymphedema (Figure 48-2) or lymphadenopathy. HIV-infected patients with KS tend to have a better prognosis if they have lesions confined to the

FIGURE 48-1 Diffuse cutaneous Kaposi's sarcoma manifesting as numerous violaceous plaques and nodules.

FIGURE 48-2 Violaceous plaques of Kaposi's sarcoma on the face with associated lymphedema.

skin, minimal to no oral involvement, a CD4 count above $200 \times 10^6/L$, no opportunistic infections, and no fever or weight loss.⁴

Iatrogenic immunosuppression-associated KS most commonly occurs in organ transplant patients who are receiving chronic immunosuppressive medications. The median time to develop KS post-transplant in one study ranged from 4 to 108 months (median 10 months), and there was a predominance of patients with Italian ancestry.⁵ Clinical presentation ranges from localized or diffuse

cutaneous disease to aggressive visceral involvement. Resolution or improvement of disease with a decrease in immunosuppression may occur.

ETIOLOGY/DIAGNOSIS

Kaposi's sarcoma-associated herpesvirus, or HHV8, is a primary factor for the development of all types of KS. Serologic studies have shown that infection rates with HHV8 parallel the incidence of KS, with low rates in the United States, intermediate rates in the Mediterranean countries, and the highest rates in Central Africa.² The acquisition of the HHV8 virus varies, with sexual transmission predominating in the developed world and early non-sexual childhood acquisition or mother-to-child transmission being most common in African countries.⁶ The diagnosis is most reliably made with histologic examination of tissue, and the findings are indistinguishable, regardless of the clinical type of disease. Histologic features include a dermal proliferation of spindle cells with numerous slit-like vascular spaces. Extravasated erythrocytes, hemosiderin-laden macrophages, and inflammation with plasma cells are often present. Immunohistochemical staining for HHV8 will highlight lesional nuclei.

GOALS OF TREATMENT

The treatment of epidemic, or AIDS-related, Kaposi's sarcoma will be the focus of this systematic review. Curative therapy is not currently available for AIDS-related KS; however, palliative therapy can be beneficial in many ways. Treatment can improve the cosmetic appearance of lesions, symptomatically improve painful or edematous lesions, and relieve symptoms caused by oral or visceral involvement. Limited disease is best treated with local therapy, while diffuse or disseminated disease may require systemic therapy.⁷

The clinical trials discussed below uniformly use (unless otherwise indicated) the AIDS Clinical Trials Group Oncology Committee criteria for evaluating KS and its response to treatment. These clinical response criteria have been standardized and include: complete response (absence of residual KS for at least 4 weeks), partial response ($\geq 50\%$ reduction in size or at least 50% flattening of the lesions), stable disease (not fulfilling the criteria for partial or progressive disease), and progressive disease ($\geq 25\%$ increase in size or change of macular lesion to papular, nodular or plaque-like).⁸

SEARCH METHODOLOGY

Randomized controlled trials of all therapy for AIDS-related Kaposi's sarcoma were included in the search. The Cochrane Library for systematic reviews (2009) and Pubmed/Medline (1966–September 2009) were searched.

QUESTION

In patients with localized AIDS-related KS, what is the efficacy, defined as a complete or partial response, of local therapies, including topical medications, intralesional injections, radiotherapy, or surgical interventions? (Table 48-1)

LOCAL THERAPY

Local therapy is helpful for treatment of cosmetically undesirable lesions or localized symptomatic disease; however, it is not useful for disseminated disease or in the prevention of the development of new lesions. Several localized therapies have been reported to be successful but have not been proven in randomized controlled trials, and these include surgical excision, laser therapy, cryotherapy, topical immunotherapy with imiquimod, and photodynamic light therapy.

INTRALESIONAL THERAPY

Efficacy

Patients with AIDS-related KS were evaluated for the efficacy and pain associated with intralesional vinblastine with or without 1% bicarbonate-buffered lidocaine (BBL). Eleven patients were enrolled and six untreated KS lesions in a similar anatomic location were selected on each patient. These lesions were randomly assigned to one of six groups: vinblastine, vinblastine mixed with BBL, vinblastine 5 minutes after BBL injection, or one of three control groups, which included BBL, saline, or no treatment. The vinblastine groups showed a complete response in 20 (61%) lesions and a complete or partial response in 29 (88%) lesions total. There was no significant difference in efficacy among the vinblastine groups. Pretreatment with BBL reduced the pain from vincristine injection significantly.⁹

Another double-blind randomized trial enrolled 16 patients and compared the clinical efficacy of intralesional vinblastine and 3% sodium tetradecyl sulfate (STS) in the treatment of oral Kaposi's sarcoma (OKS). STS is an agent that can cause fibrotic obliteration of the tumor through ischemic necrosis. The patients received one intralesional injection after local anesthesia. Mean tumor reduction size was similar in both groups, with 0.68 cm reduction in the vinblastine group and 0.61 cm reduction in the STS group. Complete or partial response was achieved in two vinblastine patients, and four STS patients had partial responses.⁷

Drawbacks

Although pretreatment with BBL in the first study reduced the vincristine injection pain, many patients reported an

TABLE 48-1—Summary of Randomized Controlled Trials of Localized Treatment for AIDS-Related KS

First author, Reference	Regimen	Study population	Sample size	Duration of treatment	Results
Boudreax (1993) ⁹	Intralesional vinblastine with or without 1% bicarbonate-buffered lidocaine vs. placebo	HIV-infected patients >18 years old with untreated cutaneous KS lesions	11	Single intralesional injection	Vinblastine groups showed a CR in 20 (61%) lesions and a CR or PR in 29 (88%) lesions total. Placebo groups showed a CR or PR in 5 (15%) lesions total. ($p<0.001$)
Ramírez-Amador (2002) ⁷	Intralesional vinblastine vs. intralesional 3% sodium tetradecyl sulfate (STS)	HIV-infected patients >18 years old, with nodular KS on the hard palate	16	Single intralesional injection	Mean tumor reduction size was similar in both groups, with 0.68 cm reduction in the vinblastine group and 0.61 cm reduction in the STS group. ($p=0.80$) CR or PR was achieved in two vinblastine patients, and four STS patients had PR. ($p=0.61$)
Bodsworth (2001) ¹⁰	Alitretinoin gel or vehicle gel twice daily	HIV-infected patients >18 years old with cutaneous KS	134	12 weeks	The overall patient response rate (CR + PR) was 37% (23 of 62) for the alitretinoin-treated patients and 7% (5 of 72) for the vehicle-treated patients. ($p=0.00003$)
Stelzer (1993) ¹¹	Radiotherapy: 8 Gy in 1 fraction vs. 20 Gy in 10 fractions vs. 40 Gy in 20 fractions.	HIV-infected patients >18 years old with cutaneous KS	14	5 times per week until completed fractions	CR was significantly higher with 40 Gy (83%) and 20 Gy (79%) than with 8 Gy (50%). ($p=0.04$)
Singh (2008) ¹²	Radiotherapy: 24 Gy in 12 fractions vs. 20 Gy in 5 fractions	HIV-infected patients >18 years old with cutaneous or mucosal KS	50	5 times per week until completed fractions	The overall patient response rate (CR + PR) was similar with 24 Gy (21/23) and 20 Gy (26/27) regimens. ($p=0.73$)

CR, complete response; PR, partial response

aching pain for 6-48 hours after the injection that could deter from additional intralesional treatment. Nearly all of the lesions that responded healed with hyperpigmentation, which may not be cosmetically desirable to some patients. Several of the enrolled patients were seen 4-7 months after treatment, and 5 of the 12 (42%) evaluated lesions that had completed responded originally had relapsed.⁹

In the second study, mouth pain and oral ulcers were common patient complaints with both agents during the first week after treatment.⁷

Comment

Intralesional therapy, such as vinblastine, may provide complete or partial improvement of localized cutaneous or oral AIDS-related KS. This may be particularly useful in patients that have few lesions, as this method may not be feasible for extensive disease. In addition, this may be a good treatment option for patients that have localized symptomatic or cosmetically undesirable lesions and are not candidates for systemic therapy.

TOPICAL RETINOID

Efficacy

After 12 weeks of twice daily topical application, the overall patient response rate (complete plus partial response) to the selected lesions of cutaneous Kaposi's sarcoma was 37% (23 of 62) for the alitretinoin-treated patients and 7% (5 of 72) for the vehicle-treated patients ($p=0.00003$). Lesions qualified for partial response if there was approximately 50% measured improvement, and complete improvement indicated the lesion was completely cleared except for pigmentation from residual hemosiderin.¹⁰

Drawbacks

Almost half (49%) of the patients reported a rash, which was further described as erythema, scaling, irritation, redness, rash, or dermatitis. Four patients (3%) withdrew from the study because of an adverse event attributed to study medication and all were considered cases of grade three dermal irritation.¹⁰

Among patients receiving alitretinoin gel, the median time to onset of response was 29 days, and this delay in improvement, as well as the continued need for treatment, could contribute to a lack of compliance in the beginning of treatment.¹⁰

Comment

In this study, 10 patients (16%) in the treatment group had both cutaneous and visceral disease, and 22 patients (36%) had received previous systemic therapy. Eight of these patients were considered either unresponsive (i.e., failed to achieve $\geq 50\%$ improvement) to at least one such treatment or wholly refractory (failed to achieve at least a partial response to all prior systemic therapies).¹⁰ The use of this treatment would be considered palliative in patients with extensive cutaneous and visceral disease.

RADIOTHERAPY

Efficacy

Fourteen patients were randomized to receive one of three radiation-dosing regimens: 8 Gy in one fraction, 20 Gy in 10 fractions, or 40 Gy in 20 fractions. Complete response (complete resolution of palpable tumor) was significantly higher with 40 Gy (83%) and 20 Gy (79%) than with 8 Gy (50%) ($p=0.04$). Median time to treatment failure (any measurable tumor growth) was 43 weeks with 40 Gy, 26 weeks with 20 Gy, and 13 weeks with 8 Gy ($p=0.003$). This study showed that fractionated radiotherapy with higher total doses resulted in improved response and control of cutaneous Kaposi's sarcoma.¹¹

Given the findings that fractionated radiotherapy with higher total doses was shown to be effective, another study was designed to determine whether a hypofractionated regimen of radiotherapy would be beneficial. Sixty patients were randomly assigned to receive the standard regimen at the study hospital (24 Gy in 12 fractions) to one arm and a shorter-duration regimen of 20 Gy in five fractions to the other arm. The difference in complete and partial response rates, as well as the median local recurrence-free survival, was similar between the two groups.¹²

Drawbacks

The incidence of acute and late radiation skin toxicity was increased in higher-dose groups; however, the side effects were limited to erythema, dry desquamation, alopecia, and hyperpigmentation.¹¹ None of the side effects required disruption of therapy. In addition, the fractions of radiation were given daily, 5 days per week. This can be a rigorous treatment schedule for many patients. In the lesions that respond to treatment, median time to treatment failure ranged from 13 to 43 weeks, and lesions may need to be retreated.^{11,12}

The first study described above only treated cutaneous lesions in a limited electron field.¹¹ Treatment of KS-related edema or disseminated cutaneous involvement may require extensive radiotherapy fields, which was beyond this study, and the clinical response and side effects may be very different.

Comment

The role of radiation therapy in AIDS-related KS is either cosmetic treatment of localized cutaneous disease or palliative therapy for painful and/or edematous lesions. If radiotherapy is chosen as a treatment for one of these reasons, the individual situation will dictate the therapeutic regimen. Fractionated radiotherapy with higher total doses will likely give greater cosmetic results, and patients may choose a regimen that requires numerous treatments with a better chance of success. On the other hand, a debilitated and bed-ridden patient with painful edematous lesions may choose a regimen, such as 8 Gy in one fraction, that may provide symptomatic relief with few visits.

QUESTION

In patients with severe or disseminated AIDS-related KS, what is the efficacy, defined as a complete or partial response, of systemic therapies? (Table 48-2)

SYSTEMIC THERAPY

The decision to initiate systemic therapy is based on multiple factors, including the extent of Kaposi's sarcoma, visceral involvement, and degree of immunosuppression.¹³ Prognostic factors for AIDS-related KS have also been determined in order to allow clinicians to make an accurate assessment of the patient and guide therapeutic decisions. Factors that are associated with a poorer prognosis include an age of 50 years or older and having another concurrent AIDS-associated illness. An improved prognosis is associated with having KS as the AIDS-defining illness and a higher CD4 count.¹⁴

CHEMOTHERAPY

Cytotoxic Chemotherapy

Before the development of liposomal anthracyclines and highly active antiretroviral therapy (HAART), cytotoxic chemotherapy regimens were the treatment of choice for disseminated and/or severe AIDS-related KS. These regimens included vinblastine alone, etoposide alone, vincristine alone, dual therapy with vinblastine and another chemotherapeutic agent, or a combination of doxorubicin, bleomycin, and vinblastine (ABV). ABV was found to be more effective than single-drug regimens in randomized trial that treated patients with severe AIDS-related KS.¹⁵

TABLE 48-2—Summary of Randomized Controlled Trials of Systemic Chemotherapy for AIDS-Related Kaposi Sarcoma

First author, Reference	Regimen	Study population	Sample size	Duration of treatment	Results
Gill (1996) ¹⁶	Liposomal daunorubicin vs. doxorubicin, bleomycin, and vincristine (ABV)	HIV-infected patients >18 years old with advanced KS, defined as ≥ 25 mucocutaneous lesions, symptomatic visceral involvement, or tumor-associated lymphedema.	232	Every 2 weeks until CR, disease progression, or unacceptable toxicity.	The overall response rate (CR + PR) was 25% (3 CRs and 26 PRs) for liposomal daunorubicin and 28% (one CR and 30 PRs) for ABV. (95% confidence interval, – 14% to +9%).
Stewart (1998) ¹⁸	Pegylated liposomal doxorubicin or bleomycin and vincristine (BV) combination	HIV-infected patients >18 years old with either ≥ 15 mucocutaneous lesions (and developed more than 5 cutaneous lesions in preceding month) OR with documented visceral KS with at least five assessable cutaneous lesions.	121	Every 3 weeks with a maximum of six cycles.	The overall response rate (CR + PR) was 58.7% for the patients treated with pegylated liposomal doxorubicin compared to 23.3% treated with BV ($p < .001$).
Northfelt (1998) ¹⁹	Liposomal doxorubicin vs. ABV combination.	HIV-infected patients >18 years old with progressive biopsy-proven AIDS-KS with ≥ 25 mucocutaneous lesions or the development of 10 or more new lesions in the preceding month, or documented visceral disease.	258	Every 14 days to a maximum of six cycles.	The overall response rate (CR + PR) was 45.9% for the patients treated with pegylated liposomal doxorubicin compared to 24.8% treated with ABV ($p < .001$).
Cooley (2007) ²⁰	Pegylated liposomal doxorubicin vs. liposomal daunorubicin	HIV-infected patients >18 years old with AIDS-related KS requiring systemic chemotherapy, a life expectancy of at least 120 days, and at least 5 measurable mucocutaneous KS lesions.	80	Every 2 weeks with a maximum of six cycles.	Overall tumor responses (CR + PR) were observed in 55.0% (33/60) of pegylated liposomal doxorubicin patients (compared to 31.6% (6/19) of liposomal daunorubicin patients).
Martin-Carbonero (2004) ²³	HAART regimen plus pegylated liposomal doxorubicin or HAART regimen alone.	HIV-infected patients >18 years old, either naive or failing HAART with moderate–advanced KS (at least 10 cutaneous lesions or mucosal or visceral involvement).	28	Liposomal doxorubicin was given every 3 weeks	After 48 weeks of follow-up, response rates (CR + PR) in the HAART plus pegylated liposomal doxorubicin group were 76%, as compared to 20% in the group treated with HAART alone. ($p=0.003$)

CR, complete response, PR, partial response, HAART, highly active antiretroviral therapy.

ABV was a commonly used multi-drug chemotherapeutic regimen for severe AIDS-related Kaposi's sarcoma until the development of liposomal anthracyclines.

LIPOSOMAL DAUNORUBICIN

Background

At the time of the study, cytotoxic chemotherapy, including the regimen of doxorubicin, bleomycin, and vincristine (ABV), was the most successful treatment modality for KS, especially for advanced disease with visceral involvement and patients with severe immunosuppression. This liposomal anthracycline formulation demonstrated a significantly better pharmacokinetic and side-effect profile than conventional daunorubicin in preliminary studies, and

this study compared liposomal daunorubicin to ABV in the treatment of advanced AIDS-related KS. Patients were randomized to receive one of the regimens every 2 weeks, and treatment was continued until complete response, disease progression, or unacceptable toxicity.¹⁶

Efficacy

The overall response rate (complete or partial response) was 25% for liposomal daunorubicin and 28% for ABV, which was not a statistically significant difference. The median survival time for the two groups (369 days for liposomal daunorubicin and 342 days for ABV) and median time to treatment failure (115 days for liposomal daunorubicin and 99 days for ABV) was similar and not significantly different between the groups. ABV patients had significantly

more alopecia and neuropathy, but the patients treated with liposomal daunorubicin experienced more severe neutropenia.¹⁶

Drawbacks

ABV patients had significantly more alopecia and neuropathy, but the patients treated with liposomal daunorubicin experienced more severe neutropenia.¹⁶

Comment

This study was done before the wide availability of HAART and was the first randomized comparison of a liposomal anthracycline medication to standard cytotoxic chemotherapy. Although the efficacy was similar in the two groups, several nonhematologic side effects were significantly decreased in the group treated with liposomal daunorubicin.¹⁶ Overall, liposomal daunorubicin was shown to be a promising alternative to the traditional chemotherapy regimens.

PEGYLATED LIPOSOMAL DOXORUBICIN

Background

At the time of the study, cytotoxic chemotherapy, including the regimens of doxorubicin, bleomycin, and vincristine (ABV), as well as bleomycin and vincristine (BV), were still the treatment of choice for advanced AIDS-related KS. The pegylated liposomal form of doxorubicin had been shown in preliminary studies to have a significantly longer plasma half-life and more targeted delivery of the medication.¹⁷ Two randomized studies compared clinical response and toxicity of pegylated liposomal doxorubicin to traditional chemotherapy, including BV and ABV.^{18,19}

Efficacy

The first study randomly assigned 121 patients to receive pegylated liposomal doxorubicin or the BV combination. Complete or partial responses were achieved in 58.7% of the patients treated with pegylated liposomal doxorubicin compared to 23.3% treated with BV ($p < .001$). Thirty-two (26.7%) of the patients who received BV withdrew from the study prematurely because of a chemotherapy-related adverse events, compared to 13 (10.7%) who received pegylated liposomal doxorubicin. The significant side effects were different for the two groups, with paresthesia and peripheral neuropathy significantly higher in patients who received BV, whereas leukopenia and oral candidiasis were more commonly seen in patients treated with pegylated liposomal doxorubicin.¹⁸

The second study randomly assigned 258 patients to receive pegylated liposomal doxorubicin or the ABV

combination. Complete or partial responses were achieved in 45.9% of the patients treated with pegylated liposomal doxorubicin compared to 24.8% treated with ABV ($p < .001$). In addition, disease progression was seen in two (1.5%) of the patients treated with pegylated liposomal doxorubicin, compared to 10 (8.0%) treated with ABV ($p < .001$). Significantly more patients treated with ABV discontinued treatment because of an adverse event (37%) compared to 11% treated with pegylated liposomal doxorubicin. Nausea and vomiting, alopecia, and peripheral neuropathy were significantly more common in patients treated with ABV. The most common adverse event in both groups was leukopenia, and there was no significant difference between the two groups.¹⁹

Drawbacks

Leukopenia is the most significant adverse event with pegylated liposomal doxorubicin treatment; however, granulocyte colony-stimulating factors can limit this side effect. Several acute infusion-related reactions occurred in the pegylated liposomal doxorubicin group, but most of these occurred with the initial infusion. Pretreatment with antihistamines and/or corticosteroids allowed for the continuation with subsequent infusions.¹⁹

Comment

These studies confirmed that pegylated liposomal doxorubicin was more effective in the treatment of severe AIDS-related KS than standard cytotoxic therapeutic regimens. The side effect profile and tolerance of pegylated liposomal doxorubicin is, over all, manageable and improved over standard chemotherapy, and liposomal anthracyclines are now considered first-line therapy.

PEGYLATED LIPOSOMAL DOXORUBICIN COMPARED TO LIPOSOMAL DAUNORUBICIN

Background

Both pegylated liposomal doxorubicin and liposomal daunorubicin are now approved treatments for AIDS-related Kaposi's sarcoma. Liposomal anthracyclines are considered first-line therapy in patients with widely disseminated KS, and the pegylated form of liposomal doxorubicin is thought to more effectively distribute the drug to tumors that have abnormal vasculature. This study evaluated the clinical benefit, tumor response, and tolerance of pegylated liposomal doxorubicin and compared it to liposomal daunorubicin. Clinical benefit was defined as improvement from baseline in at least one of five AIDS-related KS symptom categories that lasted for more than 4 weeks, in the absence of disease progression or severe

drug-induced toxicity. These symptom categories include functional impairment from KS-associated edema, symptomatic and evaluable pulmonary KS, symptomatic and evaluable gastrointestinal KS, moderate or severe KS-associated pain despite analgesic use, and KS lesions that are disfiguring and impairing. Tumor response was evaluated by comparing lesion characteristics, such as size, number, appearance, and sites of involvement.²⁰

Efficacy

Clinical benefit was achieved in 48 out of 60 (80.0%) patients receiving pegylated liposomal doxorubicin for a median duration of 62 days. Of the patients receiving liposomal daunorubicin, 12 of 19 (63.2%) achieved clinical benefit that lasted for a median duration of 55 days. Tumor responses (at least partial responses) were observed in 55.0% (33 out of 60) of pegylated liposomal doxorubicin patients (compared to 31.6% [6 out of 19] of liposomal daunorubicin patients), with a median time to tumor response similar in each group.²⁰

Drawbacks

Dose adjustments, primarily caused by hematologic toxicity, were required in 68.3% of patients receiving pegylated liposomal doxorubicin and 63.2% of patients receiving liposomal daunorubicin. Six (7.7%) doses were interrupted because of infusion-related reactions in pegylated liposomal doxorubicin patients; however, there were no dose interruptions in the liposomal daunorubicin group.²⁰

Comment

This randomized comparative trial shows that pegylated liposomal doxorubicin is a safe and effective therapy for AIDS-related Kaposi's sarcoma and has an improved clinical benefit and tumor response when compared to liposomal daunorubicin. Although the side-effect profile is similar for these medications, dose adjustments secondary to hematologic toxicity (most commonly neutropenia) were twice as common with the pegylated liposomal doxorubicin.²⁰ Over all, the liposomal formulations of both medications have allowed for a decrease in hematologic side effects and cardiotoxicity.

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY (HAART) WITH OR WITHOUT SYSTEMIC CHEMOTHERAPY

Background

Although the prevalence of KS has significantly decreased with the advent of HAART, KS and non-Hodgkin's lymphoma are still the most common causes of death from AIDS-related malignancies, accounting for a combined

total of over 40% of all malignancy-related deaths in HIV-infected patients.^{21,22} This randomized study evaluated the treatment of HIV patients with moderate to advanced KS who were either naive or failing HAART. The patients were treated with either a new HAART regimen plus pegylated liposomal doxorubicin or a new HAART regimen alone.²³

Efficacy

After 48 weeks of follow-up, response rates were clearly different between the two groups. The response rates in the HAART plus pegylated liposomal doxorubicin group were 76%, as compared to 20% in the group treated with HAART alone. These findings suggest that HAART may not be enough for adequate KS treatment in patients with moderate to advanced disease.²³

Drawbacks

In some geographical areas of the world with a particularly high incidence of AIDS-related KS, systemic chemotherapy regimens may not be available. If HAART alone is a choice of treatment, patients may still experience significant improvement of disease with this regimen.

The HAART plus pegylated liposomal doxorubicin group experienced more side effects, with an adverse event being reported in one-third of patients. The most common side effects included anemia and neutropenia.²³

Comment

This was the first randomized study to assess the direct effect of HAART on HIV-related KS regression. Several other smaller studies and anecdotal reports have shown more cases of KS regression with HAART alone; however, these were not randomized trials, many included patients with mild disease, and often patients were receiving concomitant local or systemic therapy. Although HAART may provide a decrease in the burden of disease from KS, patients who do not significantly respond to HAART alone or who have moderate to severe KS may benefit from the addition of systemic chemotherapy, such as pegylated liposomal doxorubicin.²³

OTHER SYSTEMIC THERAPY

Many systemic treatments have been considered for the treatment of AIDS-related KS, but few have been evaluated in randomized controlled trials. Many of these have been evaluated for safety and efficacy in phase II, but not phase III, trials. However, some of them are approved for treatment of KS and deserve brief mention.

Taxanes are a class of chemotherapy drug that inhibit angiogenesis and have found to be effective in AIDS-related KS. Paclitaxel is approved for treatment of KS in

the United States and has shown significant efficacy in two phase II trials, even in patients with advanced disease and KS found to be resistant to liposomal anthracyclines.^{24,25} Potentially life-threatening drug-drug interactions have been reported between paclitaxel and some HAART regimens, and dose modifications and close monitoring may be necessary.²⁶ Docetaxel is another taxane that has shown promise in treating advanced AIDS-related KS in small studies.²⁷

Other systemic therapies that have shown efficacy in phase II or small studies include interferon alpha, matrix metalloproteinases (MMP), and interleukin 12.¹³

ANGIOGENESIS INHIBITORS

Background

Angiogenesis plays a role in the development of KS lesions and has therefore become a target of therapy. IM862 is a synthetic dipeptide (*L*-glutamine *L*-tryptophan) that has no direct cytotoxic effects, but exhibits dose-dependent inhibition of angiogenesis. Other inhibitors of angiogenesis, such as thalidomide and VEGF receptor inhibitors, have been considered, but IM862 is the only one that underwent a randomized controlled trial for the treatment of AIDS-related KS.²⁸

Efficacy

Two hundred and two patients with AIDS-related KS were randomly assigned to receive 5 mg intranasally every other day of the medication or placebo. There were no complete remissions and the partial response rate was similar in both treatment arms (IM862, 23%; placebo, 21%).²⁸

What We Know

- Curative therapy is not currently available for AIDS-related KS; however, palliative therapy can be beneficial in many ways.
- Local therapy is helpful for treatment of cosmetically undesirable lesions or localized symptomatic disease; however, it is not useful for disseminated disease or in the prevention of the development of new lesions.
- Many local therapies that are used in clinical practice, including surgical excision, laser therapy, cryotherapy, topical immunotherapy, and photodynamic light therapy, have not been evaluated with proper clinical trials.
- Local therapies that have shown efficacy in randomized controlled trials in treatment of limited KS include intralesional vinblastine, radiotherapy, and topical alitretinoin.

Drawbacks

In order to qualify for the study, patients needed at least five or more measurable lesions of biopsy-proven AIDS-related KS involving the skin or the oral cavity. Patients with symptomatic visceral disease or who required chemotherapy were excluded, and this is an important group in which to investigate this medication as a primary or adjunct treatment for KS.²⁸

Comment

At the dose and schedule used in this study, IM862 was no better than placebo in treating AIDS-related KS. In addition, time to progression of disease was statistically significantly shorter in the patients taking IM862 compared to placebo, which may suggest that IM862 actually accelerates progression of KS.²⁸ More investigation of the use of angiogenesis inhibitors is needed in order to assess their potential use in AIDS-related KS.

HHV8 SUPPRESSION

Background

HHV8 is an essential factor in the development of AIDS-related KS. Because there is preliminary evidence that ganciclovir may have an antiviral effect against HHV8, it was hypothesized that valganciclovir would reduce HHV8 replication *in vivo*. Sixteen HIV-positive and 10 HIV-negative men who were observed in previous trials to shed HHV8 from the oropharynx were enrolled to receive either valganciclovir, 900 mg once daily, or placebo, for 8 weeks, and daily oropharyngeal swabs were taken.²⁹

- The decision to initiate systemic therapy is based on multiple factors, including the extent of Kaposi's sarcoma, visceral involvement, and degree of immunosuppression.
- Liposomal anthracyclines have been shown to be effective in the treatment of severe AIDS-related KS in randomized controlled trials and are currently first-line systemic therapies.
- Many other systemic agents, such as the taxanes, have been developed and show promise in the treatment of advanced KS; however, no randomized controlled trials have been conducted using these medications in AIDS-related KS.
- HAART therapy alone may not be sufficient in the treatment of moderate to severe AIDS-related KS, and systemic chemotherapy may need to be added for optimal response.

Efficacy

HHV-8 was detected on oropharyngeal swabs 44% of the enrolled days for the placebo group versus 23% in the valganciclovir group ($p=0.02$). HHV8 replication returned when the valganciclovir was discontinued, which indicated the need to use daily dosing for effective virologic control.

Drawbacks

Patients taking valganciclovir more frequently reported diarrhea, but no serious adverse events were observed during the study.

Comment

Although this study indicated that valganciclovir reduces HHV8 replication in the oral mucosa, more studies will need to be done in order to assess whether this correlates with prevention or suppression of AIDS-related KS.

Treatment of Chronic Wounds

Anne Han, M.D., and Gerald S. Lazarus, M.D.

INTRODUCTION AND SEARCH METHODOLOGIES

Chronic wounds cause significant morbidity and are a major health care burden affecting 6.5 million patients annually in the United States.¹ Almost \$25 billion per year is spent on the treatment of chronic wounds, which represents greater than 50% of all skin care expenditures in the United States.² The cost of treating chronic wounds will continue to increase rapidly because of growing health care costs, an aging population, and a sharp rise in the incidence of diabetes and obesity. Chronic wounds are often disguised as a comorbid condition associated with highly branded diseases such as diabetes. As a result, the true impact of chronic wounds on public health and the economy is often unrecognized. Furthermore, chronic wounds are treated by a wide variety of health care professionals, and less frequently by dermatologists. At present, over 1000 outpatient wound centers are in operation in the United States, which does not include wound care rendered in physician's offices, inpatient acute care hospitals, long-term facilities, and nursing homes.¹ Given the tremendous and still increasing burden of chronic wounds, dermatologists should endeavor to take greater responsibility for the management of patients with chronic wounds. In addition, wound research is a rapidly developing scientific field. Dermatologists have the opportunity to contribute to rigorous basic science, skin biology, translational and clinical investigation in this growing arena.

A chronic wound has failed to proceed through the orderly and timely process of repair.³ By definition, it is an ulcer, which does not show signs of progress after 6 weeks or manifests frequent recurrences.⁴ Chronic wounds rarely affect healthy people. Most patients suffer from comorbidities that predispose them to delayed healing. These conditions include venous insufficiency, diabetes, physical immobility, arterial disease and a myriad of dermatologic conditions such as vasculitis and pyoderma gangrenosum. In addition, poor nutrition, obesity, and wound infection play a major role in impeding the healing process. This chapter will introduce recent epidemiologic data and common etiologies related to chronic wounds. Discussion will focus on principles of wound care, current treatment modalities, and the role of wound microbiology. Up-to-date

evidence has been collected by repeated searches using PubMed, Scopus, and the Cochrane Library for frequently cited publications, articles in high impact journals, comprehensive reviews, and randomized clinical trials. The information is supplemented by the authors' firsthand clinical experience and knowledge of the subject.

ETIOLOGIES OF THE CHRONIC WOUND

Venous insufficiency is responsible for at least 75% of lower extremity ulcerations.⁵ Venous leg ulcers are the most severe manifestation of chronic venous incompetence, producing venous hypertension and turbulent flow related to reflux through incompetent valves in the lower extremities. Approximately 80% of the adult population have some degree of venous disease, manifested by telangiectases, varicose veins, edema, stasis dermatitis, lipodermatosclerosis and ulcerations.⁵ Risk factors such as obesity, prolonged standing, and genetic predisposition can increase pressure and reverse flow in the leg veins, causing structural changes in the valve leaflets and vein walls. This leads to physical distortion and distention as well as transduction in endothelial cells, which promote an inflammatory and prothrombotic phenotype. Patients with a history of idiopathic deep venous thromboses or pulmonary embolus, especially at a young age, frequently have an underlying genetic thrombophilia. These inherited defects are best remembered by the mnemonic *STALL Coagulation* and include protein S deficiency, prothrombin mutation, antithrombin III deficiency, lupus anticoagulant antibodies, factor V Leiden mutation, and protein C deficiency, in addition to hyperhomocysteinemia. The mainstay of treatment for venous ulcers is compression therapy, which counters the impact of reflux, reduces blood vessel diameter and pressure, and decreases the release of inflammatory cytokines and leakage of fluid causing edema. Venous leg ulcers are addressed in greater detail in a separate chapter entitled, "Venous Ulcers."

Diabetic foot ulcers (DFU) (Figure 49-1) are another major type of chronic wound that results from complex disease-associated neuropathic and vascular changes. Diabetics have a 15% to 25% lifetime risk of developing a foot ulcer.⁶ DFUs have a high recurrence rate, frequently lead to amputation, and are associated with a high mortality.

FIGURE 49-1 Diabetic foot ulcer

FIGURE 49-2 Pressure ulcer

Many overlapping factors can lead to a DFU. Metabolic abnormalities from diabetes cause neuropathic and vascular changes. Peripheral sensory neuropathy results in loss of protective sensation that increases the risk of acute trauma or repetitive injury to an existing ulceration. Motor neuropathy affects the muscles required for normal foot movement, altering the distribution of forces during walking and causing reactive thickening of skin (callus) at sites of abnormal load. Ischemic tissue necrosis beneath the callus leads to breakdown of skin and subcutaneous tissue, resulting in a neuropathic ulcer with a punched-out appearance.⁷ The Charcot neuropathic foot of diabetes is characterized by joint deformities that also predisposes the patient to secondary ulceration. Diabetes causes ischemia from microvascular and macrovascular disease with reduced distribution of blood to skin surfaces in need of healing. Bacterial infection is an important sequela of DFU, and in turn can cause substantial deterioration of the wound and complications such as osteomyelitis that may require amputation. Management of the DFU includes wearing off-loading shoes to redistribute the weight off the ulcer site and protective footwear to prevent repeated trauma, control of infection, and revascularization procedures as indicated.

Pressure ulcers (Figure 49-2) occur most often in patients who are immobile, paralyzed, elderly, or malnourished. Pressure ulcers are caused by prolonged pressure, friction, or shear of the skin surface leading to impaired blood supply and tissue malnutrition. Tissue compression exceeding the capillary filling pressure of 32 mm Hg that lasts longer than 2 hours can cause local ischemia and necrosis.⁸ Skin overlying bony prominences including the sacrum, malleoli, or hips is particularly vulnerable. The recurrence rates of pressure ulcers may be as high as 90%. Frequent repositioning and off-loading with special beds and cushions are the cornerstone for prevention and treatment of pressure ulcers.

The most widely accepted classification system for pressure ulcers is described by the National Pressure Ulcer Advisory Panel. This four-stage classification is designed only to describe the depth of a visible ulcer at the time of examination. Stage I represents intact skin with signs of impending ulceration: blanching and/or nonblanching erythema, warmth, and induration. It is especially important to recognize and effectively treat Stage I ulcers because they can resolve, with proper care, in 5-10 days. Stage II ulcers present as a shallow ulcer (including epidermis and most often dermis) with pigmentation changes. They are usually reversible if treated appropriately. A Stage III ulcer represents the typical pressure ulcer that appears as a necrotic, foul-smelling crater. It has full-thickness skin loss with extension through subcutaneous tissue, but not underlying fascia. Stage IV ulcers represent full-thickness skin and subcutaneous tissue loss, with ulcer penetration into the deep fascia, resulting in involvement of muscle, bone, tendon, or joint capsule.

The Braden Scale is a scoring system used to predict the risk of developing a pressure sore. It is divided into six risk categories: sensory perception, moisture, activity, mobility, nutrition, and friction and shear. The best possible interpretation is a score of 23, and the worst is a six. The Braden Scale has been correlated with levels of risk based on the percentage of patients expected to develop ulcers: 15 to 18, at risk; 13 to 14, moderate risk 10 to 12, high risk; and 9 or below, very high risk.⁹ Medicare reimbursement policies have substantially changed in the last few years, and hospitals are no longer being reimbursed for treating preventable pressure ulcers. The new policy will give hospitals a strong incentive to screen patients who might be at risk and to document if the ulcer was present at the time of admission. The National Pressure Ulcer Advisory Panel (NPUAP), a nonprofit organization whose mission is to serve as the authoritative voice for improved patient outcomes in pressure ulcer prevention and treatment through public policy,

education and research, recently convened a consensus conference held at Johns Hopkins Medical Center in Baltimore, Maryland to discuss the definition of “unavoidable” pressure ulcers. The NPUAP panelists, comprised of twenty-four multidisciplinary experts, agreed that the current definition of “unavoidable” pressure ulcers developed by the Federal Government for long-term care settings captured the spirit of pressure avoidability but could not be used in all settings. Thus a revised definition was developed:

Unavoidable means that the individual developed a pressure ulcer even though the provider had evaluated the individual’s clinical condition and pressure ulcer risk factors; defined and implemented interventions that are consistent with individual needs, goals, and recognized standards of practice; monitored and evaluated the impact of the interventions; and revised the approaches as appropriate.

Furthermore, the panel agreed there are patient situations that create unavoidable pressure ulcers. For example, critical care patients with hemodynamic instability may be medically intolerant of turning or repositioning and thus develop unavoidable pressure ulcers. In addition, patients who choose not to participate in their own pressure ulcer prevention may develop “unavoidable” pressure ulcers.

Arterial ulcers (Figure 49-3) result from inadequate blood supply to the skin. Arterial insufficiency can be caused by atherosclerotic or thromboembolic disease that causes skin infarction and ulcer formation. The risk for lower extremity arterial ulcers is increased in smokers, diabetics, elderly patients, and individuals with evidence of arterial disease at other sites.⁴ Signs and symptoms include cool extremities, skin pallor, weak pulses, claudication, and rest pain. Arterial ulcers typically have a punched-out appearance and often occur distally over bony prominences. Assessment with ankle-brachial index and Doppler ultrasound for distal pulses can confirm a compromised blood supply to the limb. Treatment is aimed to promote arterial supply to the affected area.

FIGURE 49-3 Arterial ulcer

Dermatologic conditions may also result in chronic ulcers. Pyoderma gangrenosum (PG) is a neutrophilic dermatosis that causes recurrent painful inflammatory ulcers. It is frequently associated with underlying systemic diseases, such as inflammatory bowel disease, rheumatoid arthritis, dysproteinemia, hidradenitis suppurativa, or malignancy. Pyoderma gangrenosum characteristically begins as a tender pustule that breaks down and forms an ulcer. The ulcer has a sharply circumscribed, irregular, and undermined border often with a characteristic boggy, purple appearance. Pyoderma gangrenosum ulcers occur most commonly on the lower extremities. Patients with PG demonstrate pathergy, where slight trauma to the skin can initiate a new ulcer.¹⁰ The pathogenesis is poorly understood and diagnosis is generally made on clinical grounds. Treatment of the systemic condition often leads to improvement of the skin.

Vasculitis is another dermatologic condition that causes skin ulcerations. Necrotizing inflammation of blood vessels leads to cutaneous manifestations, beginning with palpable purpura and eventually progressing to skin ulceration. Lesions are frequently painful. Vasculitides encompass a heterogeneous group and may be associated with various etiologies including autoimmune, infectious, medication-related, dysproteinemia, malignancy-related, and idiopathic. The pathogenetic mechanism involves small, medium, or large vessels and may be caused by immune complex deposition. Cutaneous polyarteritis nodosa is a vasculitis that causes a chronic relapsing course of painful nodules and ulcers.¹⁰ These ulcers are accompanied by livedo reticularis and usually occur on the bilateral lower extremities. Management involves the selection of appropriate systemic anti-inflammatories, anticoagulants, and immunosuppressants.

PRINCIPLES OF WOUND HEALING

Normal wound healing is a highly dynamic process and involves complex interactions of resident and infiltrating cells, growth factors and cytokines. The immediate goal of repair is to achieve tissue integrity and homeostasis.¹¹ To achieve this goal, an orderly, highly efficient healing process occurs in three overlapping phases: *inflammatory*, *proliferative*, and *remodeling*. The process usually takes 3 to 14 days to complete. Following hemostasis, which is achieved by platelet aggregation, the initial repair phase begins with an inflammatory response. Leukocytes infiltrate into the wound site and remove foreign material, bacteria and damaged tissue by phagocytosis. These cells, including neutrophils and macrophages, also release essential growth factors and cytokines such as platelet-derived growth factor (PDGF) and transforming growth factor beta (TGF- β).¹² Once the wound bed is cleaned, the proliferative phase begins. Granulation tissue consisting of endothelial cells, macrophages and fibroblasts begins to form. Fibroblasts produce a collagen matrix; new blood

vessels invade the granulation tissue; and epidermal cells migrate across the wound surface to close the breach. In the final phase of remodeling, the new collagen matrix becomes cross-linked and reorganized to affect connective tissue compaction and wound contraction. Wounds gain about 20% of their final strength during these first 3 weeks of collagen deposition and, by the processes of remodeling and contraction, continue to strengthen over the following months.¹³

Nonhealing wounds often suffer from inadequate circulation, poor nutrition, compromised immune status, and lack of protection from mechanical trauma.⁴ The presence of chronic inflammation will also cause healing to stall. Clinical signs and symptoms of chronic inflammation include edema, erythema, warmth, tenderness, induration, and dyspigmentation of the affected skin. The inflammatory state features the release of proteolytic enzymes such as collagenases and elastases that destroy important healing factors like PDGF and TGF- β and degrade the connective tissue matrix.¹² The presence of chronic inflammation may lead to edema and scarring and predispose tissues over the course of years to cancer development. Compression therapy acts to decrease edema and inflammation, in order to provide a suitable environment for wound repair to take place.

Chronic wounds contain persistent microbial populations, which may function as benign colonizers or pathogenic impediments to wound healing. Bacterial populations in wounds are usually polymicrobial and include both aerobic and anaerobic organisms such as *Staphylococcus*, *Pseudomonas*, *Streptococcus*, *Escherichia*, and *Bacteroides*. When growth and death of microbes are kept in balance by host defenses, a wound is considered to be colonized. Wounds become clinically infected when host defenses are overwhelmed. These wounds often demonstrate increased erythema, edema, warmth, pain, drainage and malodor. Systemic signs, such as fever, chills, and leukocytosis suggest that the infection has progressed to cellulitis, or even bacteremia or septicemia.

Whenever possible, clinically infected wounds should be cultured and microorganism susceptibilities determined before systemic antimicrobial agents are prescribed. There are usually two available methods to collect samples for culture in the clinical setting. The first is a swab of the wound slough for qualitative culture. These results are reported as none, few, moderate, and heavy. The second is a curette sample of wound tissue for quantitative culture. The latter results are reported as the number of colony forming units (CFU) per gram of tissue. A recent study has shown that qualitative culture results do not correlate with the quantitative culture results.¹⁴ Since swabs are unreliable, quantitative culture is presently the gold standard for bacterial identification and quantification in the clinical setting. Oral antibiotics are prescribed only for meaningful positive culture results (more than 100,000 CFU per gram of tissue or clinical signs of infection). The antibiotics utilized are selected

based on antibiotic sensitivities. Commonly prescribed oral antibiotics include amoxicillin for Gram-positive bacteria, trimethoprim-sulfamethoxazole for MRSA, fluoroquinones for *Pseudomonas* and metronidazole for anaerobic organisms. Anaerobic bacteria are typically difficult to culture, but exude a distinctive foul odor from the wound. As a result, oral metronidazole is frequently prescribed empirically based on clinical suspicion. *Corynebacterium* and coagulase-negative *Staphylococcus* are normal skin flora and do not need to be treated. Patients who have systemic signs of infection require hospital admission, blood cultures, and intravenous antibiotics.

Metagenomic analysis is a novel technique to study the identity and relative abundance of bacteria in chronic wounds. The 16S rRNA gene is universal for all prokaryotes including bacteria and is not found in eukaryotes such as humans. Metagenomic analysis uses high throughput sequencing of the 16S rRNA gene to identify all the bacterial genomes in a wound sample.¹⁵ Recent data using metagenomic analysis has demonstrated greater microbial diversity, in addition to the presence of previously unrecognized anaerobic bacteria. Our analysis of a series of 40 wounds identified 15 different anaerobes by pyrosequencing compared to three different anaerobes by standard quantitative culture.¹⁶

Traditionally we think of bacteria as free-living cells, such as those floating in the blood stream causing sepsis. These bacteria exist in a planktonic state. We now understand that bacteria also exist in a biofilm state in which they form sessile groups on a surface. In addition to the slough on chronic wounds, other examples of biofilms include the soft plaque found on teeth, the accretions on indwelling medical devices, and the sludge in oil pipes.¹⁷ A biofilm is a complex community of aggregated bacteria embedded in a self-secreted exopolysaccharide matrix. Biofilms develop when individual bacterial cells that are still in a planktonic state attach to a moist surface such as a wound. The cells proliferate and form microcolonies. Once the density of bacteria has reached a certain threshold or "quorum," the bacteria begin to produce quorum sensing molecules.¹⁸ These molecules enable bacteria in the developing biofilm to communicate with each other as they organize themselves and build channels to transport oxygen and nutrients throughout the biofilm. Quorum sensing molecules are involved in both intra- and interspecies signaling. The universal molecule is considered to be autoinducer-2 (AI-2), which is used by both Gram-positive and Gram-negative organisms. Quorum sensing molecules are also implicated in the regulation of virulence factors. Biofilm bacteria have a very different phenotype and exhibit different properties from the same bacteria in their planktonic form. In addition, their self-secreted exopolysaccharide matrix serves as a substantial barrier against the penetration and activity of antibiotics and immune cells and factors. As a result, biofilms confer up to 100 to 1000 times greater resistance to traditional antibiotics and are less

susceptible to host defenses. Thus, traditional antibiotics may not be effective in treating chronic wound infections.

Novel imaging techniques have also enabled us to study the structural morphology of the biofilm in chronic wounds. Epifluorescence microscopy, which uses fluorescent stains for bacteria, can produce images of bacteria in order to visualize their location within a thick biofilm. Fluorescent in-situ hybridization (FISH) uses a DNA probe that will only bind to a specific organism. As a result, specific organisms such as *Staphylococcus*, can be located in the wound. In the future, these advanced molecular and imaging techniques will enable us to better understand wound microbiology and develop targeted therapy against biofilms in order to promote healing of chronic wounds.

There is still substantial controversy regarding the role of bacteria in impeding wound healing. We believe there is often a profligate use of oral antibiotics, leading to the dangerous promotion of antibiotic resistance, as well as wasteful spending on expensive medications that are ineffective against biofilm bacteria. As a result, research into the role of bacteria in chronic wounds is of utmost importance and urgency.

In addition to antibiotics, topical cleansers, compounds, and dressings are available to decrease the bacterial burden in chronic wounds. Antiseptics are chemical agents that are broadly toxic to microbes. Commonly used topical antiseptic solutions that should not be used on chronic wounds include hydrogen peroxide and povidone-iodine, as they are toxic to human tissue and prevent re-epithelialization of the wound. Rather, patients wishing to clean their wounds at home should do so with gentle soap and water. Other antiseptic preparations may be beneficial in appropriate situations. For example, a modified Dakin's solution at a concentration of 0.025% sodium hypochlorite elicits antimicrobial effects without harming human tissue. Antiseptic dressings include Mesalt and Xeroform. Mesalt is a hypertonic sodium chloride-impregnated gauze that is highly absorbent and discourages bacterial growth as well as inhibits overexuberant granulation tissue formation. Xeroform is an antiseptic and deodorizer gauze that is impregnated with 3% bismuth tribromophenate in petrolatum. It is less adherent than plain gauze.

A recent Cochrane review described evidence in the literature to support the use of cadexomer iodine to improve healing rates.¹⁹ Cadexomer iodine is the active ingredient in Iodosorb gel and Iodoflex. The brown paste-like compound turns white corresponding with loss of bactericidal activity after extended use, indicating the need for a new application. Cadexomer, a modified starch-based polymer bead, promotes the absorption of fluid, exudates, debris, and bacteria from the wound bed while facilitating the controlled release of iodine at levels that are not toxic to human cells. Other topical antimicrobial compounds utilized in wound care include mupirocin ointment, which is particularly effective against Gram-positive organisms, including methicillin-resistant *Staphylococcus*

aureus (MRSA), metronidazole gel, cream or lotion, which provides good anaerobic coverage, and silver sulfadiazine 1% cream commonly used on burn wounds. Neomycin and bacitracin are typically avoided in chronic wound care because of their significant potential to induce contact sensitivity.

Topical dressings that contain ionic silver are believed to be effective against bacteria in wound biofilms. An in-vitro study showed that a silver-containing hydrofiber dressing was effective in killing monomicrobial biofilms composed of *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or *Enterobacter cloacae*, and a mixed polymicrobial biofilm over a contact time period of 48 hours.²⁰ Silver-containing dressings currently available include the following categories: silver foams (e.g., Mepilex Ag), silver hydrogels (e.g., Silvermed), silver alginates (e.g., Tegaderm Ag), silver hydrocolloids (e.g., Duoderm Ag), silver hydrofibers (e.g., Aquacel Ag), and silver-containing collagen dressings (e.g., Prisma). The various silver-containing dressings all possess a silver reservoir, but differ in the way in which the silver ions are released. Because silver ions, not silver atoms, produce the antimicrobial effects, silver must be present in a solution in order to exert its bactericidal properties. Therefore, dry silver dressings require contact with wound moisture in order to release the active agent. Silver ions have efficacy against Gram-negative bacteria and antibiotic-resistant organisms like MRSA and vancomycin-resistant enterococci (VRE). Silver ions kill bacteria by binding to and disrupting bacterial cell walls, damaging intracellular and nuclear membranes, poisoning respiratory enzymes, and denaturing bacterial DNA and RNA. Although some species of bacteria (*Pseudomonas* in particular) have demonstrated resistance to certain silver preparations, silver has a far lower propensity to induce bacterial resistance than classic antibiotics on account of its multitargeted mechanism of action. Disadvantages of silver products include potential irritation or discoloration of the surrounding tissues (argyria).

Hydrofera Blue is a simple and safe moist foam dressing. It contains two organic pigments with broad-spectrum bacteriostatic protection. These pigments, methylene blue and gentian violet, have been used safely in medicine for over 50 years and have efficacy against a variety of microorganisms including MRSA and VRE. Hydrofera Blue is an inexpensive option compared to other topical antimicrobial wound dressings and compounds.

TREATMENT MODALITIES

Moisture and occlusion are also important principles of wound care, which have been articulated since ancient times.²¹ Nevertheless, for nearly 2000 years, therapeutic efforts focused on drying the wound site, with absorptive gauzes as the mainstay. In the 1960s, Hinman and Maibach showed in human skin wounds that occlusion compared to air exposure resulted in more rapid re-epithelialization and

wound closure.²² Occlusion keeps moisture in the wound, which prevents dehydration of delicate new epithelial cells and allows their migration and survival on the wound. While moisture is essential for proper healing, excessive wetness on the wound bed can be problematic. Highly exudative wounds may cause maceration to the surrounding skin, resulting in tissue that appears soft, white, and friable. The macerated skin has a tendency to break down, which can delay wound healing or make the wound deteriorate further. Furthermore, fluid from chronic wounds contains biologic molecules that may actively interfere with the healing process by inhibiting fibroblast proliferation and destroying extracellular matrix. Occlusion works for other reasons as well: protection from external contamination, stimulation of collagen synthesis, creation of a hypoxic environment to promote angiogenesis and, for certain dressings, lowering the pH at the wound surface to create an environment inhospitable to microbial growth.²³

Wound dressings constitute the most basic wound management strategy. They are used to manipulate the local environment to optimize wound healing. An important goal is balancing the moisture content at the wound base. Thus, some dressings are used for absorbency of excess exudates, while others provide moisture for a dry wound base. Recent studies show that the use of occlusive dressings is also associated with fewer clinical infections, greater patient comfort, and reduced scarring. Other purposes of dressings include protection from external contamination and physical trauma, promotion of antimicrobial action on wound microbial flora, and pain relief. It is important to choose dressings that do not cause a contact allergy. Since wounds evolve over time, the appropriate dressing will need to be changed to suit the particular condition of the wound. The major categories of wound dressings include gauze, film, hydrogel, hydrocolloid, alginate, and foam. In conjunction, barrier creams, ointments, and other periwound protectants are frequently used because skin around a wound is vulnerable to damage from wound-associated inflammation, excess moisture, wound fluid proteases, dressing adhesives, and contact allergic reaction.

Plain dry cotton gauze has historically been one of the most popular wound dressings, yet it has several shortcomings. Dry gauze promotes dessication of the wound. Similarly, a wet-to-dry dressing, which involves using saline-moistened gauze that eventually dries over the wound, will stick to the wound base causing pain and trauma during dressing changes. Dry gauze also has a limited ability to protect against external contamination, especially when wound exudate has saturated the entire thickness of the gauze. A recent prospective multicentered study of 767 wounds treated using standardized dressing protocols revealed that gauze dressings compared to moisture-retentive dressings (e.g., hydrocolloids, alginates, foams) are associated with slower healing times.²⁴ Furthermore, gauze dressings are less cost effective over time even though they may be more affordable per individual dressing.

Films are transparent, adhesive, thin and semiocclusive, permitting exchange of oxygen and water vapor, but not of liquid and bacterial contaminants. Thus, films should be reserved for wounds with minimal exudate. When used as a primary dressing, transparent films allow visualization of the wound so dressing changes may occur less frequently and only as needed. When used as secondary dressings, films help secure nonadhesive dressings in place. Caution is needed when removing films because the adhesive may strip delicate new epidermis from the wound. A recent prospective open controlled study showed that film dressing is more effective than conventional treatment with ointments and gauze in the management of severe pressure ulcers.²⁵

Hydrogels are best suited for dry wounds or those with limited exudate. They are ideal for patients with painful wounds, since they can be applied and removed with minimal trauma to the wound. Patients often experience pain relief with hydrogels, likely because of their cooling effect. Hydrogels promote autolytic debridement of slough and necrotic tissue and are suitable when sharp debridement is contraindicated because of pain. Hydrogels are water-based products available in amorphous gel and sheet forms. Two sheet hydrogels frequently used in our clinic are the *Curagel* and *Xcell* brands. Recent prospective studies of hydrogel dressings have suggested their effectiveness in chronic wounds.²⁶⁻²⁷

In contrast to the fluid-donating hydrogels, hydrocolloids maintain a moist healing environment by absorption of excess exudate forming a hydrophilic gel covering. Hydrocolloids are ideal for low to moderate exudative wounds. They have a relatively long wear time and protect against shear force. A meta-analysis of 12 randomized-controlled trials comparing hydrocolloid dressings to conventional gauze dressings found that hydrocolloids improved the rate of healing in 72% of the wounds, particularly in pressure ulcers.²⁸ The most frequently used hydrocolloid in our clinic is *DuoDERM CGF*, which has a foam backing. Hydrocolloids should not be used for wounds with too much exudate because the large amount of moisture will cause the dressing to separate or cause periwound maceration. In addition, hydrocolloids have a tendency to produce a brown, malodorous drainage, which can be mistaken for infection and be troubling for the patient.

Fibrous dressings, including alginates and hydrofibers, have very high absorbency and are used for wounds with heavy exudates. Alginates are derived from brown seaweed and can hold up to 20 times their weight. Alginates require moisture to function, thus they should not be used over dry wounds. They contain calcium and sodium salts of alginic acid, a polymer of mannuronic and glucuronic acids. When placed over a moist wound, an ion exchange reaction occurs between calcium in the alginate and sodium in the wound fluid, producing soluble calcium-sodium alginate and forming a gelatinous mass. The resultant gel helps to maintain a moist healing environment. Because of

a tendency to absorb fluid across the entire surface of the dressing (lateral wicking), some alginates may cause peri-wound maceration if they overlap with normal skin. Thus, alginates should be cut to the shape of the wound bed. Several prospective, randomized-controlled studies have demonstrated that alginate dressings accelerate wound healing as compared to control dressings (e.g., gauze, dextranomer paste).²⁹⁻³⁰ A commonly used alginate in our clinic is *Silverlon*, which can be cut into strips and used to pack the tunnel in deep wounds, thus wicking the drainage out of wounds. A unique advantage of some fibrous dressings such as *Aquacel Ag* is that they are inherently hemostatic and can be used to control minor bleeding.

Foam dressings protect against shear force, provide thermal insulation, and offer different levels of absorption depending on their thickness. Some foam dressings are nonadherent, thus avoid traumatic dressing changes. Some have a film backing to prevent exudate leakage and provide an additional barrier against bacterial contamination. In studies, foam dressings are comparable to hydrocolloids in terms of ulcer healing.³¹ Like hydrocolloids, foams may promote development of excessive malodorous drainage necessitating frequent dressing changes.

Compression therapy is considered the first-line treatment for venous leg ulcers, and is also used for other wounds associated with the presence of edema and inflammation. Compression reduces edema and stasis by decreasing distention in superficial veins and assisting the calf muscle pump in venous return. It also stimulates healthier granulation tissue. The use of compression is not without risk in patients with arterial disease, which may result in ischemia because of impaired blood supply. As a result, arterial insufficiency must first be ruled out by obtaining vascular studies for arterial-brachial index (ABI) or great toe pressure. A normal ABI is in the range of 0.8 to 1.2, and an acceptable great toe pressure is above 50 mm Hg. Readings outside the normal limits should be referred to the vascular surgeon for further advice. If a patient feels significant pain or discomfort while under compression, we instruct the patient to cut off the bandage at home. We often prescribe compression stockings for patients who cannot tolerate compression bandages. Uncompensated congestive heart failure is also a relative contraindication to compression therapy.

Various forms of compression exist, ranging from multilayered bandages to stockings. The optimal pressure to overcome venous hypertension and prevent capillary exudation is generally thought to be an external pressure of 35 to 40 mm Hg at the ankle. Compression bandages can be applied up to 60 mm Hg of pressure depending on the style of the application.³² Used for both prevention of recurrent ulcers and treatment of acute ones, compression stockings can provide up to 35 mm Hg of pressure. A Cochrane systematic review of 39 randomized-controlled trials found that compression therapy was more effective than noncompression therapy for the treatment of venous

leg ulcers. Furthermore, multicomponent bandages worked better than single-component bandages. Multicomponent systems appeared to perform better when one part was an elastic bandage.³²

The Unna boot is a commonly used compression bandage, consisting of a zinc oxide-impregnated gauze wrap applied over the skin from the base of the toes to the popliteal flexure, covered with a layer of soft cotton, and wrapped with an elastic bandage that supplies compression. The zinc oxide protects the periwound skin and is thought to also enhance wound re-epithelialization and decrease inflammation. Compression boots are typically left in place for a week, although they may need to be changed more frequently if the wound is especially exudative. Proper application of an Unna boot to supply the appropriate degree of pressure requires training and experience. The tensile strength of a newly healed wound is low. As a result, it is important to continue compression, frequently at a lower pressure with stockings, for an additional 6 weeks. In addition, long-term use of compression stockings will help to prevent recurrence or new ulcers from forming.

Debridement is the medical removal of bacterial biofilm, exudate, and nonviable, unhealthy tissue, which may appear as slough or eschar, from the wound bed. There is no question that adequate debridement is necessary to improve healing because it enables normal, well-vascularized tissue to proliferate within the wound while reducing the bacterial burden and risk of wound infection. Callus, or hyperkeratosis at the rim of the wound, frequently seen in neuropathic ulcers such as DFUs also require debridement. Debridement converts chronic wounds into acute wounds, which improves ulcer bed perfusion and activates the acute wound healing response. Neutrophils and macrophages recruited to the area can then secrete growth factors and phagocytize bacteria and nonviable tissue. There are a wide range of removal techniques, which include surgical, conservative sharp, wet-to-dry, autolytic, enzymatic, maggot, high-pressure fluid irrigation, and ultrasound mist therapy. Debridement may be painful for a patient even with local anesthesia.

Conservative sharp debridement is the most rapid and precise method and is performed using a curette, scalpel, forceps, or scissors. A prospective controlled study demonstrated that chronic venous leg ulcers undergoing sharp debridement had faster healing rates and greater chance of closure compared to ulcers without intervention.³³ Sharp debridement can be used in venous, diabetic, and pressure ulcers, but caution should be exercised with arterial ulcers because ischemic tissue tends to desiccate after debridement, potentially causing ulcer enlargement.

While sharp debridement is the preferred method in our clinic, alternative techniques are also available. Autolytic debridement is a gentle process that involves rehydrating the slough and necrotic tissue in a wound to aid separation from healthy tissue. Moisture-donating dressings or the application of ointments or creams under occlusion

provide a moist environment for autolytic debridement to occur. This process may take several weeks but can be useful when sharp debridement is contraindicated, such as in patients with bleeding diatheses. A newer technique is enzymatic debridement, which uses ointments containing enzymes that break down the collagen and fibrin in wound exudates and necrotic tissue. Enzymatic debridement may also take several weeks, and examples include papain, urea, and collagenase. Current evidence suggests that *Accuzyme*, a papain-urea preparation, and *Santyl*, a collagenase, have similar efficacy.³⁴ Care should be taken to avoid application on the normal skin surrounding a wound.

Offloading, or pressure dispersion, works by spreading the pressure forces over a wide area in order to reduce pressure over the at-risk or previously ulcerated area. Offloading devices are important in the prevention and treatment of diabetic foot ulcers. The threshold for offloading (expressed as a peak pressure level or pressure-time integral), which is required to adequately heal neuropathic foot ulcers in diabetic patients is currently unknown.³⁵ Common methods to offload the foot include the following: bed rest, wheelchair, crutch-assisted gait, total contact casts, removable cast walkers, half-shoes, therapeutic shoes, custom splints, felted foam or heel lift devices, wheelchair cushions, and specialty beds including air loss beds and alternating pressure beds. Given the vast array of offloading methods, patients will need assistance from experienced practitioners to select an appropriate, cost-effective pressure redistribution device.

Although theoretically effective and frequently prescribed, crutches, wheelchair and bed rest rarely work in practice for DFU patients. Crutches often cause additional pressure to be applied to the contralateral limb, thus putting it at risk for ulceration. Wheelchairs are effective pressure reduction devices, but for many DFU patients, their homes are not designed to accommodate the bulkiness of wheelchairs. Compliance with bed rest is often difficult, especially when DFU patients do not feel discomfort or pain in their insensate foot and thus resume normal daily activities.

The gold standard for achieving pressure redistribution for DFUs is by total contact casting. The total contact cast (TCC) employs a well-molded, minimally padded cast that maintains contact with the entire plantar aspect of the foot and lower leg. The intimate fit of the cast material to the plantar surface of the foot increases the plantar weight bearing surface area to help distribute the plantar pressure from one or two distinct areas to the plantar foot as a whole. Total contact cast is quite effective in treating the majority of noninfected, nonischemic plantar DFUs, with healing rates ranging from 72% to 100% over the course of 5 to 7 weeks.³⁶ A recent randomized, controlled study compared TCC with a removable cast walker (RCW) and a half shoe. Removable cast walkers are cast-like devices that can be removed frequently to allow for self-inspection of the wound, application of topical therapies, or to bathe and

sleep more comfortably. Half shoes consist of a wedge sole that ends just proximal to the metatarsal heads to eliminate propulsive gait and dissipate ground reactive forces of the forefoot. They are commonly used because they are inexpensive and easy to apply, but are not as effective as TCCs and RCWs. This study demonstrated that patients using a TCC had far greater healing rates compared to patients using a RCW or half shoe.³⁷ Armstrong and his colleagues also observed in this study that patients treated with TCCs were significantly less active, with 600 daily steps compared to >1400 daily steps taken by those in the two other treatment groups. Furthermore, 85% of patients in the RCW and half shoe treatment groups wore the footwear most of the time while outside the home, but only 15% of them wore them at home. Thus, patient compliance and activity level appear to be important factors related to the success of offloading devices.

An innovative approach to offloading combines the clinical efficacy of TCC with the relative ease of application of the RCW. The instant total contact cast (iTCC) involves wrapping an RCW with a single layer of cohesive bandage, Elastoplast, or casting tape. The iTCC addresses the limitations of both the TCC and RCW, in that it enforces compliance and pressure redistribution while allowing for ease of application and examination of the ulcer when needed. A randomized trial comparing the standard TCC and the instant TCC found no differences in healing rates and the mean healing time between both groups.³⁸ Thus, iTCCs are comparable to the gold standard.

Pressure ulcers, frequently found in patients with spinal cord injuries or those who are bedridden because of a critical illness or poor health, also require offloading techniques for prevention and treatment. As a result of immobility, patients with sacral pressure ulcers benefit from devices that redistribute pressure while sitting or lying down for extended periods of time, such as wheelchair cushions and beds. A study comparing three commonly prescribed wheelchair cushions for pressure relief found that the Roho cushion was more effective than the Jay and Pindot cushions.³⁹ Each cushion represented the three major categories of cushion construction materials: air (Roho), gel (Jay), and polyurethane foam (Pindot). The alternating pressure air mattress (APAM) is used for bedridden patients and reduces the intensity and duration of pressure and shearing forces by alternating the area under pressure. They generate alternating high and low interface pressures between body and support surface by alternating the inflation and deflation of air-filled cells. The periodic pressure relief enables the restoration of blood supply to tissues. A review of 35 studies concluded that APAMs are likely to be more effective at relieving pressure and more cost-effective than standard hospital mattresses.⁴⁰ A Cochrane review of support surfaces for pressure ulcer prevention found that higher-tech mattresses including alternating pressure and constant low pressure mattresses have comparable effectiveness.⁴¹

Negative pressure wound therapy (NPWT), or vacuum-assisted closure (VAC), devices consist of a fenestrated evacuation tube embedded in a foam dressing and covered with an airtight film dressing. The tube is attached to a vacuum source. Sub-atmospheric pressure of – 125 mm Hg (with a range of – 50 to – 200 mm Hg depending on the nature of the wound) is applied in a continuous or intermittent manner.⁴² A canister is attached to the vacuum pump to collect the excess wound fluid. Negative pressure wound therapy dressings hasten wound healing by maintaining a moist environment, removing wound exudates, reducing bacterial loads, increasing local blood flow and granulation tissue formation, and applying mechanical pressure to promote wound closure. Another potential mechanism is the idea that microstrain, or cell stretching, stimulates cell division and proliferation in the presence of soluble mitogens, whereas retracted cells remain quiescent.⁴³

Negative pressure wound therapy technology has been in use since the 1940s. The United States Food and Drug Administration (FDA) most recently expanded the approved indications for NPWT devices, which now include chronic, acute, traumatic, subacute, and dehisced wounds, flaps and grafts, pressure ulcers, venous ulcers, and diabetic ulcers. Negative wound pressure wound therapy dressings are not appropriate for ischemic wounds because they may cause necrosis of the wound edges. They are also contraindicated for wounds associated with untreated osteomyelitis, fistulas to body cavities or organs, malignancy present in the wound, treatment that would place the NPWT over a wound with exposed arteries or veins. Wounds must be thoroughly débrided of all necrotic tissue before beginning therapy. The foam component of the dressing should be changed every other day. In some patients, dressing changes may be painful or cause trauma to the wound bed because of the in-growth of new granulation tissue into the foam; the use of denser sponges and more frequent sponge changes can help alleviate this problem.

For many years, the clinical evidence supporting the use of NPWT was based largely on clinician perception, case series, small cohort studies, and weakly powered randomized trials. The Cochrane Collection confirmed these conclusions in their review in 2000 and cited the need for more rigorous clinical trials to study the efficacy of NPWT devices. Since then, several large prospective, randomized, controlled studies have been conducted demonstrating that the wound healing rate and rate of granulation tissue formation are significantly greater with NPWT than with standard moist wound therapy (MWT).⁴⁴⁻⁴⁶

Despite the high cost of the device, NPWT has also been shown to be more economical than traditional wound care. A study of diabetic patients with postamputation wounds was performed comparing treatment with NPWT and MWT. The average total cost to achieve healing was \$25,954 for patients treated with NPWT compared with \$38,806 for the MWT group. The MWT group required more surgical procedures (including debridement), more

office visits, and more dressing changes. Thus, NPWT resulted in a greater proportion of patients who obtained wound closure at a lower overall cost of care compared to MWT.⁴⁷

Hyperbaric oxygen therapy (HBOT) is used as an adjunct to standard wound care. HBOT, which involves breathing 100% oxygen at supra-atmospheric pressures between 1.5 to 3 ATMs while inside of a compression chamber, is based on the rationale that tissue hypoxia contributes to the failure of many chronic wounds to heal. Hyperbaric oxygen therapy increases arterial oxygen pressure, which increases oxygen delivery to tissues as well as results in vasoconstriction and aids in the reduction of edema. Hyperoxygenated plasma enhances angiogenesis and ultimately collagen formation to aid in wound healing.⁴⁸ Hyperbaric oxygen therapy has also been found to be effective against anaerobic bacteria, which survive better in the body's deeper tissues. Increased tissue oxygenation also enhances leukocytes in their ability to fight infection. Hyperbaric oxygen treatments are administered 1 to 2 times daily and last 60 to 90 minutes.

The benefits of HBOT remain controversial. A Cochrane review found that the use of HBOT significantly reduced the risk of major amputation in patients with diabetic foot ulcers and that it might improve the possibility of wound healing at 1 year.⁴⁹ There was insufficient evidence to suggest benefits for venous, arterial, or pressure ulcers. In contrast, topical oxygen therapy, which involves inserting the wounded limb into an airtight bag and surrounding it with oxygen under slightly elevated pressure, is generally considered clinically ineffective.⁵⁰ Medicare reportedly reimburses HBOT as adjunctive therapy for diabetic wounds of the lower extremities if certain conditions are met, including a diabetic ulcer that is grade III or higher by the Wagner classification system and unresponsive to standard wound therapy for at least 30 consecutive days. Medicare will not continue to cover if there are no measurable signs of healing within any 30-day period of treatment.

Clinicians should first assess the degree of peri-wound hypoxia and the likelihood of favorable response to HBOT with transcutaneous oximetry prior to initiation of HBOT. The transcutaneous oxygen measurement at the wound edge should be less than 40 mm Hg. The patient's tissue response to 100% oxygen via mask should result in a transcutaneous oxygen level increase by at least 10 mm Hg.⁴⁸ A trial of HBOT should result in a transcutaneous oxygen measurement greater than 200 mm Hg. Hyperbaric oxygen therapy is associated with several potential adverse events. Absolute contraindications to HBOT include untreated pneumothorax, restrictive airway disease, and concomitant chemotherapy. Hyperbaric oxygen therapy is considered safe if the therapy does not exceed 2 hours and the pressure does not exceed three ATM. Myopia is a reversible adverse effect. Other adverse effects include otic, sinus, or pulmonary barotraumas, neurologic oxygen toxicity,

and claustrophobia. Air breaks, where oxygen breathing is interrupted, can decrease the risk of oxygen toxicity. Fire is always a risk with HBOT and safety checks are conducted prior to entering the chamber.

Growth factors and skin substitutes are among the most recent advances in wound care. Growth factors control many of the key cellular activities involved in the normal tissue repair process, including cell division, cell migration, angiogenesis, and synthesis of extracellular matrix components. Some have suggested that a deficiency of growth factors may exist in chronic wounds. Thus, investigators have examined the benefits of exogenous growth factor application for wound healing. Recombinant human platelet-derived growth factor isoform BB or becaplermin is the only topical growth factor approved by the FDA for the treatment of chronic wounds, indicated for use on chronic neuropathic lower extremity diabetic ulcers. The biologic activity of becaplermin is similar to that of endogenous PDGF-BB, in that it promotes the chemotactic recruitment and proliferation of cells involved in wound repair. Be caplermin has been shown to increase the number of completely healed ulcers at 20 weeks compared to placebo in four multicentered, prospective, randomized, controlled trials.⁵¹

Tissue engineered skin substitutes use living cells, such as fibroblasts and keratinocytes, in a scaffold or natural or synthetic extracellular matrices. The goals of skin substitutes include wound coverage, complete wound closure, reduced healing time, reduced pain, reduced postoperative contracture, and improved aesthetics and functional abilities. Dermal skin substitutes help prevent wound contraction and offer greater mechanical stability. Examples include bovine collagen and Dermagraft, a cryopreserved dermal substitute composed of fibroblasts that is indicated in the treatment of full thickness DFUs greater than

6 weeks duration. Combined dermal and epidermal skin substitutes include Apligraf, an allogeneic, bilayered skin substitute containing both keratinocytes and fibroblasts in a bovine collagen I matrix. Multicentered prospective, randomized clinical trials have demonstrated that Apligraf in conjunction with standard compression therapy is well tolerated and more efficacious in patients with VLUs when compared to compression therapy alone, especially in patients with full-thickness ulcers of >6 months duration. In addition, Apligraf in conjunction with standard diabetic foot care is well tolerated and superior in efficacy, when compared to diabetic foot care alone for refractory full-thickness neuropathic diabetic foot ulcers.⁵²

New biologics that are currently in the pipeline include a suspension of living, growth-arrested, allogeneic keratinocytes and fibroblasts cultured from neonatal foreskin in a fibrin gel for venous leg ulcers. Similar research involves a reconstructed skin substitute made with the patient's own cells. DERMAGEN, a sponge composed of collagen and glycosaminoglycans, reticulated by ionic bonds with chitosan before freeze-drying, is another novel dermal replacement under investigation. This substitute, cellularized by functional allogeneic fibroblasts, is being tested in patients with diabetic foot ulcers.⁵³

CONCLUSION

Wound care represents a great opportunity for dermatologists who are the "skin" doctors, especially when half the total health care budget is spent on wounds every year and most of the reimbursements are paid to other types of healthcare providers. In addition, the staggering expenditures related to chronic wounds continue to burden our health system and will only worsen as obesity and diabetes become more prevalent in the ageing population.

What We Know

- Chronic wounds cause significant morbidity and are a major healthcare burden. Almost \$25 billion per year is spent on the treatment of chronic wounds, which represents greater than 50% of all skin care expenditures in the United States.
- Chronic wounds fail to proceed through the orderly and timely process of repair. The etiologies of chronic wounds are wide ranging and include venous insufficiency, diabetes, physical immobility, arterial disease and a myriad of dermatologic conditions such as vasculitis and pyoderma gangrenosum.
- Chronic wounds contain persistent polymicrobial populations, which affect wound healing. Bacteria in chronic wounds form in a biofilm, a complex community of aggregated bacteria embedded in a self-secreted

exopolysaccharide matrix. Traditional antibiotics are inadequate therapy against biofilm in chronic wounds.

- Current treatment modalities for chronic wounds include moisture and occlusion with appropriate wound dressings, compression, debridement, offloading, negative pressure wound therapy, hyperbaric oxygen therapy, growth factors and skin substitutes. Appropriate therapeutic choice depends on many factors including the specific type of ulcer, the nature of the ulcer base, the presence of bacteria, the vascular supply, and the general health and underlying disease status of the patient.
- Wound care represents a great opportunity for dermatologists to develop more expertise in both its clinical and research frontiers.

The wide variety of etiologies and available treatment modalities make ulcers a complicated diagnostic, therapeutic, and investigative endeavor. Research is still ongoing for evidence-based practices and much work remains in developing suitable protocols to diagnose and treat chronic wounds. Dermatologists are the skin biologists yet much of the wound research conducted is by researchers with limited experience in skin disease. More education is needed to remedy the dearth of wound care expertise among dermatologists in the United States. Medical dermatology has a major responsibility to shape the future of care for skin ulcers.

Treatment of Venous Leg Ulcers

Julia Escandon, M.D., and Robert S. Kirsner, M.D., Ph.D.

INTRODUCTION

Venous leg ulcers are commonly encountered in the medical practice, and treated by a diversity of healthcare professionals and physicians of various medical specialties, including dermatologists. While a wide variety of devices, dressings, and other products have been used to treat venous leg ulcers, many of these treatments lack a high level of evidence to support their use. The objective of this chapter is to present the evidence for the commonly used treatments for venous leg ulcers.

EPIDEMIOLOGY

Venous leg ulcers are both prevalent and costly. Venous ulcers represent up to 80% of lower leg ulcers in the United States and a single venous ulcer costs approximately \$27,493 for people treated with standard care.^{1,2} Overall, care for a venous ulcer represents 1% of the U.S. healthcare budget. The prevalence of venous ulcers increases with age and is higher among women.³ The estimated lifetime prevalence for leg ulceration in developed countries is 1%.⁴ The UK Healthcare Commission has estimated that currently leg ulcer care costs the NHS £300-600 (€330-661, \$447-895) a year.⁵ However, even in those successfully treated, venous insufficiency is a life-long disease and recurrence is common. Recurrence is reported to be high; up to 37% - 48% at 3 and 5 years, respectively.^{6,7}

PATHOPHYSIOLOGY

The venous system in the legs is comprised by the deep venous system that is supported by the calf muscles, the superficial system that lacks external support, and the communicating veins that connect both systems. Leg veins have one-way valves that normally cause the blood to flow from the extremities to the heart. Failure of the calf muscle pump, by either venous disease (valve dysfunction) or failure of other components of the muscle pump can lead to sustained ambulatory venous pressure (venous hypertension). Venous hypertension leads to dilation and elongation of the veins and venules, disruption of microcirculation

with increasing permeability and leaking of plasma and red blood cells into the tissue.⁸⁻¹¹

Sustained pressure in the venous system leads to venous pooling, tortuosity, and increased hydrostatic pressure in capillaries.

Clinically patients present with edema and an aching pain in the affected limb, worse at the end of the day and with dependency, and improved with leg elevation.¹² This is the typical presentation of Chronic Venous Disease and one important consequence of this process is the formation of a venous leg ulcer.¹³

Increased ambulatory venous pressure causes leukocyte trapping in the postcapillary circulation, resulting in leukocyte margination and activation releasing proteolytic enzymes, free radicals, cytokines such as TNF α , interleukin 1, and leukotrienes. It all results in inflammation and tissue hypoxia. Damage to vessels leads to increased endothelial spaces, extravasation of matrix proteins, such as fibrinogen, which leads to a pericapillary fibrin cuff, and trapping of growth factors within the cuff.¹⁴⁻¹⁹

This cascade of events is thought to set the environment for skin changes and eventually ulceration. Getting to know the pathology of venous ulceration, several treatment alternatives have emerged some of them still under research and some of them already proven effective.

DIAGNOSIS

The diagnosis of a venous leg ulcer can often be made by the clinical appearance of the leg and associated wound. The classic presentation of a venous leg ulcer is an irregularly shaped wound with well-defined borders, surrounded by erythematous or hyperpigmented indurated skin. Venous ulcers are not deep and the presence of exposed tendon or bone suggests alternative diagnoses. The indurated fibrotic surrounding tissue is termed chronic lipodermatosclerosis. Within the ulcer bed, a yellow-white exudate is commonly observed. Venous ulcers vary in size and location, but are usually found on the distal medial aspect of the lower leg ("gaiter" area). A lateral venous ulcer may be associated with short saphenous insufficiency. Varicose veins are often present in the venous ulcer patient. Typically, there are telangiectatic veins of the medial ankle, so-called corona

phlebectatica, and indicative of chronic venous insufficiency. Edema of the ankle area is common, although as mentioned above in some patients, the skin is fibrotic and as a result the ankle circumference is actually narrowed.²⁰ Confirmation of the venous disease is desirable and color duplex ultrasound scanning is useful in providing anatomic and physiologic data, helping to confirm venous disease and possibly a venous etiology for the leg ulcer.²¹ However, it must be recognized that venous disease may occur in wounds of various etiologies.

Among the common causes of lower extremity ulceration, there are neuropathic (diabetic) ulcers, arterial ulcers, pyoderma gangrenosum, neoplasia, vasculitis, sickle cell anemia ulcers, and venous leg ulcers. Each condition has its own characteristics that should be considered when making a differential diagnosis and in the overall management of the patient when more than one condition exists.

SEARCH METHODOLOGY

Pubmed and the Cochrane Database for Systematic Reviews were searched for “venous leg ulcers” and “treatment”; wound groups guidelines and relevant bibliographies were reviewed.

RESEARCH QUESTIONS AND ANSWERS

Several interventions have been used in the approach to venous leg ulcers. Figure 50-1 shows an evidence-based algorithm of treatment to this condition. In this chapter, we will describe each one of these interventions as well as other alternatives that have been used, even in the absence of evidence.

COMPRESSION

The primary cause of venous ulceration is venous hypertension. Venous hypertension is defined as the increased hydrostatic pressure in the venous circulation that is caused by a diseased venous system or failure of the calf muscle pump. While in normal persons, ambulation and resultant return of venous blood reduces pressure in the venous system, in venous hypertension, pressure of the deep system may fall either minimally or not at all during ambulation. This increased pressure may be then transmitted to the superficial system. The term sustained ambulatory venous hypertension more accurately describes the condition known as venous hypertension.¹ Venous hypertension is associated with venous ulceration. Compression is meant to reverse the effects of increased hydrostatic pressure in the leg veins. Compression works, in part, by relieving the edema caused by local hydrostatic pressure. Additionally it is thought that compression also has an effect in lymph propulsion and enhances fibrinolysis. Compression helps venous return, even in patients with incompetent valves by approximating the valve leaflets.¹ The external pressure

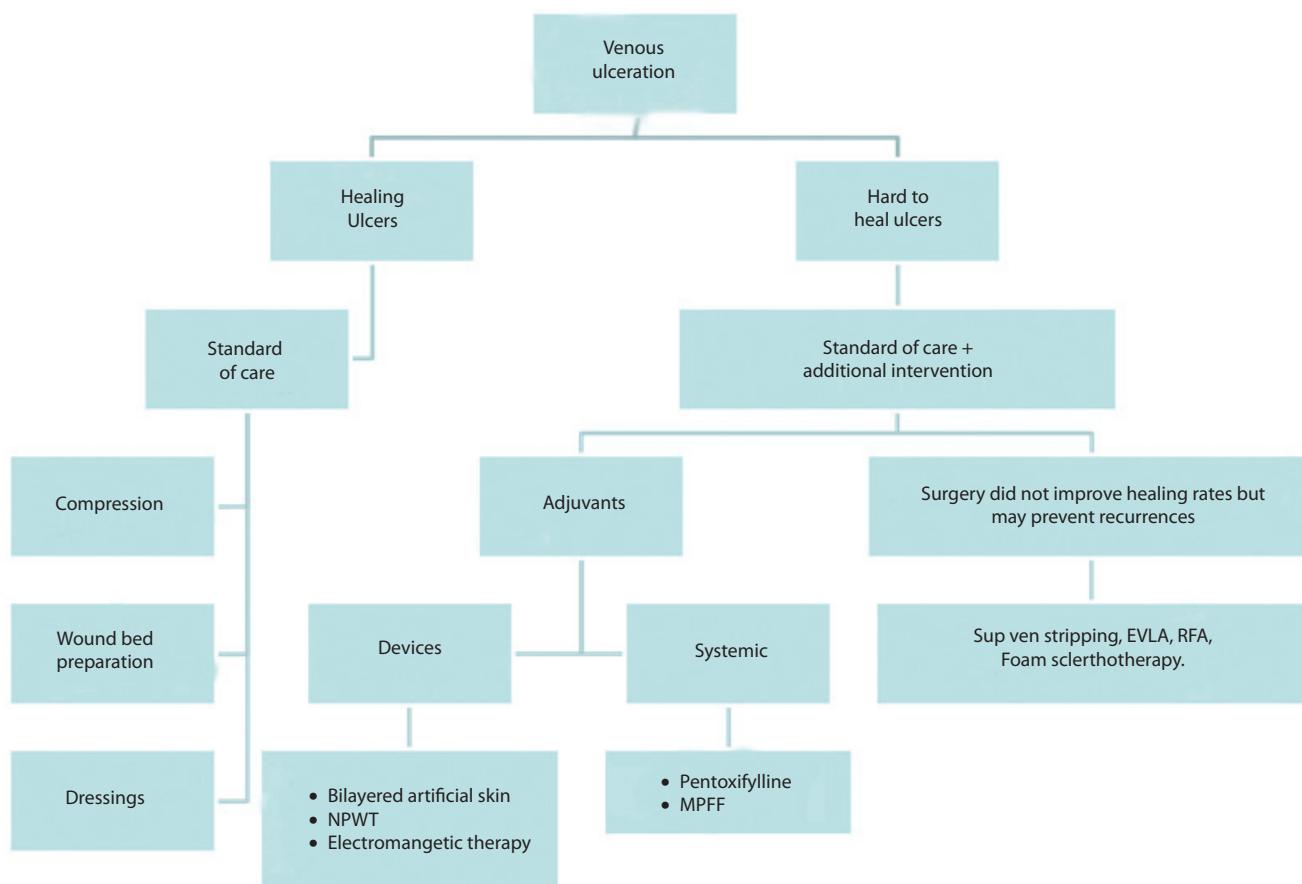

applied is not well defined but is generally agreed that 30 to 45 mm Hg at the ankle would overcome hydrostatic pressure and prevent capillary exudation.²² There are several modalities to achieve this goal, they are similar in effectiveness but can differ significantly in comfort and cost.²³ Two phases of compression exist in the treatment of venous leg ulcers, the first is edema management and the second is maintenance compression.¹

Three broad groups of compression alternatives exist: elastic compression, inelastic compression, and intermittent or pneumatic compression. Elastic compression provides working and resting pressure caused by elasticity of the stretch bandages; this kind of compression can be used in the initial and ongoing treatment of venous ulceration.^{1,22} The ankle-brachial index or ABI is the ratio of the systolic blood pressure in the ankle over that in the arm (brachial) and is used to assess peripheral arterial disease. In the supine patient, the normal value is 1 and is reduced in patients with arterial disease of the lower limb. The more severe the arterial disease is, the lower the ABI. As mentioned it is critical to adequately assess arterial flow before applying elastic compression, as excessive compression can be harmful in a poorly perfused limb. The cut-off point for application of elastic compression, used in many studies is an ABI of 0.8.²³ In some cases with minimal arterial disease, inelastic compression can be used. Prototype for inelastic compression is the Unna boot. Inelastic compression provides high working pressures but does not provide compression in a resting limb, so its effectiveness depends on the patient ambulation but it is safer because of this. This modality of compression is helpful during the edema management phase and is an alternative in patients with peripheral arterial disease. Intermittent or pneumatic compression can be used with or without compression dressings and can provide another option in patients that are not candidates for another compression modality.²³

Once the ulcer is healed, maintenance compression with stockings is necessary in the long term to prevent venous ulcer formation.²⁴ There are four classes of compression stockings based on the compression exerted at the ankle. Compression class I stockings exert an ankle pressure of 20 to 30 mm Hg and are indicated for varicose veins, mild edema, or leg fatigue. Compression class II stockings are 30 to 40 mm Hg and are indicated for moderate leg edema, severe varicosities, and moderate venous insufficiency. Compression classes III (40-50 mm Hg) and IV (≥ 60 mm Hg) are indicated for severe edema or elephantiasis and severe venous insufficiency with secondary post-thrombotic edema.¹

What is the evidence for Compression when treating and preventing venous leg ulcers?

The evidence from a systematic review by the Cochrane collaboration suggests that venous ulcers heal more rapidly with compression than without compression and that

NPWT: Negative pressure wound therapy. MPFF: Micronized purified flavonoid fraction, Sup ven stripping, Superficial venous stripping/ EVLA: Endovenous laser ablation, RFA: Radio frequency ablation.

FIGURE 50-1 Venous leg ulcers: Evidence based algorithm of treatment.

multi-component systems achieve better healing outcomes than single-component compression.²³ When competing systems comprising two components were compared, there was some evidence suggesting that those including an elastic component may be more effective. The data suggest that costs associated with compression treatment are lower than those for strategies not involving compression.²³

Recently a multicenter study in Germany compared short stretch bandages with U-stockings in 121 patients. U-stockings are a type of compression that has two overlapping stockings with graduated compression, and when applied are additive in compression applied. In this study, complete healing within 12 weeks was found in 47.5% patients using the U-stockings compared to 31.7% using short stretch compression group ($p=0.0129$).²⁵

A group called VenUS studied 387 patients using two different compression modalities for 12 months. One group received a four-layer bandage and the other group a short-stretch bandage. They found that ulcers in the short-stretch bandage group healed in a mean of 126 days and those in the four-layer bandage healed in 92 days. Additionally, a difference of 34 days in the median time to healing between

groups was observed. Wounds healed in 76.5% of patients using the short-stretch bandage compared to 80.5% using four layer bandages, but the difference was not statistically significant.^{26,27}

Recently published Guidelines state that pneumatic compression devices appear to have improved outcomes and should be considered in combination with compression in nonresponding ulcers.²¹

Evidence-based guidelines present evidence that patients with signs of increased ambulatory venous pressure and/or postphlebitic syndrome should use compression stockings regularly and forever.²⁴

WOUND BED PREPARATION

Wound bed preparation is defined as the management of the wound to accelerate endogenous healing or to facilitate the effectiveness of other therapeutic measures.²¹ The rationale for debridement is focused on removing nonviable tissue, decreasing bacterial burden, and stimulating epithelialization.²⁸ Debridement is envisioned to remove nonviable tissue (necrotic, pus, slough, callus), thereby promoting

granulation tissue formation. The result is anticipated to be an epithelializing edge and the removal of infected and possibly fibrotic tissue. Initial debridement tends to be a more extensive removal of nonviable tissue. Debridement to improve the wound bed even when the wound bed may appear clinically adequate has been suggested to control the bacterial bioburden, and stimulate healing and it has been mentioned as maintenance debridement.²⁹

Several methods of debridement exist. Autolytic debridement is achieved using occlusive or semiocclusive dressings (material and properties are selected according to a particular patient or wound characteristics). This method uses the patients own wound tissue fluid, which contains proteolytic and other enzymes for debriding the wound base. It is relatively painless and is specific for nonviable tissue.

Chemical debridement uses agents with enzymatic properties to remove necrotic tissue and the formation of healthy granulation tissue. In the United States, agents currently available include collagenase, papain, and trypsin.

Mechanical debridement includes wet-to-dry dressings, hydrotherapy, irrigation, sharp debridement, with the latter most commonly employed and thought to be most advantageous. When performing sharp debridement, certain considerations regarding anesthesia, analgesia, and bleeding should be taken in account.²⁸

What is the evidence for wound bed preparation when treating venous leg ulcers?

Limited data exists to support debridement for venous ulcers. The importance of debridement stems primarily from treatment of diabetic foot ulcer, where debridement initially was supported from secondary analysis of a randomized, double blind, placebo-controlled, multicenter trial of the safety and efficacy of topically applied Rh PDGF, in the treatment of chronic diabetic ulcers. In this analysis, it was found that centers performing the most frequent debridement had the highest wound closure rates in both the treatment group and placebo treatment groups. Similarly, the centers that performed the least frequent débridements had the lowest healing rates.²⁹

Despite limited data, expert opinion supports debridement and it has been included in various venous ulcer guidelines. These guidelines state that sharp debridement is often the most advantageous. However, the chosen method depends on the status of the wound, the capability of the health provider, the overall condition of the patient and professional licensing restrictions.²¹

DRESSINGS

Once the wound has been prepared and before the leg is compressed, it is necessary to assure a proper wound

environment for the ulcer to heal. The ideal situation would be to keep a moist wound base, rid the wound of excessive proteases, inflammatory cytokines, and harmful bacteria.

Two papers published in the 1960s provided evidence for the concept that wounds had faster re-epithelialization when exposed to a moist local environment, as opposed to being allowed to desiccate when uncovered.²² However, on the other hand, studies have showed that fluid from chronic wounds may be detrimental to cellular proliferation because of its altered levels of proinflammatory cytokines, including interleukin-1 and 6, and tumor necrosis factor alpha.³⁰

In order to keep a balanced wound environment, there are many options for wound dressings. Table 50-1 summarizes the available dressings.

What is the evidence for dressings in the treatment of venous leg ulcers?

A recent systematic review included 42 randomized-controlled studies that compared the effectiveness of hydrocolloids, foams, alginates, hydrogel dressings and a group of miscellaneous dressings. No evidence was found that any one dressing type was better than others with regard to complete healing were. The most common dressing studied was a hydrocolloid dressing. Current evidence did not find that hydrocolloids are more effective than simple low adherent dressings used beneath compression with regard to healing. Due to limited data, other comparisons were found to have insufficient evidence.³¹

A randomized, open, controlled, multicenter, multinational trial in venous leg ulcers compared cadexomer iodine paste, hydrocolloid dressing, and paraffin gauze

TABLE 50-1—Dressings for the Treatment of Venous Leg Ulcers

Moisture control	Bacteria control	Proteases control
<u>Severe exudate</u> <u>Alginates</u> <u>Foams</u>	Cadexomer iodine	Homogenous mixture of 55% bovine collagen and 45% oxidized regenerated cellulose
<u>Moderate exudate</u> <u>Collagens</u> <u>Foams</u>	Silver dressings	Sulfonated polymer dressing with the ability to bind and inactivate proteases
<u>Minimal exudate</u> Hydrocolloids Transparent films	Methylene Blue and Gentian Violet	
Poor moisturized wound Hydrogels	Polyhexamethyl biguanide and chlorhexidine gluconate	

dressing and short-stretch compression bandages throughout the study. A total of 153 patients entered the study and were treated for 12 weeks or until cessation of exudation. The study found the healing rate was significantly higher for cadexomer iodine than for paraffin gauze and that was more cost effective than hydrocolloid dressing or paraffin gauze.³²

Another open, multicenter, block-randomized and controlled study included fifteen centers in seven countries, studied performance of silver foam dressings plus compression versus foam dressings for 4 weeks (a surrogate endpoint), plus compression. This study found the silver-releasing dressing to reduce the wound area significantly faster than the traditional dressing, as well as decreasing odor, leakage, and maceration, suggesting good exudate management capabilities of the silver-releasing dressing.³³

Current recommendations conclude that when choosing the adequate dressing, the cost-effectiveness should be considered while managing the local exudate but keeping a moist environment, preventing maceration, and taking in account the particular susceptibility to contact dermatitis in venous leg ulcer patients.²¹

SURGERY

Despite compression therapy, a group of patients exists whose ulcers are refractory to treatment. To address nonhealing wounds, surgical approaches have been used to treat the ulcer and the surrounding tissue with excision and grafting, as well as techniques that address the diseased venous system.

Venous Surgery

The surgical approaches that exist for venous insufficiency have been developed depending on the anatomic location of the condition. Different surgical procedures exist for the superficial system (saphenous), perforators and deep venous system. Table 50-2 summarizes the surgical approaches used in venous insufficiency.

Radical excision and free flap

This technique consists of the radical excision of the ulcer bed, the fibrotic suprafascial tissues, and the diseased superficial and perforating veins. This is often accompanied with coverage of the large soft tissue defect with a free flap.¹

No randomized-controlled trials for these procedures exist but Kumins et al. reported their experience treating 22 patients. They performed 25 free tissue transfers (23 muscles and 2 omentum) in 22 patients. Free tissue transfer was successful in 24 (96%) of 25 flaps and the last case healed after a second flap was performed.³⁴

Kawamura et al. evaluated retrospectively eleven patients who underwent free and pedicled flap transfer

TABLE 50-2—Venous Insufficiency Surgical Approaches

Superficial System (Saphenous) Reflux Treated with Superficial Venous Surgery

1. Saphenous vein stripping

3. Radiofrequency ablation (RFA)
4. Ultrasound guided Foam sclerotherapy (UGFS)
5. Transilluminated powered phlebotomy

Backflow of the Deep System to the Superficial System Treated with Perforator Surgery

1. Subfascial endoscopic perforator surgery (SEPS)
2. Linton and Cockett procedure

Deep-Vein Incompetence Treated with Valvuloplasty

1. Percutaneous vein valve bioprosthesis

for treatment of intractable venous ulcers. No ulcer recurrences were noted in the territory of the transferred flap after a mean of 11 years during follow-up. However, four patients developed new ulcers in the same leg after the flap transfer at 18, 24, 52, and 81 months, respectively. It was proposed that these patients were recurrent because of incomplete excision of surrounding lipodermatosclerotic tissue.³⁵

Skin grafting

Skin grafts have been used to treat venous ulcers. These grafts can be derived from a variety of sources including from the patient's own intact skin (autograft), from a donor-cultured cells as bioengineered skin (allograft) and also from an animal donor (xenograft). Bioengineered skin is considered a device and will be reviewed later in this chapter.

Autograft techniques can be divided into split thickness skin graft (STSG), and full-thickness grafts. STSG consist of skin with epidermis and part of the dermis.

Kirsner et al. reported an analysis of venous leg ulcers treated with meshed STSG. While the majority 'took', 52% of ulcers remained healed after 3 months, 26% were partially healed, and 22% recurred. This study concluded that meshed split-thickness skin grafting is a safe and effective therapy for recalcitrant lower extremity ulcers.³⁶

However, a recent meta-analysis investigated the effect of applying a skin graft in healing a venous ulcer when compared to standard care. It concluded that there is not enough evidence to support the use of skin grafting when treating venous leg ulcers.³⁷

What is the evidence for Surgery to treat venous leg ulcers?

Vein Surgery

The ESCHAR (Effect of Surgery and Compression on Healing and Recurrence) study was a randomized-controlled trial

of venous intervention. The results found that superficial venous surgery does not speed healing but does prevent recurrence when added to compression.³⁸ In the venous surgery group, 12% of ulcers recurred compared to 28% in the compression alone group. The intervention used was superficial venous stripping but did not include ELA, RFA, and foam sclerotherapy.³⁷ The precise role of perforating vein surgery is not well defined at present but is often used in combination with superficial venous surgery, where incompetent calf perforating veins are identified by duplex ultrasound imaging. This procedure is not suitable when the patient has severe deep venous disease with either deep reflux or obstruction.^{21,39}

Regarding surgical valve repair, a meta-analysis found that selected patients can benefit from surgical valve repair, femoral vein transposition, or venous segment transplantation, but the majority of patients with deep valve incompetence with obstruction or residual thrombus are not candidates for these procedures. This treatment achieves moderate and sustained clinical improvement but clinical data is insufficient for general recommendations.⁴⁰

Radical excision and free flap

There is no evidence that supports recommendations for this procedure. Currently there are no definite indications for this intervention and cost and morbidity are a matter of consideration.¹

Adjuvant Therapy

These are additional methods developed to help those ulcers that fail to conventional treatment.

ARTIFICIAL SKIN

One bilayered skin substitutes is FDA approved for the treatment of venous ulcers. The bilayered skin substitute is a skin construct containing an outer live allogeneic human keratinocytes, overlying a layer of live allogeneic fibroblasts placed in type 1 bovine collagen. Both cell types are harvested from neonatal foreskin.²⁸

What is the evidence of Artificial skin grafts when treating venous leg ulcers?

A Cochrane meta-analysis³⁷ found 15 trials that studied separately autografts, allografts, xenografts, bilayered artificial skin, and single layer artificial skin. Two studies that compared bilayered artificial skin versus standard of care were found. Falanga, 1998 treated 154 patients with bilayered artificial skin and 155 patients with a dressing, after 6 months 63% patients from the treatment group had healed compared to 49% of the control group. Brown-Etris, 2000 treated 17 patients with bilayered artificial skin and 19

patients with a dressing, after 6 months 71% of the patients in the treatment group had healed compared to 37% in the control group. Pooling the results of these studies, found a relative risk of healing (RR) of 1.51, suggesting the use of bilayered artificial skin helps healing in venous leg ulcers. This meta-analysis found one study that compared bilayered artificial skin with an autograft, it involved 12 ulcers and no difference was found between the groups.

There was not enough evidence from the other trials analyzed by Cochrane to determine whether other types of skin grafting increased the healing of venous ulcers. Further research is needed to assess whether other forms of skin grafts increase ulcer healing.³⁷

Cultured epithelial autografts or allografts in randomized-controlled trial have not been demonstrated to improve healing of venous ulcers.²¹

Vacuum-assisted closure (VAC) or negative pressure wound therapy (NPWT) or yopical negative pressure (TNP)

This therapy consists of an adhesive sealed dressing on the wound that is connected to a vacuum machine; it creates continuous or intermittent negative pressure about -50 mm Hg to -125 mm Hg.⁴¹ The postulated mechanisms of action are to remove excessive exudate, to enhance the capillary flow and vascular perfusion, to remove slough, to reduce the bacterial burden and to create mechanical stress that physically and biologically alter cells, to stimulate angiogenesis and tissue growth.⁴²

What is the evidence of vacuum-assisted closure when treating venous leg ulcers?

Current guidelines point that experience in venous ulcer regarding NPWT is limited but it may be useful prior to a skin graft or flap for granulation tissue development, or postoperatively by preventing shearing and removing exudates.^{21,41}

ELECTROMAGNETIC THERAPY

Electromagnetic therapy applies pulsed short wave electrical current to the wounded tissue using different voltages. It is hypothesized that electrical stimulation influences the migratory, proliferative and synthetic functions of fibroblasts, and also results in increased expression of growth factors. A moist wound environment is essential to maintain the flow of an endogenous or applied current.⁴³

What is the evidence of electromagnetic therapy when treating venous leg ulcers?

A recent Cochrane meta-analysis reviewed three studies on this topic. Ieran in 1990 treated 22 patients with

electromagnetic therapy and 22 with sham therapy. Follow-up was lost in three and four patients of each group respectively. After 90 days, a 67% healing rate in the treatment group and 32% healing in the control group was found. These results may be biased because the ulcer size in the control group was larger than the treatment group. Kenkre 1996 treated 10 patients with electromagnetic therapy and nine with sham therapy, after 50 days 20% of ulcers healed in the treatment group and 22% of ulcers healed in the control group. Stiller in 1992 compared electromagnetic therapy with topical therapy and found at eight weeks that 47% of ulcers in the treatment group reduced its size and 49% of ulcers in the control group increased its size. These studies were underpowered and methodologically weak, their results were not pooled because of differences in each other's design. Electromagnetic therapy requires further evaluation in larger, well-designed studies. Future trials will require a well-designed protocol to achieve reliable results.⁴³

Current guidelines state that electromagnetic therapy may be useful in reducing the size of venous leg ulcers. Data regarding whether the electrical stimulus should be high voltage, low voltage, or pulsed and whether AC or DC current is superior is not available.²¹

LASER THERAPY

For wound healing, gas lasers such as Helium Neon (HeNe) and Gallium Arsenide (GaAs) are used for biostimulation. The proposed mechanism of action is increased protein synthesis and the proliferation of cells such as fibroblasts and macrophages associated with wound healing.⁴⁴

What is the evidence of laser therapy when treating venous leg ulcers?

A meta-analysis included four studies and did not demonstrate a statistically significant improvement in venous leg ulcer healing with the use of low-level laser therapy. The only suggestion of therapeutic benefit is shown in one small RCT where a combination of laser and infrared light, led to an improvement in the healing rates of venous ulcers.⁴⁴

ULTRASOUND THERAPY

This therapy delivers ultrasonic energy to the wound bed, producing a thermal effect that has been hypothesized as capable of increasing blood flow, and might produce in the physical attributes of collagen-rich structures; a vibration effect may also lead to alteration of cellular or tissue structures.⁴⁵ However, the most important effects of ultrasound treatment is cavitation, which is the occurrence of oscillating "bubbles" which lead to alteration or disruption of cell membranes and other, noncellular structures and has a debriding effect.⁴⁶

What is the evidence of ultrasound therapy when treating venous leg ulcers?

There is insufficient evidence in this review to support the routine use of therapeutic ultrasound in practice. The available evidence suggests that there may be a benefit from ultrasound therapy in healing venous leg ulcers, however because of quality issues of the studies included results should be interpreted with caution.⁴⁵

HYPERBARIC OXYGEN THERAPY (HBOT)

The rationale for hyperbaric oxygen therapy is that, despite the wide range of causative pathologies, the common denominator in many wounds is tissue hypoxia. Some elements of tissue repair are extremely oxygen dependent, for example collagen elaboration and deposition by fibroblasts and bacterial killing by macrophages. Certainly, wounds that lie in hypoxic tissue beds are those that most often display poor or absent healing.⁴⁷

What is the evidence of hyperbaric oxygen therapy when treating venous leg ulcers?

Hyperbaric oxygen therapy is currently used as an adjuvant therapy in many types of chronic wounds, a meta-analysis found one trial made in venous ulcers finding wound size reduction and healing rate improvement in the treated group and suggesting a benefit of HBOT, however, no conclusive data is available yet to recommend this approach when treating venous leg ulcers.⁴⁷

SYSTEMIC AND TOPICAL ADJUVANTS

Pentoxifylline

Pentoxifylline, a xanthine derivative, improves blood flow properties by decreasing blood viscosity, has hemorheologic properties, increases red blood cell membrane flexibility, increases leukocyte deformability and inhibits neutrophil adhesion and activation. It also inhibits tumor necrosis factor-alpha synthesis and improves tissue oxygenation. Relatively safe and well tolerated, its adverse effects are mainly gastrointestinal disturbances.⁴⁸

It is approved for intermittent claudication and several studies support its use in other areas including venous leg ulcer management.

What is the evidence for the use of pentoxifylline in venous leg ulcer treatment?

In a recent meta-analysis of twelve trials involving 864 participants with venous leg ulcers, it was found that pentoxifylline is effective in promoting leg ulcer healing

when used in combination with compression treatment. It was also found in a subgroup of hard to heal ulcers, that pentoxifylline may be effective in VLU healing without compression, which may result in an alternative tool in patients that are unable to use compression. The data also suggests a cost savings.⁴⁹

The optimal dose of pentoxifylline may be higher than used for claudication. A prospective, randomized, double-blind, multicenter, placebo-controlled study randomized 131 patients all with compression therapy to pentoxifylline 400 mg, pentoxifylline 800 mg, or placebo tablets three times a day. The median time to healing was faster with pentoxifylline in a dose-dependent fashion. Venous ulcer healing was found to be 100 days for placebo, 83 days for pentoxifylline 400 mg TID, and 71 days for pentoxifylline 800 mg TID, suggesting not only that pentoxifylline accelerates healing of leg ulcers but also that a higher dose is more effective than lower dose.⁵⁰

MICRONIZED PURIFIED FLAVONOID FRACTION

Micronized purified flavonoid fraction (MPFF) is an orally delivered compound, consisting of 90% diosmin and 10% flavonoids (hesperidin). MPFF has an effect on venous, lymphatic, and capillary circulation. MPFF decreases the interaction between leucocytes and endothelial cells by inhibiting expression of endothelial intercellular adhesion molecule 1 (ICAM-1), and vascular cell adhesion molecule (VCAM), as well as the surface expression of some leucocyte adhesion molecules, MPFF presumably acts through an anti-inflammatory mechanism. There are few known side-effects, and interactions with other drugs have not been reported, it is currently indicated for venous and hemorrhoidal disease.^{51,52}

What is the evidence for MPFF in the treatment of venous leg ulcers?

Data from small studies support MPFF use in VLU treatment. A meta-analysis was published that studied the use of micronized purified flavonoid fraction (MPFF) combined with compression treatment.⁵¹ The mean healing time was 16 weeks in patients treated with MPFF plus compression compared to 21 weeks in patients with compression alone. Combined data showed an average duration of the ulcer was 13.5 years and the average size was 10.4cm.^{2,51} In the absence of studies that compare MPFF effect in smaller and shorter duration ulcers, it is thought that MPFF be considered an adjuvant in long-standing and larger ulcers.

ASPIRIN

Aspirin is widely used as an anticoagulant because of its antiplatelet aggregation properties. As an eicosanoid, it also

has an anti-inflammatory effect. Whether ulcer healing was promoted by inhibiting platelet aggregation or by reducing inflammation has yet to be determined.¹

What is the evidence for the use of aspirin in the treatment of venous leg ulcers?

A randomized-controlled trial in 20 patients using compression, comparing daily oral enteric-coated aspirin 300 mg with placebo in 20 patients, found that after 4 months of treatment, 38% of the patients receiving aspirin compared to 0% of those receiving placebo had healed. Additionally, 52% of the aspirin-treated group showed significant reduction in ulcer size compared with 26% of placebo recipients ($p < 0.007$).^{8,52}

However, current guidelines suggest that results of a small single study is not enough evidence to make a recommendation.²¹

What is the evidence for the use of stanozolol in treating venous leg ulcers?

Stanozolol is an androgenic synthetic androgen with testosterone properties that is used in the treatment of hereditary angioedema and muscle building. Possessing fibrinolytic properties, for venous leg ulcers, it is thought stanozolol may be able to break down pericapillary fibrin cuffs because of these fibrinolytic properties, it has been effective in chronic and acute lipodermatosclerosis but no studies have demonstrated an increase in the rate of healing of ulcers within affected skin.¹

What is the evidence for phlebotonics in venous leg ulcer treatment?

There are several members in this drug group such as rutosides, hidrosmine, and diosmine, calcium dobesilate, centella asiatica, French maritime pine bark extract, aminafitone, grape seed extract, and horse chestnut seed extract. There is a suggestion of phlebotonics improving edema, although this is of uncertain clinical relevance.^{51,53}

A wide review of the efficacy of phlebotropic drugs have been published in a Cochrane Review. Evidence exists to show a reduction of edema in chronic venous disease; however, no superiority was demonstrated over compression in treatment of venous ulcers or in preventing venous ulcer recurrence. These findings may suggest edema reduction alone is insufficient to treat leg ulceration. This study analyzed different phlebotonic drugs without finding significant difference between each other. Further well-designed studies comparing different types of phlebotonics with compression in the setting of venous ulceration may give stronger evidence for its use.^{39,53}

What is the evidence for antitumor necrosis factor- α agents when treating venous leg ulcers?

As pentoxifylline has been shown to help heal venous ulcers even with a slight effect on tumor necrosis factor- α it has been suggested that other agents with tumor necrosis factor- α inhibition properties may have benefit in treatment of venous ulcers. Additionally, chronic wound fluid has been studied and local alterations in levels of proinflammatory cytokines and tumor necrosis factor alpha (TNFa) levels have been found compared to normal skin and acute wounds. Chronic wound fluid adversely affects young, rapidly proliferating fibroblasts such and that, which induces fibroblast senescence. Weinstein proposed that the mechanism of action of anti-TNF α agents is not only to blocks TNFa but to reduce the number of monocytes/macrophages thus, reducing TNFa levels and regulating key inflammatory cells.⁵⁴ Currently there are laboratory and pilot studies whose results suggest its potential use.^{16,55}

What is the evidence for isosorbide dinitrate in the treatment of venous leg ulcers?

Isosorbide dinitrate (ISDN) causes vasodilation in arterial and venous capillaries through nitric oxide (NO). A spray that contained ISDN was studied in a randomized double-blinded placebo controlled trial. Forty-five patients were treated with ISDN (2.5 mg) or placebo for 12 weeks daily plus continuous elastic support and leg elevation. Biopsies at the beginning of the study and 1 month later were taken. Fifteen patients received the drug and 30 patients received placebo. Patients who received ISDN treatment showed an improvement of 71.29% wound size reduction at 3 months compared to 54.35% of the patients treated with placebo ($P=.05$). The histopathologic improvements showed an increment in the number of hyperplastic capillaries from 1.2 to 1.6 in the ISDN-treated group and 0.8 to 1.0. However, hypertrophic capillaries in the ISDN-treated group were less (0.6- 0.8) than in the control group (1.0-1.6).⁵⁶

What is the evidence for honey in the treatment of venous leg ulcers?

Honey has been used for centuries in wound healing and there is literature that avails its properties: antibacterial, stimulation of cell growth cytokine release, etc, that may ultimately aid in healing.⁵⁷

Jull et al. in an open-label randomized trial randomized 368 patients to usual care or to calcium alginate dressings, impregnated with manuka honey (all participants were on compression), and were followed for 12 weeks.

One hundred and four ulcers (55.6%) healed in the treatment group and ninety ulcers (49.7%) healed in the control group. This difference was not significant and surprisingly increased frequency of infection was seen in the treatment group compared to the placebo group.⁵⁸

What is the evidence for using *calendula officinalis* when treating venous leg ulcers?

Calendula officinalis is a plant that is native to southern Europe. Calendula flowers are used in medicine either in infusions, tinctures, liquid extracts, creams or ointments, or in one of a number of skin and hair products available over-the-counter across the globe.⁵⁹

It has antimicrobial, analgesic, anti-inflammatory, and antioxidant properties and has been used in venous leg ulcers, burns, trophic ulcers, and skin lesions.⁶⁰

Duran et al. conducted a randomized-controlled trial in 34 venous leg ulcer patients receiving 7.5% Calendula ointment or saline dressings for 3 weeks and showed that wound area decreased by 42% in the Calendula group compared to 15% in the control group. The difference between the two groups was statistically significant ($P<0.05$).⁶¹

What is the evidence for pale sulfonated shale oil when treating venous leg ulcers?

A randomized, controlled, observer-blind, multicenter study compared pale sulfonated shale oil (PSSO) and compression versus compression and the PSSO vehicle.⁶² One hundred nineteen patients were of which 62 received PSSO and 57 received the vehicle. After treatment, ulcer size was significantly smaller in the PSSO group compared to the vehicle group $P=.0005$. Cumulative reduction in ulcer area was significantly greater in the PSSO group compared to the vehicle group ($P<.0001$). There was no difference in adverse events compared to the vehicle, neither was there difference in pain. Additionally, the new agent was safe and well tolerated. The proposed mechanism of action of PSSO is anti-inflammatory action and it has also shown antibacterial in vitro.

GROWTH FACTORS

During wound repair there is an orchestrated humoral and cellular response that is altered in chronic wounds. It has been found that growth factors levels are decreased in chronic wound fluid; it justifies studying growth factors as potential therapeutic options. The most promising growth factors that require clinical testing are vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), and granulocyte monocyte colony stimulating factor (GM-CSF). Platelet-derived growth factor (PDGF-BB) has

already been approved by the FDA for diabetic ulcers.^{16,63}

Granulocyte monocyte colony stimulating factor (GM-CSF) has been shown to be increased in the epidermis in wounded skin. It is particularly important during the inflammatory stage of wound healing, increasing the number of neutrophils, and enhancing their function at the wound site. In vitro studies have shown GM-CSF to increase keratinocyte proliferation and thus enhance reepithelialization. It has been suggested that GM-CSF works directly on the keratinocyte but also indirectly by up-regulating IL-6.⁶³

It has been reported that GM-CSF treatment is followed by VEGF transcription in the ulcer bed by different cell populations. This effect is associated with a higher number of proliferating keratinocytes at the wound edge, increased formation of granulation tissue and enhanced neovascularization. This effect is not significantly appreciated in wound fluid of acute wounds in healthy subjects.⁶⁴

What is the evidence for growth factors in the treatment of venous leg ulcers?

A phase I study in venous leg ulcers and periulcer injection of a replication incompetent adenoviral construct, expressing platelet-derived growth factor-beta (PDGF-beta), demonstrated the initial safety, feasibility, and biologic plausibility of using H5.020CMV.PDGF-beta to treat venous leg ulcer disease.⁶⁵

Several case reports and pilot studies have demonstrated that granulocyte-macrophage colony-stimulating factor (GM-CSF) administered locally promotes significant healing of venous ulcers. One clinical study that involved thirty-eight patients with venous ulcers were treated with topical rhu GM-CSF and compression dressing. Complete healing was observed in 47 of the 52 ulcers (90.4%). The average healing time was 19 weeks. No systemic or local side-effects from the therapy were observed. After 40 months, no reulceration of the healed ulcers was observed, but two patients developed new ulcers on the same leg.⁶⁶

Intralesional GM-CSF has been studied as well. A double-blind, randomized, placebo-controlled study which enrolled 60 patients with chronic venous leg ulcers, whom were treated with placebo or with 200 or 400 ug of granulocyte-macrophage colony-stimulating factor by perilesional injections of the drug in 4 weekly treatment episodes. The placebo group had 19% of ulcers healed at week 13, 200 ug of GMCSF had 57% healing and the 400 ug group had 61% healing.⁶⁷

What is the evidence for the use of zinc in the treatment of venous leg ulcers?

Zinc is an essential trace metal that is necessary for some enzymes and hormones to function. It also has anti-inflammatory effects on phagocytic cells. Zinc-deficient

individuals demonstrate slower wound healing and are more prone to infections and are thought that by treating zinc deficiency with 30 to 150 mg per day wound healing would improve.⁶⁸

Current guidelines state that adding zinc to patients without a deficient total body zinc reservoir will not improve healing of chronic wounds such as venous ulcers.²¹

A meta-analysis that involved diabetic foot ulcers and venous ulcers found seventy patients in four studies that compared oral zinc sulphate with placebo in people with venous ulcers and did not find a statistically significant difference between the two groups. These studies did not meet quality criteria for its results to be determinant, larger and well-designed studies will give more information regarding zinc supplementation in venous leg ulcer healing.⁶⁹

ANTIBIOTICS AND ANTISEPTICS

As an opening in the skin barrier, a venous ulcer is a potential entrance door for local and systemic infection, the use of topical and systemic antiseptics and antibiotics may appear to make sense when treating venous leg ulcers, but considerations regarding emerging resistant organisms suggest paying attention when including such an agent in the wound treatment scenario.

Some of the topical preparations that have been used in venous leg ulcers are cadexomer iodine, povidone iodine, peroxide-based preparations, ethacridine lactate, acetic acid, silver preparations and mupirocin.⁷⁰

What is the evidence for antibiotics and antiseptics in the treatment of venous leg ulcers?

Current guidelines state that systemically administered antibiotics do not effectively decrease bacterial levels in granulating wounds; however, topically applied antimicrobials can be effective and should be discontinued after the infection has cleared to minimize any possible cytotoxic effects because of the antimicrobial agent or emergence of bacterial resistance to the agent.²¹

As a result a recent Cochrane meta analysis showed that evidence does not support the use of systemic antibiotics to treat venous leg ulceration but found a statistically significant difference in group comparison in favor of the anti-helminthic levamisole when compared with placebo. This result may have been by chance due to the characteristics of the study. Systemic antibiotic therapy should be used in established cellulitis and or further extended infection. Results of this study support the use of cadexomer iodine as topical preparation.^{21,71}

What We Know

- Venous leg ulcers are the result of sustained ambulatory venous hypertension, which is caused by calf muscle pump failure most commonly caused by venous disease and valvular incompetence.
- The prevalence of venous ulcers increases with age and is higher among women. The estimated lifetime prevalence for leg ulceration in developed countries is 1%.
- Confirmation of the venous disease is desirable and color duplex ultrasound scanning is useful.
- Several compression modalities exist for treating and preventing the recurrence of venous ulceration, selection of a definite modality depends on a particular patient.
- Wound bed preparation is helpful to decrease the bacterial bioburden, remove debris and de vitalized tissue, stimulate healing and set the environment for dressings and adjuvants to work.
- Dressing choice would rely on cost-effectiveness and exudates management as well as patient tolerability. There is evidence of cadexomer iodine to increase healing rate compared to other dressings.
- Superficial venous surgery does not speed healing but prevents recurrence when added to compression.
- The use of bilayered artificial skin helps healing in venous leg ulcers.
- Limited evidence exists for NPWT in venous leg ulcer healing. It may be useful prior to or after a skin graft.
- Electromagnetic therapy may be useful in reducing the size of venous leg ulcers.
- Laser therapy and hyperbaric oxygen therapy do not have enough evidence to recommend their use in the treatment of venous leg ulcers.
- Pentoxyphilline is effective in promoting leg ulcer healing when used in with compression treatment.
- Micronized purified flavonoid fraction is helpful in long-standing and larger ulcers.
- Phlebotonics decrease leg edema but do not improve healing rate in venous leg ulcers.
- Promising therapies such as TNF α inhibitors are currently under investigation.
- Zinc supplements in patients without a deficient total body zinc reservoir will not improve healing of chronic wounds such as venous ulcers.
- The use of systemic antibiotics to treat noninfected venous leg ulceration has no effect in speeding healing.
- Isosorbide dinitrate showed statistically significant reduction compared to placebo in a small group of patients.
- Honey dressings compared with calcium alginate did not show statistical significant results in healing and increased the frequency of infection.
- Calendula officinalis versus saline showed reduction in wound area.
- Pale sulfonated shale oil decreased ulcer size in one study.

Treatment of Hypertrophic and Keloid Scarring

Donna Perry, B.Sc. (Hons), PG.Dip. M.C.S.P., and Ardeshir Bayat, B.Sc. (Hons), M.B.B.S., M.R.C.S. (Eng, Edin), Ph.D.

INTRODUCTION

In the developed world alone, over 100 million people acquire new scars every year and 11 million of these individuals go on to develop keloid scarring as a result.¹⁻⁷ Of the 4 million burn scar victims, 31-91% develops hypertrophy and in general, hypertrophic (HT) scarring occurs in 40% of individuals following surgery.^{1,5,7,8} After either accidental or elective dermal trauma, a complex healing process is initiated with the ultimate aim of wound closure.¹ The accompanying scar formation and continued development is governed by the nature of the inflammatory response initiated and has a tendency to be further exacerbated when the original injury reaches a critical depth of wounding.⁹⁻¹³ Skin scarring is not an aberrant or pathologic process, but normal healing activity being expedited in order to prevent life-threatening infection.^{13,14} Many mammalian embryonic studies have demonstrated that early gestation skin wounds can heal without scarring, but this ability is lost as fetal development progresses.^{14,15} Wound healing may result in a spectrum of scars, differing in quality and quantity between individuals. Indeed, variations in scar quality and consistency have been described within the same individual and even within the same lesion.^{1,16} Several scar types have been described, ranging from a fine line scar to atypical scars such as widespread scars, atrophic scars, HT scars and keloids (Figure 51-1 thru 53-4). Typically, HT scars appear red, raised and inflamed, but they can be defined by the characteristic that they stay within the boundaries of the original lesion and often regress spontaneously^{1,8} (Table 51-1). In contrast, keloid scars are distinguished by their raised irregular-shaped appearance and tough fibrous texture which characteristically spreads past the original margins of the wound and invades the surrounding normal tissue without penetrating below the dermal structure.¹ Keloid lesions are not harmful or life-threatening and typically grow from small nodular lumps at the site of a skin surface injury.¹⁷ They can vary in size from a few millimeters to the size of a small ball, or larger, and severe cases

appear reminiscent of neoplastic disease albeit benign.^{18,19} They do not regress spontaneously, but continue to grow with time and recur following surgical excision. Keloids histologically harbor thick hyalinizing nodular bundles of collagenous tissue which are typically absent in HT scars.²⁰ They are unique to humans and have a higher incidence rate in darkly pigmented skin such as in the African and Asian populations.²¹⁻²³ A strong genetic predisposition for keloid scarring has been suggested because of increased familial clustering, the prevalence in certain races and identical twins.^{24,25} However, keloid disease appears to be heterogeneous as both the dominant and recessive inheritance has been reported.²³ The condition may also be a cutaneous manifestation of an underlying fibroproliferative disorder and keloid-affected individuals, in contrast to HT, can exhibit an incidence of allergic responses.^{26,27} Both keloid and HT scars can occur at any site in the body, however, keloid scars are more prevalent and tend to have an increased severity in sites of increased tension or motion such as the chest and shoulder girdle, which is considered an 'activation' factor. Immune and hormonal changes, often during puberty increase scarring propensity and this can return in pregnancy. The growth pattern of keloid lesions is often lobular in an ear site (frequently post ear-piercing), butterfly shaped on the outer shoulder (after vaccination) or on the midchest (commonly after an acne spot).¹ Both scar types develop with the same prevalence in males and females, they typically present initially between 10-30 years of age and are less likely to occur in early years or later life.²⁸ It has been proposed that this occurs because of a combination of more traumatic events in the young with an increased dermal tension in younger skin.²³ Frequently, scars can remain within the boundary of the original lesion like HT lesions, but grow rapidly in size similar to keloid scarring – these have loosely been coined 'intermediate' scars²⁹ (Figure 51-5). Given the continuum of scar types, a well-defined distinction between these different scars does not exist.^{1,30} This reflects the broad variety of factors, which

FIGURE 51-1 An illustrated example of a flat stretched scar.

FIGURE 51-2 An illustrated example of a depressed scar.

FIGURE 51-3 An illustrated example of a hypertrophic scar.

FIGURE 51-4 An illustrated example of a keloid scar.

TABLE 51-1—Table of the Clinicopathologic Differences between Hypertrophic and Keloid Scars

Hypertrophic	Keloid
● Raised, linear, firm and generalized erythema	● Raised, lobulated, hard, and erythema at the periphery
● Develops soon after (within 3 months) time of dermal injury	● Often develops months (up to 1 year) after trauma/wound closure
● Occur at any anatomical site	● Occur in anatomical site patterns
● Growth remains within the margin or the original dermal injury	● Growth extends outside the margin of the original tissue and invades healthy tissue
● Often regresses spontaneously	● Does not normally regress
● Parallel orientated collagen type III	● Disorganized collagen type I and III
● No known associations with ethnicity, genetics and hormonal imbalance	● Are commonly associated with ethnicity, genetics and hormonal imbalance

operate synergistically during the wound healing process on a genetic, physiologic and biochemical level.^{13,16,28,31}

As scars mature during the remodelling phase they often continue to express a wide variety of characteristics and symptoms which may regress or exacerbate.³² Such symptoms commonly reported with cutaneous scarring are hypertrophy, redness, pruritus, paraesthesia and pain.^{32–35}

Symptomatic provocation is more common in raised scarring and arises regardless of cause, size, or depth of the injury.^{34,36} It has been suggested that abnormalities associated with the small nerve function surrounding raised scars lead to a neuropathy effect with the outcome of pruritus and pain stimulation.³² Additionally, mast cells involved in the healing process contain mediators (including histamine and substance P³⁷). Raised scars have been shown to have higher levels of substance P nerve fiber density, greater substance P quantities and an increased number of mast cells.³³ Substance P is thought also to mediate pain via small unmyelinated C nerve fibers³⁸ and in raised scars may contribute to an exuberant neuroinflammatory response caused by a reduction in its regulatory (endopeptidase) enzyme.³⁹

Hence, scars possess both subjective and objective dimensions, therefore a thorough scar assessment should encompass both.⁴⁰ It is reported that all types of scarring can adversely affect cosmesis, function, psychological state, and growth.¹⁴ Subjectively many well-known tools are currently utilized such as the Manchester Scar Scale (MSS)^{41,42} (Figure 51-6) and additional questionnaires have been recently developed to incorporate the evaluation of ‘quality of life’ for scar sufferers.^{43–45} To the affected individual, unsatisfactory scars can represent a visual history of a traumatic event and serve as a ‘flash-back reminder.’ In addition, if an operation is involved, the

TABLE 51-2—The Structured Scar Management Plan (As Practiced by the Senior Author)

1. Assess the Patient	<ul style="list-style-type: none"> ● History (including history of presenting condition, presence of other raised scars, past family history of keloid scarring, medical history, drug history, allergy) ● Examination (4-S/10-S Guide, Manchester Scar Scale, objective assessment of scar morphology) ● Investigations (consider USS, CT, MRI if indicated) ● Diagnosis (Differential diagnosis, scar type) ● Photograph (Pretreatment)
2. Counsel the Patient	<ul style="list-style-type: none"> ● Expectations ● Time course of Rx ● Compliance: Need for regular and long-term follow-up ● Psychosocial needs- ? referral
3. Appropriate Treatment	<ul style="list-style-type: none"> ● Leave alone (wait and watch! approach if scars are asymptomatic and non-progressive) ● Noninvasive (often first line of Rx but not always!) ● Invasive (choose appropriate option based on level of evidence or nature of scarring/symptoms/progression) <p>*Multi-disciplinary approach: Involve occupational therapy, physiotherapy, pain specialist, clinical psychologist if necessary.</p>
4. Regular Follow-up	<ul style="list-style-type: none"> ● History (Monitor changing symptoms) ● Examination (Monitor changing signs) ● Photograph (At every visit and post-treatment) ● Keep family physician informed of Rx & progress.

person's perception of the success of an operation can be negatively affected.⁴⁶ A focused clinical assessment is a prerequisite for the correct management strategy to be chosen and evaluated in abnormal scarring. A thorough initial structured assessment process (Table 51-2) should include a medical history, gender, ethnicity, age, the scar history (including age of onset, cause, progression and rate, previous home and clinical treatments, and recurrence) allergies, drug history, and psychosocial, family and fibrotic scar history. Following this, the clinical assessment should comprise the '10-S Guide to Clinical Assessment of Abnormal Skin Scars'³⁰ (Table 51-3); symptoms, severity, stigma, site, size, shape, shade, surface, surroundings and substance. Alternatively, the 4-S guide¹ can be used as a quick and brief clinical assessment in a busy clinic (Table 51-4). It is recommended that a standardized color photograph be taken as a reference point, especially for those with growing or recurrent lesions.^{30,47} In general, linear scar redness is considered to persist an average of seven months but often varies depending on existing pathogenic characteristics, time taken to wound closure, original wound depth and scar locality.^{1,9,48} While burn scar hypertrophy specifically has been noted to increase gradually between 2-6 months and most significantly from 6-12 months, then begins to regress and flatten at 18-24 months.^{3,49} The use of a skin substitute in the grafting process may also affect burn scar formation.^{49,50} Studies have reported the general prevalence of hypertrophic scarring in spontaneously healing wounds at 30% in dark-skinned individuals and 15% in the Caucasian population.^{4,5}

TABLE 51-3—The 10-S Guide to Clinical Assessment of Abnormal Skin Scars³⁰

Scar Guide	Range of Clinical Findings
1. Symptoms	Pruritus, pain, altered sensation, dryness
2. Severity	Disfigurement and functional impairment or disability (e.g., joint contracture)
3. Stigma	Psychological (e.g., lack of self esteem, depression), and social problems (e.g. unable to interact socially)
4. Site	High risk anatomic areas (sternum, deltoid) to low risk areas (e.g., legs, feet)
5. Size	Small (<3 cm), medium (3-5 cm), large (5-10 cm), giant (>10 cm)
6. Shape	Regular (geometrical design, e.g. ovoid) to irregular (no obvious geometry, invasive expansion into surrounding skin)
7. Shade	Color (hyperpigmented to hypopigmented scar) and erythema (matt or shiny)
8. Surface	Raised, flat or depressed contour
9. Surroundings	Distinct or indistinct margin
10. Substance	Scar texture and consistency: Soft, firm or hard

High numbers of these patients will receive scar modulation therapy. Numerous treatment modalities have been employed with varying degrees of success, and standardized criteria that define response or failure have not been established in every scar type.⁵¹ Currently

TABLE 51-4—The Quick 4-S Guide to Clinical Assessment of Abnormal Skin Scars¹

1. Site	Anatomic location of scar
2. Symptoms	Pain, itching, dryness etc
3. Severity	Of appearance/functional impairment
4. Stigma	Psychosocial impact on patient

abnormal skin scarring is often subject to an array of scar management modalities. These therapies can be administered in isolation, or, in combination, and are thereby termed as ‘monotherapy’ or ‘polytherapy’ treatment programs. Many raised scars do not respond satisfactorily to current treatments and the working evidence-base behind many treatment mechanisms is limited.⁵² A suitable management plan must always be carefully considered as attempts at some therapies can exacerbate the scarring already present, as keloids frequently recur in 50–80% of cases.^{18,28} The healthcare field is consistently being driven to supply safe and effective interventions, which provide the greatest quality care and value for money. Therefore, evidence-based medicine is key and requires the practitioner to integrate clinical knowledge and judgment with the best available evidence^{53,54}. There have been a number of large critical review papers,^{8,28,51,55–59} which provide recommended guidelines.⁶⁰ However, what constitutes the best evidence also requires the ability to identify, critique, and categorize the available literature by placing it into the ‘hierarchy of evidence’ with a ranked-order.⁵⁴ This ranking has been attempted previously for keloid scarring treatment only,⁶¹ but not incorporated keloid and HT lesions together. Therefore, although both types of scarring are in true-form separate entities, clinically these appear to overlap frequently.^{27,55,60,62} This chapter aims to identify primary clinical studies, which evaluate the management of HT and keloid scar treatments over the last 20 years, and to assign hierarchical levels of evidence to the therapeutic modalities assessed.

METHOD

A broad literature search was conducted to identify relevant clinical studies published in the last 20 years and indexed in the following databases: Medline, Cinahl, Embase, Scopus, Pubmed and Scirus (1990 – 2010). This included the keywords (applied individually and in a variety of combinations): “scar”, “keloid”, “treatment”, “hypertrophic”, “management”, “silicone”, “silicon”, “cryotherapy”, “cryosurgery”, “steroid”, “corticosteroid”, “injection”, “surgery”, “excision”, “laser”, “pulsed light”, “irradiation”, “radiation”, “radiotherapy”, “fluorouracil”, “interferon”, “verapamil”, “imiquimod”, “mitomycin”,

“pressure”, “compression”, “paper tape” and “dressing”. Only English language publications of clinical studies and case reports for the prevention or management of keloid or hypertrophic scar were included. The bibliographies of relevant literature review articles obtained were examined for further significant published evidence, until no additional study papers could be established.

The full-text articles were grouped into principal therapeutic management categories, and then sub-classified into monotherapy and polytherapy groups. Where a single study compared a monotherapy to a polytherapy, the article was listed in both subgroups. Examination of the methodological quality of each study was undertaken in order to assign a level of evidence (LOE) for each clinical trial⁶¹ adapted from the Oxford Centre of Evidence-based Medicine.⁶³

In order to establish the LOE, study methodologies were inspected for their overall study design (including retrospective or prospective analysis), the sample size, the randomization and allocation of concealment technique, the outcome parameters and standardized tools selected, assessor blinding, placebo controls and total duration of the follow-up. The randomized-controlled trial (RCT) is considered the gold standard of the ‘hierarchy of evidence’ by most clinicians.⁶⁴ This encompasses a double-blinded, randomly allocated and placebo or active comparator designed study.⁵⁵ Studies were downgraded if these qualities were absent according to Table 51-5. The overall conclusive findings were also reviewed to determine the statistically significant positive or negative therapeutic outcomes or the documented effectiveness levels (e.g., for comparative studies) in each modality evaluated.

TABLE 51-5—Levels of Evidence

Level	Study Type
LOE-1	Systematic review (SR) of RCTs High quality RCT
LOE-2	Low quality RCT SR of cohort studies Cohort study/non-randomized-controlled trial
LOE-3	SR of case-control studies Case-control study
LOE-4	Case-series Low-quality cohort study/ Non-randomized controlled trial Low-quality case-control study
LOE-5	Case reports Expert opinion without critical appraisal/based on physiology/bench research/first principles'

(Adapted from the Oxford Centre for Evidence-Based Medicine)^{61,63}

RESULTS

A total of 173 primary studies were determined using the search strategy described here. These were divided into 17% RCTs, 1% systematic reviews, 9% case-control studies, 15% comparative studies, 49% case-series, and 9% case reports (Table 51-6). Individual results for each treatment modality are discussed separately and are listed in Tables 51-7 thru 51-19.

SILICONE-BASED THERAPY

Since the early 1980s, silicone gel (SG) has been used widely in the management of HT and keloid scars.^{60,65,66} Silicone products are available in various forms with a range of compositions, durability, and adhesive properties. To date most clinical trials have involved the assessment of pure adherent silicone gel sheeting (SGS).⁶⁰ However, other forms of liquid SG or oil,⁶⁷⁻⁷⁴ silicone cream (SC)^{75,76}, nonadherent silicone gel cushion (SGC)^{77,78} and SG with added vitamin E⁷⁹ have been trialled.

Silicone gel sheeting is a soft, semiocclusive dressing, made from medical grade silicone (dimethylsiloxane cross-linked polymer) reinforced with a silicone membrane backing⁶¹. All forms of SG are topically applied agents, which are noninvasive, easy to use, painless, convenient, and present at a relatively low-cost therapeutic option.^{80,81} While this modality is widely used for the management and prevention of pathogenic scarring, the exact mechanism continues to remain elusive.^{81,82} However, the main postulated occlusive effect of SGS is thought to lead to a reduction in the transepidermal water loss, establishing

homeostasis in the epidermal barrier layer and leading to a possible advanced state of wound repair.^{81,83} SGS or silicone in its various forms is frequently used as a monotherapy in raised scarring, especially in burn hypertrophic lesions. It is also combined frequently with intralesional steroid (ILS) injections,^{72,84-87} cryosurgery (CS),⁷² laser,⁸⁸⁻⁹⁰ pressure therapy,^{85,86,91} and after surgical excision^{84-86,90,92} for problematic keloid lesions. SG products are generally well tolerated by HT and keloid scar patients.^{67,79,93-95} SGS is often required to be worn for 10-24 hours^{77,79,96,97} each day and for several months.^{94,98} Nevertheless, studies frequently report a small percentage of side-effect in treated cases including the presence of a rash, persistent pruritus, skin maceration, or breakdown.⁹⁹⁻¹⁰² These minor problems quickly resolve upon removal of the silicone and may be avoided if patients are correctly instructed on the methods of daily cleaning and reapplication to prevent bacterial irritations.^{96,99,103} Therefore, patient vigilance and compliance is essentially important, along with an enhanced education program from the clinician.^{27,104}

A number of randomized and nonrandomized trials have demonstrated the effectiveness of silicone monotherapy to soften scars, reduce the height, erythema, diminishing symptoms such as pain and pruritus, improve the overall pliability and contracture rate associated with HT,^{67-73,77,79,88,94-99,102,105-109} and keloid^{68,69,72,77,79,88,96,105,110} scars (Table 51-7). Additionally, silicone can be used prophylactically to prevent abnormal scar development.^{67,68,70,94,95,102,109,111,112} Five RCTs (LOE-2)^{94-96,102,113} compared SGS to untreated control scars. In De Oliveria's⁹⁶ study, 41 (HT and keloid) scars in 26 patients were trialled

TABLE 51-7—Monotherapy and Polytherapy Published Clinical Trials: Silicone Treatment Modality

Silicone	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Monotherapy										
O'Brien ¹⁰⁵	2	Systematic review	RCT & controlled trials evaluating the effectiveness of SGs	HT & K	15 trials involving 615 people age 2-81 years were included	Reduction in scar parameters & symptoms	Various SGs & non-SGs (adhesive and nonadhesive) to other therapies or controls	n/a	+weak benefit for SGs as a preventative strategy (NS)	Treatment trials for SGs use in K and HT scarring are of generally poor quality and highly susceptible to bias. Evidence is weak for the benefit of SGs as a preventive strategy for abnormal scarring in high-risk individuals. Overall the poor quality research leaves a great deal of uncertainty.
De Oliveira ⁶⁶	2	RCT	SGS vs placebo sheet vs untreated control	HT & K	26 patients (7 ethnicity or skin type) with 41 HT or K scars, excluded if radiation or steroid therapy in previous 12 months, or lesion <3 months old	Scar size, coloured, induration & symptoms	Sheet: 24 hrs/day	4.5 months (prospective)	+SGS +placebo sheet	Significant reduction in parameters for silicone and control sheet groups compared to the control scars. No significant difference identified between silicone and control sheet groups.
Chan ⁶⁷	2	RCT	SG vs placebo gel	HT	50 patients (Asian ethnicities) with 14 day old standardized sternotomy wounds, excluded if infection or allergy to SG	Scar pigmentation, vascularity, pliability, height & symptoms	Gel: 2 x day application	2.5 months (prospective)	+SG	Significant reduction in all scar parameters for the SG scar areas. SG is effective in the prevention of HT scar development in sternotomy wounds.
Wittenberg ¹¹³	2	RCT	SGS vs PDL vs untreated control	HT	20 patients (Fitzpatrick skin type I-IV) with a linear HT scars ≥ 8cm long, excluded if received scar treatment in previous 2 months,	Scar blood flow, pliability, volume, symptoms & histologic biopsy assessment	SGS: ≥ 12 hrs/day, PDL: 4 treatments at 8 week intervals	10 months (prospective)	- SGS (NS) - PDL (NS)	Overall significant reduction in blood flow, volume and pruritus was recorded during the monitored phase in all scar regions. There was no difference in the improvement in scars sections treated with SGS or PDL compared to control sections.

(Continued)

TABLE 51-7—Monotherapy and Polytherapy Published Clinical Trials: Silicone Treatment Modality (Continued)

Silicone	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Majan ⁹⁴	2	RCT	SGS vs untreated control	HT	11 patients (7 ethnicity or skin type) with postoperative scars, excluded if known allergy to SGS, keloid scarring or underlying serious pathology	Scar pigmentation, height, pliability & vascularity, symptoms & overall scar appearance	SGS: 23 hrs/day	12 months (prospective)	+SGS (NS)	Results suggest the SGS group experienced greater and more rapid improvements compared to the control group.
Momeni ⁹⁷	2	RCT	SGS vs placebo sheet	HT	38 patients (7 ethnicity or skin type) HT burn scars, excluded if wound infection, open wound or sensitivity to SGS	Scar pigmentation, vascularity, pliability & symptoms	Sheet: 12-24 hrs/day	4 months (prospective)	+SGS	All scar parameters were significantly reduced in the SGS group in comparison to the control region after 4 months, except pain. For HT burn scars, SGS is an effective treatment.
Palmieri ⁷⁹	2	RCT	SGS vs SGC with added vitamin E	HT & K	80 patients (7 ethnicity or skin type) with HT and keloid scars, no exclusion criteria stated	Scar symptom, color, size & cosmetic appearance	Sheet: 10 hrs/night	2 months (prospective)	+SGC with vitamin E (NS)	SGC with added vitamin E scored better than simple SGS at both 1 and 2 month periods studied
Berman ⁷⁷	2	RCT	SGC vs SGS	HT & K	32 patients (7 ethnicity or skin type) with HT or K scars \geq 7 months old, no exclusion criteria stated	Scar size, volume, symptoms, color & induration	SGC/SGS: \geq 10 hrs/day	4 months (prospective)	+SGC (NS) +SGS (NS)	SGC and SGS are both effective treatments of K and HT scars, although no statistically significant results exist between the groups.
De Giorgi ⁶⁸	2	RCT	SG vs placebo control	HT & K	110 patients (Fitzpatrick skin type I-IV) with standardized surgical wounds and management, excluded dermatofibromas, sebaceous cysts and inflammatory cutaneous lesions	Scar vascularity, sensory stimulation & symptoms	Gel: 2 times/day	8 months (prospective)	+SG (NS)	SG reduced the formation of K and HT scars, along with improving the signs and symptoms associated with the healing process but not significantly.

Ahn ¹⁰²	2	RCT	SGS vs untreated control	HT	48 patients (7 ethnicity or skin type) with new wounds or HT scars, no exclusion criteria stated	Scar elasticity & volume	SGS: ≥12 hrs/day	6 months (prospective)	+SGS	New wound scars significantly reduce in volume in the SGS group compared to the controls. Established HT scars saw a significant improvement in elasticity over the control group.
Gold ⁹⁵	2	RCT	SGS vs untreated control	HT	96 patients (7 ethnicity or skin type) with low (n=50) and high (n=46) risk history of abnormal scarring, no exclusion criteria stated	Scar symptoms, embarrassment, color, height, texture & function	SGS: ≥12 hrs/day	6 months (prospective)	+SGS	Statistically significant reduced incidence of abnormal scarring in the high-risk patient group using SGS. There was no added benefit from additional silicone therapy in the low-risk group.
Sproat ¹⁰⁶	2	RCT	SGS vs ILS	HT	14 patients (7 ethnicity or skin type) with sternal scars, no exclusion criteria stated	Scar size, height, color & symptoms	SGS: 12 hrs/day, 12 weeks ILS (TA 40 mg/ml); 1 dose	3 months (prospective)	+SGS (NS)	SGS provided improved signs and symptoms more quickly than ILS.
Wigger-Alberti ¹⁰⁷	2	RCT	SGS vs polyurethane dressing	HT	60 patients (7 ethnicity or skin type) with HT scars ≥60 mm long, extensive exclusion criteria including K scarring and other treatments in the last 2 months	Scar overall appearance, color, matte/shiny, contour, distortion & texture	SGS/dressing: 23-24 hrs/day for 3 months to half of scar	3 months (prospective)	+polyurethane dressing > +SGS	Both regimes demonstrated a significant reduction in the clinical HT scar signs over 3 months. However, the polyurethane dressing was significantly better at reducing the clinical signs at 4 and 8-week reviews and was tolerated more than the SGs.
Polytherapy										
Sawada ⁷⁵	2	RCT	SC with light dressing vs SC with occlusive dressing vs placebo with occlusive dressing	HT & K	47 patients (7 ethnicity or skin type) with HT or K scars, excluded if infected or ulcerated scars	Scar redness, elevation, hardness, itching & symptoms	Cream: 1-2 times/day	3-5 months (prospective)	+SC with occlusive dressing > SC with light dressing	Statistically significant improvement in the SC and occlusive dressing group compared to the SC and light dressing group, with an improvement in redness, tenderness, itching and hardness recorded.

TABLE 51-7—Monotherapy and Polytherapy Published Clinical Trials: Silicone Treatment Modality (Continued)

Silicone	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Harte ⁹¹	2	RCT	Pressure therapy & SGS vs pressure therapy	HT	22 Caucasian patients with HT burn scars, excluded other scar types, presence of an infection or skin condition	Scar height, vascularity, pliability & pigmentation	Pressure therapy: pressure garment, SGS: applied under the garment for 23 hrs/day	6 months (prospective)	Pressure therapy & SGS = pressure therapy alone	No significant differences were established at 12 or 24 weeks between the two treatment groups, however both groups showed a general decrease in their group scar scores. Evidence here is inconclusive and a larger scale RCT is required.
Li-Tsang ¹²⁰	2	RCT	SGS & massage vs massage	HT	45 patients (Chinese ethnicity) with post-traumatic HT scars, no exclusion criteria stated	Scar thickness, pigmentation, height, vascularity, pliability & color	SGS: 24 hrs/day Massage: 15 mins/day for 6 months	6 months (prospective)	+SGS & massage > massage	Significant reductions in scar thickness at 2 and 6 months were noted in the SGS and massage group. Symptoms, pliability and pigmentation also improved with SGS and massage therapy.

RCT, randomized controlled trial; NS, not significant, +, positive; –, negative; SG, silicone gel; SGS, silicone gel sheet; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; 2, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; IL, intralesional steroid; IL, intrallesional; Exc, excision; ILExc, intralesional excision; ELExc, extrallesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetone; BM, betamethasone sodium phosphate.

to compare SGS with a nonsilicone occlusive dressing (if the patient had two scars present) and an untreated control (if the patient had 3 scars). The SGS was applied for 24 hours a day and nonvalidated measurements of scar size, induration, color, and patient-reported symptoms were recorded with intracutaneous pressure. There was no significant difference observed between the two treatment groups, but both treatments significantly improved parameters in comparison to the control scars. However, the randomization method was not stated, blinding occurred for only one outcome measure, a limited follow-up was completed, and both scar types were analyzed together. Ahn¹⁰² completed a RCT of 48 patients with new wounds or existing HT scars and utilized adjacent or mirror image scars on the same patient as a control. SGS was worn for a minimum of 12 hours a day and patients were followed up to 6 months. Scar elasticity using an elastometer and volume were the only outcomes monitored. No details of the randomization or blinding were reported and 10 patients were lost to follow-up. Significant improvements in existing HT scar elasticity were reported and new wounds significantly reduced in volume compared to controls.

Another HT scar RCT⁹⁵ focused on subgrouping participants based on the individual history of 96 patients with a high or low risk for abnormal scarring postsurgery. SGS was compared to a control routine postoperative care group. The patient and unblinded clinician observed scar changes using a nonvalidated linear score with scaled photographic analysis. A marginal improvement was observed in the high-risk group and a significant difference was obtained in those patients undergoing scar revision surgery. There was no added benefit from additional silicone therapy in the low-risk group. A small RCT⁹⁴ of 11 patients trialed SGS on 6 postoperative scars for 23 hours a day for a maximum 1 week, while the 5 postoperative controls had no treatment. A randomization sequence was completed and scars were evaluated using the Vancouver Scar Scale (VSS),¹¹⁴ along with rating symptomatic changes. The SGS treatment group experienced larger and more rapid improvements compared to the control group, with only one patient lost at the 12 months review point.

Alternatively, Wittenburg and colleagues¹¹³ compared SGS with PDL and untreated controls in 21 patients with linear scars. They found no difference in scar volume, erythema, or symptoms between treated and untreated regions. The authors' methodology consisted of computer randomization and assessor blinding coupled with a range of quantitative objective measures and 10 month monitoring. Hence, these added components may account for their contradictory results. Seven other RCTs (LOE-2)^{67,68,77,79,97,106,107} evaluated SG products against other treatment modalities or placebo therapies. Chan⁶⁷ administered a semi-liquid SG or a gel control to 100 14-day-old sternal scars in 50 patients. After 3 months, statistically significant improvements in all VSS parameters were recorded by a blinded assessor. A similar comparative

study⁶⁸ in two separate patient groups (i.e., treatment and control), with a follow-up period of 8 months demonstrated a reduced formation of both HT and keloid scars and improved symptom control. Two studies^{97,107} compared SGS to a placebo occlusive sheet. Momeni⁹⁷ completed a randomized and double-blinded trial of 38 HT burn scars divided into two separate halves. After 4 months, all VSS parameters except pain were significantly reduced compared to the placebo control sheet. Alternatively, 60 patients with HT scars received similar randomized treatment for 3 months and objective monitoring using a modified version of the MSS,⁴² quantitative chromometry and a nonstandardized patient questionnaire. The authors¹⁰⁷ found the polyurethane dressing to be significantly more effective than SGS. The variability of results from SGS versus occlusive dressing studies and the evidence against silicone penetration into the scar or stratum corneum^{115,116} pose a questionability of the requirements of silicone as an active component and positive requirement in these constructs.^{92,96} Berman⁷⁷ investigated SGS compared to a nonadherent SGC, a product reported to induce greater negative static-electric charges. However, after 16 weeks no statistically significant differences were determined, hence challenging the adherent occlusion to induce hydration theory. Additionally, when 80 patients were randomized to receive SGS alone or SGC plates coated with vitamin E and taped in place for 10 hours, the SGC with vitamin E proved more effective.⁷⁹ Nonvalidated outcome assessments, the limited follow-up period and lack of randomization detail do conversely weaken the methodology. In another study, Sproat¹⁰⁶ compared 14 patients with HT sternotomy scars receiving SGS for 12 hours a day for 12 weeks or a single dose of ILS. After 3 months, the blinded assessors and patients determined greater benefit to the scars treated with SGS.

Four case-controlled studies determined LOE-3, compared various types of SGS to untreated control scars^{69,99,108,109} and additionally to liquid SG.⁶⁹ Three studies^{69,108,109} involving a combined 92 patients reported statistically significant difference in outcomes treated with SGS. The participants treated with liquid SG, or liquid SG and SGS described a greater improvement than SGS alone.⁶⁹ Alternatively, Niessen⁹⁹ evaluated occlusive SG versus SGS compared to routine treatment in 155 breast reduction patients. One hundred and twenty-nine patients were available at the 1-year point for scar size measurements and objective device measurements of color, depth, and blood flow. No keloid scars were observed. Neither SG nor SGS prevented HT scar formation and in contrast to other studies, the silicone-treated groups fared worse and developed significantly more hypertrophy than the control group. The control group did, however, receive routine paper-taping and the authors suggested the SGS intervention may have been initiated too soon, as treatment started on day 3 postoperatively.

The remaining studies were case-control studies,^{88,110} low-quality non-randomized comparative studies^{70–73,98,117} and case-series^{74,78,111,112,118,119} comprising level 4 evidence. All studies concluded positively in light of the benefits of silicone-based therapy, except in three cases.^{72,110,117} Additionally, a single meta-analysis has been completed for the Cochrane review by O'Brien.¹⁰⁵ This includes 13 controlled studies of 559 patients and found that SGS reduced the incidence of HT scarring in individuals with a high propensity to develop the condition. A significant reduction in scar thickness and color was also determined after SGS therapy, but results were highly susceptible to bias.

Silicone therapy is frequently combined with other adjuvant treatments (see Table 51-7 and its electronic version). Three RCTs (LOE-2)^{75,91,120} exist to compare the efficacy of silicone-based products in combination with other therapeutic modalities. SC with a combined occlusive dressing was statistically more effective than SC with a light dressing, or a placebo cream and occlusive dressing.⁷⁵ Results were recorded using a nonvalidated assessment and no details of the blinding or randomization were documented however. SGS has also been trialled in combination with deep massage for HT scars and proved an effective combination therapy to significantly reduce scar thickness and improve scar color as measured using standardized spectrophotometer and ultrasound devices.¹²⁰ Harte⁹¹ combined SGS with pressure therapy for a small sample study of 22 patients and found no significant difference in outcome compared to pressure therapy alone. Other combination therapy studies were non-randomized comparative trials^{72,88,92} or case-series^{76,84–87,89,90} of level 4 evidence and often involving some form of removal procedure, especially those studies encompassing keloid lesions.

CRYOSURGERY

Cryosurgery (CS) can be used as a monotherapy or in combination with a range of other therapies to treat in particular recurrent or difficult keloid lesions^{27,121,122} (Table 51-8 and its online version). Contact probes,^{121,123–125} sprays^{122,126} and intralesional CS (ILCS)^{127–130} needles can be used to apply the modality direct to the scar tissue. Liquid nitrogen is the most frequently used agent to freeze problematic HT or keloid lesions. Scar flattening is achieved through the process of selected tissue necrosis because of an induced cell and microvascular damage.^{103,125} This has been shown to positively affect collagen fiber architecture.¹²⁸ Interestingly, pathogenic-raised scarring does not occur post ‘frostbite’, therefore it is postulated that the fibroblasts may respond differently to the proinflammatory signals present.²⁷ Repeated CS sessions appear to have a beneficial effect on the outcome of HT and keloid scars and prevent relapses.^{125,130–132} CS is a success in 28–100%^{121,126,131,133} of cases with no reoccurrences reported at up to 6 years in

some studies.^{131,134} Younger patients,¹²⁵ with younger¹²⁸ or smaller¹³³ scars respond better to CS. However, there is a high drop-out rate for treatment because of the pain experienced and time taken for healing.^{103,135} Every 2–6 weeks the scar site should be assessed and the lesion subjected to 20–30 second thaw cycles (2.5 minutes in some cases),¹²¹ repeated 1–12 times in total dependent on overall lesion size.^{72,121,123,125,128,129} During the freezing process and immediately after treatment pain can be experienced. Hypopigmentation is a common side-effect of the treatment along with atrophy.¹³⁴ Rare incidences of auricular cartilage damage have also been reported.¹⁰³

One small double-blinded RCT (LOE-2)¹²³ of 11 patients compares CS to ILS injections and untreated controls in acne keloid scars. Patients received randomized treatment (n=1–3) over an 8-week period by an independent physician with an additional 8 weeks of follow-up. A spot freeze technique was applied, this allows the ice-ball to reach the outer limits of the scar under treatment and includes a margin of normal tissue.¹²³ The same observer evaluated palpability via a nonvalidated method and further clinical examination was completed using standardized length, depth, and blood flowmetry devices. Both treatments significantly improved height and palpability, with vascular lesions responding better to CS especially. CS was significantly more effective than ILS and back scars had a better result than chest lesions. A single non-randomized comparative study conducted by Yospovitch¹²² provided positive level 4 evidence for significant improvements using CS in conjunction with ILS, over CS or ILS alone. A spray freeze technique was employed from a distance of 1 cm continuously for 30 seconds. 10 patients were monitored for 10 months in total (8 months post-treatment) and although clinical evaluation was performed by the same observer, no blinding was described, except photographic ratings. A further 9 level 4 case-series studies, mainly evaluating CS with keloid scarring have demonstrated the positive benefit of this therapeutic modality.^{125–131,134} Four of these studies^{127–130} employed the method of ILCS, utilizing a probe with a sharp tip to penetrate dense HT or keloid scar tissue. One level 5 case report further affirmed the use of CS.¹²⁴ In addition, 4 (LOE-4) polytherapy trials combining CS with ILS,^{121,122,133} and ILS and SG⁷² have also proved positive with statistically significant results achieved in 2 studies.^{72,122}

STEROIDS

Intralesional injections of corticosteroids are considered the standard first line treatment for keloid scars and a secondary treatment for HT scars.^{65,136} Intralesional steroids (ILS) can also be administered as an adjunct therapy to reduce recurrence after various excision techniques.¹⁰³ A range of steroid preparations are available for intralesional injection, including hydrocortisone acetate, methylprednisolone

TABLE 51-8—Monotherapy and Polytherapy Published Clinical Trials: Cryotherapy Treatment Modality

Cryotherapy	Study Design LOE	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Monotherapy</i>									
Layton ¹²³	2	RCT	CS vs ILS vs untreated control	K	11 patients (?ethnicity or skin type) with multiple acne K scars, no exclusion criteria stated	Scar height, depth, blood flow & pliability	CS & ILS (TA 5 mg/mL):?1-3 treatments	4 months (prospective)	+CS >+ILS

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; IL, intrallesional steroid; IL, intralesional; Exc, excision; ELExc, extralesional excision; ELExc, extralesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetone; BM, betamethasone sodium phosphate.

acetate (MP), dexamethasone, betamethasone sodium phosphate (BM) and the most popular triamcinolone acetonide (TA). Injection of corticosteroids leads to the regression of keloid and HT scars by attenuating the inflammatory process, altering collagen gene expression, inhibiting collagen and glycosaminoglycan synthesis.¹³⁷⁻¹³⁹ Steroid-induced suppression of vascular endothelial growth factor may also further prevent fibroblast proliferation, promote fibroblast degeneration, and inhibit growth.^{28,140-142} Ultrastructural changes can also occur in keloid scars post-treatment to enhance collagen bundles and alter characteristic collagen nodules.¹⁴² Overall, the exact mechanism by which ILS aids scar size reduction and prevents reoccurrence is not fully understood. Some scars become resistant to ILS therapy when treated with hydrocortisone, this may be caused by the altered efficacy of some compounds on keloid fibroblasts¹⁴³.

Triamcinolone acetonide can be used at a combination of doses (1-40 mg/mL),¹⁴⁴⁻¹⁴⁸ and may be used in combination with lidocaine to reduce the pain from intralésional injections, especially in tender lesions.^{106,133,149} A needle or Dermo-Jet-injector can be used to administer the drug.^{28,137,146,150} Frequently, a series of injections are required for a satisfactory outcome, and this may occur every 1-4 weeks^{110,122,146} for 1-16 months.^{121,151,152} Response rates are highly variable, figures usually range from 50-100% and reoccurrence rates from 6-50%, but when ILS is combined with some adjuvant therapies such as a surgical excision, 'cure' rates can reach 80%.^{147,153-155} Topical steroid ointments are also available and have demonstrated some success.¹⁵⁶

Not only are steroid injections painful but they are also associated with a variety of side-effects: adverse hypopigmentation, telangiectasia, and skin atrophy was observed in 50-63% of tissue receiving ILS alone.^{65,145} Hypopigmentation often continues for years post ILS and is more highly visible in darker pigmented skin.^{8,57} Early administration of ILS postsurgical excision can also lead to wound dehiscence¹⁰³. Therefore, it has been suggested that sutures should remain in situ for an increased time if this adjuvant therapy is planned.^{85,157,158}

Seven RCTs (LOE-2, Table 51-9 and its electronic version)^{106,123,144-147,150} compare the use of ILS alone with various other treatments. Berman¹⁴⁴ conducted a study involving 20 patients comparing ILS with tumor necrosis factor (TNF)-a in keloid scars over a year old and ≤2cm in length. Equal study groups (n=10) received 20 mg/mL TA or 25 mg/mL etanercept intralesionally at baseline and 4 weeks later after an undisclosed randomization process. A visual analogue scale (VAS) was used by the clinician and patient to rate tolerability (erythema, pain and tenderness) and efficacy (cosmesis, pigmentation, satisfaction and pruritus). Induration, volume, and scar size were also assessed using various devices. Although the author-reported scar evaluations were blinded, it is unclear how this was achieved exactly, because assessments were completed by the study investigator. No statistically

significant differences were calculated from baseline levels over the short study period of 2 months for either treatment group or between treatment groups. TA did however, improve 11/12 parameters in comparison to etanercept which only proved effective on 5/12.

Another RCT¹⁴⁶ examined the potential benefit of combining ILS with 5-fluorouracil (5-FU) via a double-blinded parallel group trial. Over a 3 month period, 40 patients received weekly injections TA (40 mg/mL) or TA and 5-FU (50 mg/mL) for a total of eight treatments. Overall, seven drop-outs were reported between the groups (n=4 in ILS, n=3 in ILS and 5-FU). After 12 weeks, significant parameter improvements were seen in the ILS and 5-FU treatment arm compared to ILS alone. Patients reported a statistically significant overall scar improvement after combined therapy, whereas the trained observer response was not significantly beneficial. A computer-generated randomization and an external assessor were incorporated into the study design; however, a nonvalidated linear 5-point scale was used to measure erythema, induration, pruritus, and overall improvement.

These results echo a similar study¹⁵⁰ by the same group, which observed that ILS and 5-FU administered weekly for 2 months was statistically more effective than ILS alone. Nevertheless, the TA dose used was 25% lower in this study (TA, 10 mg/mL) and only a single-blinded design was presented. When an additional study arm here incorporated pulsed-dye laser (PDL) with ILS and 5-FU, additional significant improvements in itch and erythema were recorded, which yielded both patient and external observer statistical benefits. Other authors¹⁴⁵ determined that the addition of 5-FU does not increase the efficacy of ILS (TA 20 mg/mL) as a treatment in keloid or HT scar patients. This study divided long sternotomy scars into five sections with all 4-study treatment arms (PDL, ILS, 5-FU, ILS and 5-FU) randomized to different tissue sites along the length of the lesion. A 1 cm untreated barrier was marked-out between regions and one control site separated for further comparison. Treatment patterns (i.e., intervals and number of treatments) varied widely between the intralésional therapy groups. Outcome measures were largely standardized, validated, and parameter-specific quantitative instruments, with no assessor blinding described. Overall, all treated segments improved statistically, but no significant difference was determined between the groups. However, intralésional therapies resulted in a faster resolution than PDL. Although a small study (n=10), all patients received treatment into the same scar and it is assumed all were followed-up to the 8 months point as no drop-outs are recorded.

One RCT¹⁴⁷ compared 100 scars (n=58 keloid and n=42 HT) in 65 patients receiving ILS alone, β-radiation (RXT) alone, excision with β-RXT against excision with pre- and postoperative β-RXT. Patients were regularly followed-up for nearly 10 years. The ILS was administered according to the lesion surface area (1-2 cm², 20-40 mg; 20-6 cm², 40-80 mg;

TABLE 51-9—Monotherapy and Polytherapy Steroid Treatment Modality Published Clinical Trials

Steroids	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Monotherapy										
Berman ¹⁴⁴	2	RCT	ILS vs TNF- α	K	20 patients (2ethnicity or skin type) with K scars ≥ 1 year old, ≤ 2 cm in length, extensive exclusion criteria including prior scar treatment in last 6 weeks	Scar erythema, symptoms, pigmentation, induration, volume & overall appearance	ILS (TA 20 mg/mL) or TNF- α : 2 treatments at 0 and 4 weeks	2 months (prospective)	+ILS (NS) +TNF- α	Both treatments improved several scar parameters at week 8, with ILS performing better than TNF- α although not significantly different compared to baseline. No statistical difference was apparent between groups, however TNF- α significantly reduced pruritus.
Sproat ¹⁰⁶	2	RCT	SGS vs ILS	HT	14 patients (2ethnicity or skin type) with sternal scars, no exclusion criteria stated	Scar size, height, color & symptoms	SGS:12 hrs/day, 12 weeks (TA 40 mg/mL); 1 dose	3 months	+SGS (NS)	SGS provided improved signs and symptoms more quickly than ILS.
Manuskiatti ¹⁴⁵	2	RCT	PDL vs ILS vs 5-FU vs ILS & 5-FU vs untreated control	HT & K	10 patients (Fitzpatrick skin type I-IV) with HT and K sternotomy scars, ≥ 6 months old, excluded if previously treated	Scar height, erythema, pliability, overall scar appearance & histology	PDL/ILS (TA 20 mg/mL); 6 treatments, 4 week intervals 5-FU (50 mg/mL); 10 treatments, every 2-4 weeks ILS (TA 1 mg/mL) & 5-FU (45 mg/mL); 10 treatments, every 2-4 weeks	≤ 8 months (prospective)	+PDL +ILS +5FU +ILS & 5-FU	Clinically and statistically all scars improved after ILS, ILS & 5-FU, 5-FU and PDL comparably. ILS, ILS & 5-FU and 5-FU alone resulted in faster resolution and better scar induration than the PDL treatment group. PDL produced the best treatment for scar texture and ILS lead to greater adverse reactions
Layton ¹²³	2	RCT	CS vs ILS vs untreated control	K	11 patients (2ethnicity or skin type) with multiple acne K scars, no exclusion criteria stated	Scar height, depth, blood flow & pliability	CS & ILS (TA 5 mg/mL);?1-3 treatments	4 months (prospective)	+CS > +ILS	Both treatments significantly improved height and pliability, with vascular keloid lesions responding better. The CS group had a significant positive difference compared to the ILS scars

TABLE 51-9—Monotherapy and Polytherapy Steroid Treatment Modality Published Clinical Trials (Continued)

Steroids	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Asilian ¹⁵⁰	2	RCT	ILS vs ILS & 5-FU vs ILS & 5-FU & PDL	HT & K	69 patients (ethnicity or skin type) with HT or K scars ≥10mm long, excluded patients who had received scar treatment in past 6 months, those pregnant, planning to conceive, or with renal, liver or blood count abnormalities	Scar erythema, pliability, height symptoms & size	ILS (TA 10 mg/mL); 1/week for 8 weeks, 5-FU (40 mg/mL); 1/week for 8 weeks, PDL: at 0, 4 & 8 weeks	3 months (prospective)	+ILS & 5-FU & PDL > +ILS & 5-FU > ILS	All groups demonstrated improvements in nearly all measures but these were statistically more significant in the ILS & 5-FU and ILS & 5-FU & PDL groups. Overall efficacy of ILS & 5-FU was comparable to ILS & 5-FU & PDL, but ILS & 5-FU & PDL produced better results.
Daroughheh ¹⁴⁶	2	RCT	ILS vs ILS & 5-FU	HT & K	40 patients (ethnicity or skin type) with HT or K scars, ≥10mm long, excluded if received prior scar treatment in last 6 months or failed renal, liver or blood count tests, or pregnant	Scar erythema, symptoms, pliability, height, size & overall scar appearance	ILS (TA 40 mg/mL); 1/week for 8 weeks ILS (TA 40 mg/mL) & 5-FU (50 mg/mL); 1/week for 8 weeks	3 months (prospective)	+ILS & 5-FU	Both treatment groups demonstrated an acceptable improvement in nearly all parameters measured, this was more significant in the ILS & 5-FU group, and patients felt the polytherapy outcome was more acceptable.
Darzi ¹⁴⁷	2	RCT	β-RXT vs β-RXT & exc & β-RXT vs Exc & β-RXT vs ILS	HT & K	65 patients (ethnicity or skin type) with 100 K or HT scars, no exclusion criteria stated	Scar symptoms, height & reoccurrence	β-RXT: 400cGY 2/week, ≤16Gy total β-RXT & exc & β-RXT: 400cGY 2/week, ≤16Gy, exc & repeat course Exc & β-RXT: Exc & 400cGY 2/week, ≤16Gy ILS (TA 20-40 mg/mL; 4 treatments every 1-2 weeks	<10 years (prospective)	+β-RXT (NS) -β-RXT & exc & β-RXT (NS) +Exc & β-RXT (NS) +ILS (NS)	β-RXT alone eradicated 55% of symptoms but only reduced scar height by 11%. Surgical excision and β-RXT postoperatively yielded a 67% success rate, rising to 75% if delivered with 48 hours of surgery. ILS reduced 72% of symptoms and completes flattening in 64% of lesions. There was no advantage found in receiving preoperative β-RXT.

Polytherapy								
Sclafani ¹⁶⁵	2	RCT	Exc vs Exc & ILS vs Exc & RXT (10Gy) vs Exc & RXT (7Gy)	K	42 patients (ethnicity or skin type) with 50 earlobe K scars, no exclusion criteria stated	Overall scar appearance & reoccurrence	Exc & ILS: injections day 0 & 3 further treatments Exc & RXT: 1 fraction of 10Gy or 7Gy	12 months (prospective)
Darougheh ¹⁴⁶	2	RCT	ILS vs ILS & 5-FU	HT & K	40 patients (ethnicity or skin type) with HT or K scars, ≥10mm long, excluded if received prior scar treatment in last 6 months or failed renal, liver or blood count tests, or pregnant	Scar erythema, symptoms, pliability, height, size & overall scar appearance	ILS (TA 40 mg/mL): 1/week for 8 weeks ILS (TA 40 mg/mL) & 5-FU (50 mg/mL): 1/week for 8 weeks	3 months (prospective)
Omraniard ¹⁴⁸	2	RCT	PDL vs ILS & pressure vs erbium laser	HT	120 patients (Fitzpatrick skin scale III) with HT scars ≥4cm long, <1 year old, excluded if received previous treatment within last 6 months	Scar pigmentation, vascularity, pliability & height	PDL/ILS (TA 5–10 mg/mL)/ erbium: no. of treatments, every 4 weeks pressure therapy: garments	≤12 months (prospective)
Manuskiatti ¹⁴⁵	2	RCT	PDL vs ILS vs 5-FU vs ILS & 5-FU vs untreated control	HT & K	10 patients (Fitzpatrick skin type I-IV) with HT and K sternotomy scars, ≥6 months old, excluded if previously treated	Scar height, erythema, pliability, overall scar appearance & histology	PDL/ILS (TA 20 mg/ml): 6 treatments, 4 week intervals 5-FU (50 mg/ml): 10 treatments, every 2–4 weeks ILS (TA 1 mg/mL) & 5-FU (45 mg/ml): 10 treatments, every 2–4 weeks	≤8 months (prospective)

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; PL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; ILS, intralesional steroid; IL, intrallesional steroid; Exc, excision; ILExc, intralesional excision; ELExc, extrallesional excision; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

6–12 cm², 80–120 mg) every 1–2 weeks and courses were repeated if necessary. The monotherapy groups were evaluated for reduction in scar height and symptomatic benefits, while the polytherapy groups were rated on reoccurrence only. Although no formal statistical analysis was completed, ILS fared better than β-RXT (400 cGy every 2 weeks up to 16Gy total) alone for reducing symptoms by 72% compared to 55%, and flattening 64% of lesions compared to 11%. Although a simple randomization method was employed, this did not include entering HT scars into the surgical excision groups. Therefore, this poses a difficulty when directly comparing treatment groups to evaluate the overall effect in raised scarring. Treatment regimen proves important, when Sproat¹⁰⁶ (described previously) administered only one ILS (TA 10 mg/mL) injection, this failed to prove beneficial in comparison to 12 weeks of SGS therapy. Furthermore, Layton's¹²³ (described previously) ILS (TA 5 mg/mL) injection schedule also appeared to lack a strict routine follow-up and readministration of the drug, therefore ILS treated keloid lesions did not respond as well as CS.

An attempted systematic review¹⁵⁹ rated level 3 evidence, assessed 61 articles of patients with clinically 'active' keloid scars to explore the most effective concentration and frequency application of TA injections. Overall, no studies were identified which fitted the strict inclusion criteria stated. This may be caused by the long-term nature of keloid scarring and the frequent path of failed treatments patients have endured; therefore finding subjects with keloid scars who have not receive any form of clinical or surgical treatment (as set out in the study inclusion criteria) is undoubtedly a difficult task. Other monotherapy studies (LOE-4) reported positively attributed results to ILS therapy, these included downgraded case-control studies,¹¹⁰ low-quality nonrandomized comparative studies^{122,160–162} or case-series accounts.^{163,164} Four RCTs (LOE-2)^{145,146,148,165} exist to examine the effect of ILS as a polytherapy adjuvant treatment. As described previously, when ILS is combined with 5-FU significant improvements are observed in parameters measured and this occurs faster and patients perceive this as more acceptable.^{145,146} When used in conjunction with pressure therapy in a large trial (n=120), HT scars benefited significantly post-treatment but other modalities fared better¹⁴⁸. In comparison to RXT therapy, post-surgical keloid scar excision, ILS was not as effective at preventing reoccurrences.¹⁶⁵ After surgery and ILS 33% regrew in contrast to only 12.5% after RXT and patients were more likely to complete RXT treatment.

One level 3 case-control study utilized TA (0.1%) in a topical steroid preparation in conjunction with a liquid occlusive and hydrating agent.¹⁵⁶ Forty-one patients with HT (n=32) and keloid (n=9) lesions applied the liquid compound twice a day for 2–5 months. A nonvalidated evaluation scale was employed to assess the scars in comparison to control lesions by the study author. Overall, all scar symptoms were relieved and a significant response was observed in 84% of HT scars in comparison

to 44% of keloid scars. All other polytherapy low-quality nonrandomized comparative trials^{72,149,160,162,166–171} or case-series^{84–87,121,151,152,154,157,158,172–178} reports of level 4 evidence, confirmed the positive addition of ILS, although some combinations were more favorable than others.

SURGERY

Surgery is a common management option for HT or keloid scars. This may be applied with an aesthetic or functional aim, such as HT burn scars may require release to prevent joint contractures.¹ Whereas, recurrent HT and keloid lesions require careful risk-benefit evaluation, often involving a clinically reasoned preoperative plan for adjuvant postoperative management strategies.³⁰ Keloid surgery normally focuses on two key objectives: (1) to resect or (2) to debulk. Keloid excision alone is associated with a high rate of reoccurrence (45–100%), therefore tissue resections should be combined with adjuvant therapy.⁶⁰ Combining surgery with ILS has been previously reported to reduce the reoccurrence by 50%, and if combined with perioperative RXT therapy this could be reduced to 10%.^{60,147,179,180} Debulking procedures alternatively aim to relieve patient symptoms and promote quality of life.^{44,181} This may include removing infected tissue tracts which often occur in hair-bearing regions of the scalp or anterior chest,¹⁸² or simply reducing mass so it does not show through clothing.⁴⁴ Some authors suggest adjuvant therapy post mass reduction should be addressed with caution because of the potential for excessive exposure to toxic therapies (e.g., RXT) or the side-effects of the cumulative use of other treatments (e.g., corticosteroids)²⁷.

Many different types of surgical excision strategies are available for keloid and HT scar revision. These include linear closure, excision with skin grafting, z-plasty, w-pasty and a flap coverage if other options fail.⁵⁷ Careful surgical incision along the lines of tension, not crossing them and closure without skin tension is critical.¹⁸³ Serial scar excisions may be applied for large keloids involving repeated intralesional excision procedures, to avoid a build-up of skin tension before a final extralesional excision, incorporating a margin of normal skin.^{184–186} Some authors have described a core excision procedure in which the fibrous keloid is excised to leave the epidermis and thin dermal layer to resurface the defected area.^{187,188} Tissue-engineered skin-substitute grafts composed of an artificial dermis of purified bovine collagen and human fibroblast supporting keratinocytes have also been trialed.¹⁷⁸ The type of suture material used is a controversial topic and has been found not to affect rates of HT scarring in the face.¹⁸⁹ However, others have recommended nonabsorbable sutures to be applied in regions of high tension such as the chest and shoulder girdle because of skin tension levels in that region.^{27,190}

Although surgical excision in the pathogenic scar population is rarely carried out in isolation clinically, six studies (LOE-2: 1, LOE-4: 4, LOE-5: 1) were found which evaluated

surgery alone for keloid^{165,171,181,187,191} and hypertrophic¹⁸⁶ scars (Table 51-10 and its electronic version). One RCT¹⁶⁵ included 42 patients with 50 keloid earlobe scars, however only 31 participants completed treatment and were available for follow-up at 12 months. These individuals received surgical excision only (n=3), surgical excision and ILS (n=12, treated with TA 40mg/mL intraoperatively and 3 further treatments), surgical excision and RXT postoperatively (n=16, either at the randomly assigned 10Gy or 7Gy) using either superficial x-rays or electron beams. No statistically significant difference were observed between the groups that completed treatment, although the low completion rate particularly in the excision-only group may be attributed to recurrence during this time.

Berman¹⁷¹ completed a retrospective cohort study (LOE-4) which compared the recurrence rate of keloids treated by excision alone with the results of postoperative TA or interferon (INF)- $\alpha 2\beta$. Patients lost to follow-up were assumed to have reoccurred which may have affected the study analysis of 74 cases and length of postsurgery observation varied dramatically up to 47 months, but with a mean time of 7 months. Based on these facts, recurrence rates after excision alone were thought to be 51% and this was significantly less effective than excision and INF- $\alpha 2\beta$. Another study incorporating extralesional scar excision, compared this surgical technique to and without the addition of 5-FU.¹⁹¹ Scars receiving combination therapy were perceived to improve greater than excision alone. Assessments were completed by a blinded clinician using a nonvalidated version of the VSS, but only 50% (average) patients attended each review time-point up to 6 months and no recurrence data was presented. Intralesional excisions of HT facial scars have also provided good aesthetic results,¹⁸⁶ and keloid scar flap core excision procedures have demonstrated no recurrence after the absence of adjuvant therapy¹⁸⁷ in two case-series studies (LOE-4). Other authors¹⁸¹ have advocated the use of regular debulking surgery before the inevitable recurrence in severe aggressive keloid disease. Polytherapy is a frequent strategy especially in the management of keloid scars and three RCTs (LOE-2)^{147,165,192} have examined the use of surgical excision with other treatments options. An excision procedure combined with postoperative β -RXT can yield a 67% success rate in preventing recurrence in keloid lesions with a long-term follow-up period (up to 10 years).¹⁴⁷ Over shorter monitoring periods, two out of 16 keloid scars reoccurred when treated with the same adjuvant, as opposed to four out of 12 scars after excision and ILS.¹⁶⁵ The addition of IFN- γ failed to significantly improve the effect of excision surgery to prevent regrowth of keloid lesions and after 12 weeks, 40% had recurrence.¹⁹²

Other level 4 evidence of non-randomized comparative studies,^{92,166–169,171,191,193–195} case series,^{84,85,151,154,157,158,174,177,184,196–226} and case reports,^{86,90,178,188,227,228} with adjuvant RXT, IFN, ILS, 5-FU, verapamil, imiquimod, mitomycin C, pressure therapy and various SG products, have been reported

with overall positive results to improve cosmesis and prevent recurrence. One case report¹⁷⁸ also documented the benefit of staged surgery incorporating tissue-engineered allografts to reduce the depth of the patient-derived tissue graft required to close a large lesional defect on the sole of the foot. Another report¹⁸⁸ illustrated a similar core excision procedure as described previously but via an autograft route rather than a flap methodology.

LASER

Laser therapy has evolved over the past 20 years into a potential key treatment strategy for the management of HT and keloid scars.²²⁹ The early promise shown by carbon dioxide (CO₂) lasers for the excision of keloid scars failed to curb their regrowth and recurrence, but newer CO₂ models have proved to be more effective.^{60,88,230} The outcome of lasers is tissue-specific and dependent on the wavelength applied because of the oxyhemoglobin absorption peak at 542 nm.²³¹ Lasers commonly applied in the management of raised scarring are neodymium:yttrium-aluminum-garnet (Nd:YAG, 1064 nm), CO₂ (1060 nm), intense pulsed light (IPL) (515-645 nm), erbium (1550 nm) or pulsed-dye laser (PDL). Currently the PDL wavelengths 585 nm and 595 are most frequently used therapeutically.^{58,232} PDL focuses on the principle that hypervascularity has a key role in scar appearance. The proposed mechanism centers around selective photothermolysis by which direct energy is absorbed by oxyhemoglobin, leading to thermal injury in the microvasculature and reducing collagen by thrombosis and ischemia.²³³ Levels of decreased growth factor may occur because of destruction of the vascular supply which disrupts the stimulus from endothelial cells and fibroblasts.⁸ Additionally, keloids regress following PDL-induced reduction in transforming growth factor (TGF)- β_1 expression, fibroblast proliferation and the deposition of type III collagen.^{234,235} Wound angiogenesis may also be controlled to minimize scarring by early PDL intervention.⁵⁸

The primary indication for PDL is to reduce scar redness, but it can also reduce scar volume and improve texture.^{57,58} Laser may also aid to diminish the intense pruritus experienced after a burn injury during the healing process and scar maturation.²⁷ However, multiple treatments are required to provide a better scar outcome and are made possible due to the low adverse-effect profile.²³⁶ Laser therapy is safe in dark skinned individuals although hypo- and hyperpigmentation can occur.²³⁷ The development of post-therapy itching and purpuric spots, which resolve within a week is often documented.^{150,237} Typically 1-24 treatment sessions at 4-8 week intervals have been administered.^{113,145,238–240} Ultimately, the exact treatment protocol, laser wavelengths, energy fluences and adjuvant therapies selected all influence the therapeutic response and long-term outcome in problematic scarring lesions.

TABLE 51-10—Monotherapy and Polytherapy Published Clinical Trials: Surgical Excision Treatment

Surgical Excision	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Monotherapy										
Scalfani ¹⁶⁵	2	RCT	Exc vs Exc & ILS vs Exc & RXT (10Gy) vs Exc & RXT (7Gy)	K	42 patients (?ethnicity or skin type) with 50 earlobe K scars, no exclusion criteria stated	Overall scar appearance & reoccurrence	Exc & ILS: injections day 0 & 3 further treatments Exc & RXT: 1 fraction of 10Gy or 7Gy	12 months (prospective)	+Exc & RXT (10Gy or 7Gy) (NS)	No statistically significant difference was observed between the groups, RXT appears to be simpler, has a better patient compliance and is more effective than ILS in preventing K scar reoccurrence.
Darzi ¹⁴⁷	2	RCT	β-RXT vs β-RXT & exc & β-RXT vs Exc & β-RXT vs ILS	HT & K	65 patients (?ethnicity or skin type) with 100 K or HT scars, no exclusion criteria stated	Scar symptoms, height & reoccurrence	β-RXT: 400cGY 2/ week, ≤16Gy total β-RXT & exc & β-RXT: 400cGY 2/ week, ≤16Gy, exc & repeat course Exc & β-RXT: Exc & 400cGY 2/week, ≤16Gy ILS (TA 20-40 mg/mL: 4 treatments every 1-2 weeks	<10 years (prospective)	+β-RXT (NS) -β-RXT & exc & β-RXT (NS) +Exc & β-RXT (NS) +ILS (NS).	β-RXT alone eradicated 55% of symptoms but only reduced scar height by 11%. Surgical excision and β-RXT postoperatively yielded a 67% success rate, rising to 75% if delivered with 48 hours of surgery. ILS reduced 72% of symptoms and completes flattening in 64% of lesions. There was no advantage found in receiving preoperative β-RXT

Sclafani ¹⁶⁵	2	RCT	K	Exc vs Exc & ILS vs Exc & RXT (10Gy) vs Exc & RXT (7Gy)	Overall scar appearance & reoccurrence 42 patients (?ethnicity or skin type) with 50 earlobe K scars, no exclusion criteria stated	Exc & ILS; injections day 0 & 3 further treatments Exc & RXT: 1 fraction of 10Gy or 7Gy	+Exc & RXT (10Gy or 7Gy) (NS)	No statistically significant difference was observed between the groups, RXT appears to be simpler, has a better patient compliance and is more effective than ILS in preventing K scar reoccurrence.
Broker ¹⁹²	2	RCT	K	Exc & IFN-γ vs Exc & placebo control	9 patients (?ethnicity or skin type) with ≥2 K lesions, extensive exclusion criteria	Exc, IFN-γ: 10 treatments, 1/ week	- IFN-γ (NS)	There was no significant difference in scar size or height between the IFN-γ and the placebo control group at 3 months. Small sample size prevented further time point analysis. IFN-γ did not prevent reoccurrence of K scarring in this study.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; ILS, intralesional corticosteroid; IL, intrallesional; Exc, excision; ILExc, intralesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

Six RCTs (LOE-2, see Table 51-11 and its electronic version)^{113,145,148,236-238} have compared the efficacy of PDL on HT and keloid lesions. PDL was evaluated against IPL in 15 patients receiving both treatment modalities via 2 applications, 2 months apart to alternative HT scar regions.²³⁸ Randomly presented post-operative side-by-side photographs were scored using a nonvalidated scale for improvement by a single physician. The PDL treated scars benefitted 80% after two treatments in comparison to 65% change in the IPL scars. There was no significant difference, however between study treatments arms and patients rated IPL as a more painful therapy. Laser pain also caused six patients to drop out of Wittenberg's¹¹³ study, where PDL was no more effective than SGS.

When PDL and erbium laser were compared to combined ILS and pressure therapy, both laser modalities proved significantly better at treating HT scars¹⁴⁸. The large single blinded and randomized trial employed three trained clinicians to minimize inter-observer error when assessing using the VSS and dial caliper. Overall, the PDL proved more effective than the erbium laser when patient opinions were evaluated (70% scar improvements compared to 65%), but the actual total number of monthly treatments received (up to a maximum of 12) was not provided. In pulse width studies²³⁷ of the same sternotomy scar comprising 19 patients treated on 3 occasions with a 595nm laser at either 0.45- or 40ms at monthly intervals, PDL significantly decreased scar volume. The previously untreated scars were randomized and blindly assessed using a range of validated tools over 6 months. Segments treated with PDL (pulse width 0.45 ms) reduced in size and had improved pliability to a statistically significant degree, but neither pulse width significantly affected erythema. Spots of purpura were noted in 21% of the PDL 0.45 ms group only. An earlier study by the same group,²³⁶ divided 10 similar scars into 4 segments and randomly treated each with 585 nm PDL at an energy density fluence of 3, 5 and 7 J/cm² every 4 weeks for 6 total treatments. Clinical assessment of scar height and erythema was carried out as before, and pliability was recorded using a standard scale. A significant improvement in all parameters was noted in all laser treated regions but no statistical difference was determined between fluences, although a trend for better response with lower fluences is observed. Other authors concluded that PDL significantly improved HT and keloid scar appearance and produced the best results for scar texture, but was no more beneficial than ILS, 5-FU or ILS & 5-FU.¹⁴⁵

Five case-control studies (LOE-3) compared PDL with untreated controls and statistically significant improvements were documented in all scar color, height, texture and symptoms recorded.²⁴¹⁻²⁴⁵ However, in one study these were not significant when compared to the normal maturation process in the control HT scar.²⁴⁴ Liew²⁴³ determined that PDL treatment should be considered in the early management of HT scarring, but treatment may need to continue past the 3 month point as initial scar

improvements decreased at 3 and 6 months post therapy completion.²⁴³ The positive results achieved by one PDL case-control study²⁴² after 2 months were in contrast to other research, which suggested that objective improvements could be observed from 16 weeks onwards.²³⁶ Bowes²⁴⁵ study additionally compared the 532 nm Nd:YAG laser using two different modes of pulsing energy delivered (Q-switched or variable pulse). The Nd:YAG (Q-switched) results were comparable to the PDL, but patients preferred the results achieved by the Nd:YAG in pigmented HT scars. Further nonrandomized comparative trials and case-series (LOE-4) provided positive evidence to support the use of PDL,^{117,246-248} CO₂ laser,⁸⁸ IPL,^{239,249} Nd:YAG¹⁷⁵ and erbium laser.²⁵⁰ Two additional case-series studies negated any benefits from CO₂ laser²⁴⁰ or PDL²⁵¹ and two case reports (LOE-5)^{230,252} supported the application of CO₂ and KTP for raised scarring. One polytherapy RCT¹⁵⁰ previously described documented additional beneficial results when PDL was added to the ILS and 5-FU treatment programme. Here PDL provided the added advantage that it lightening pigmented lesions to increase patient satisfaction, but this treatment modality did induce 7-10 days of pruritic symptoms. Other nonrandomized comparative studies (LOE-4),^{88,149} cases-series (LOE-4)^{89,173,176} and case reports (LOE-5)⁹⁰ were all favorable to the addition of laser in polytherapy management.

RADIOTHERAPY

Irradiation (RXT) treatment is considered an option in particular for recurrent keloid lesions.⁵⁹ RXT can be administered via the techniques of brachytherapy, β-RXT, superficial x-ray or low-energy electron beam transmission. It is hypothesized that an improved balance between collagen synthesis and degradation is achieved by the irradiation destruction, which takes place in the fibroblasts, connective tissue stem cells, extracellular matrix gene expression and other acute inflammatory cells^{153,177}. Irradiation monotherapy however has limited success in reducing scar height and symptoms.¹⁴⁷ Therefore, the use of RXT with other treatment modalities, especially surgery has been suggested to improve effectiveness and can provide preventative success rates between 67-98%.^{147,193,200,227} This is often initiated immediately postoperatively or within 48 hours,^{147,194,202,203} with the total dose limited to 7.5-40 Gy.^{203,205,208,253} Multiple descriptions of various treatment intervals (1-11 fractions), single dose levels (1.5-7 Gy) and cumulative doses exist.^{177,195,201,203,208,227}

Most safety concerns associated with this scar treatment modality are in respect to the risk of inducing malignant tumors for the management of essentially a benign condition. Nevertheless when surveyed, 78% of radiation oncologists recognize that RXT is an acceptable treatment for keloid scarring.^{254,255} Therefore, it is essential appropriate dose therapy is provided in conjunction with the adequate provision of surrounding healthy

(text continued on page 790)

TABLE 51-11—Monotherapy and Polytherapy Published Clinical Trials: Laser Treatment Modality

Laser	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Monotherapy										
Bellew ²³⁸	2	RCT	PDL vs IPL	HT	15 HT scars (Fitzpatrick skin type I-III) 6-8 weeks old, excluded if received previous scar treatment	Overall scar appearance, pain	PDL/IPL: 2 treatments, 2 months apart	4 months (prospective)	+PDL +IPL	PDL and IPL are effective and significant treatment outcomes for HT surgical scars from baseline comparisons, but neither modality performed to a statistically significant level above another. Patients rated IPL more painful than PDL.
Wittenberg ¹¹³	2	RCT	SGS vs PDL vs untreated control	HT	20 patients (Fitzpatrick skin type I-V) with a linear HT scars ≥ 8cm long, excluded if received scar treatment in previous 2 months,	Scar blood flow, pliability, volume, symptoms & histological biopsy assessment	SGS: ≥ 12 hrs/day, PDL: 4 treatments at 8 week intervals	10 months (prospective)	-SGS (NS) -PDL (NS)	Overall significant reduction in blood flow, volume and pruritus was recorded during the monitored phase in all scar regions. There was no difference in the improvement in scars sections treated with SGS or PDL compared to control sections.
Manuskiatti ²³⁶	2	RCT	PDL vs PDL vs PDL (at different fluences) vs untreated control	HT	10 patients (Fitzpatrick skin type I-IV) with HT stenotomy scars, ≥6 months old, excluded if received prior treatment	Scar height, erythema, pliability & overall appearance	PDL: 6 treatments, every 4 weeks	8 months (prospective)	+PDL	Scar parameters improved significantly in all PDL treated scar areas, but there was no significant difference in the outcome dependent on the laser fluence administered (although there was an improvement trend towards lower fluences). Multiple treatment sessions achieved greater response.
Omraniard ¹⁴⁸	2	RCT	PDL vs ILS & pressure vs erbium laser	HT	120 patients (Fitzpatrick skin scale III) with HT scars ≥ 4cm long, <1 year old, excluded if received previous treatment within last 6 months	Scar pigmentation, vascularity, pliability & height	PDL/ILS (TA 5-10 mg/mL)/ erbium?: no. of treatments, every 4 weeks pressure therapy: garments	≤ 12 months (prospective)	+ILS & pressure < +PDL +erbium laser	All three groups significantly improved post treatment, but the results in the PDL and erbium laser treatment groups was significantly higher than the ILS & pressure group.

(Continued)

TABLE 51-11— Monotherapy and Polytherapy Published Clinical Trials: Laser Treatment Modality (Continued)

Laser	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Manuskiatti ¹⁴⁵	2	RCT	PDL vs ILS vs 5-FU vs ILS & 5-FU vs untreated control	HT & K	10 patients (Fitzpatrick skin type I-IV) with HT and K sternotomy scars, ≥6 months old, excluded if previously treated	Scar height, erythema, pliability, overall scar appearance & histology	PDL/ILS (TA 20 mg/mL): 6 treatments, 4 week intervals 5-FU (50 mg/mL); 10 treatments, every 2-4 weeks ILS(TA 1 mg/mL) & 5-FU (45 mg/mL); 10 treatments, every 2-4 weeks	≤8 months (prospective)	+PDL +ILS +5-FU +ILS & 5-FU	Clinically and statistically all scars improved after ILS, ILS & 5-FU, 5-FU and PDL comparably. ILS, ILS & 5-FU and 5-FU alone resulted in faster resolution and better scar induration than the PDL treatment group. PDL produced the best treatment for scar texture and ILS lead to greater adverse reactions
Manuskiatti ²³⁷	2	RCT	PDL vs PDL (different pulse widths)	HT & K	19 patients (Fitzpatrick skin type III-IV) with HT and K sternotomy scars, ≥6 months old, excluded if previously treated	Scar volume, height, erythema & pliability	PDL: 3 treatments, 4 week intervals	6 months (prospective)	+PDL (pulse width 0.45 ms)	PDL of both pulse widths significantly decreased the volume of scar segments. PDL (pulse width 0.45 ms) was statistically more effective in reducing scar size and improving pliability than PDL (pulse width 40 ms). Pulse width did not significantly effect scar erythema.

Polytherapy	Asilian ¹⁵⁰	2	RCT	ILS vs ILS & 5-FU vs ILS & 5-FU & PDL	HT & K 69 patients (?ethnicity or skin type) with HT or K scars ≥ 10mm long, excluded patients who had received scar treatment in past 6 months, those pregnant, planning to conceive, or with renal, liver or blood count abnormalities	Scar erythema, pliability, height symptoms & size ILS (TA 10 mg/ mL); 1/week for 8 weeks, 5-FU (40 mg/ mL); 1/week for 8 weeks, PDL: at 0, 4 & 8 weeks	+ILS & 5-FU & PDL > +ILS & 5-FU > ILS 3 months (prospective)	+ILS & 5-FU & PDL > +ILS & 5-FU > ILS All groups demonstrated improvements in nearly all measures but these were statistically more significant in the ILS & 5-FU and ILS & 5-FU & PDL groups. Overall efficacy of ILS & 5-FU was comparable to ILS & 5-FU & PDL, but ILS & 5-FU & PDL produced better results.
-------------	------------------------	---	-----	---------------------------------------	--	--	--	---

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; ILS, intralesional steroid; IL, intralesional; Exc, excision; ILExc, intralesional excision; ELExc, extrallesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

tissue protection, in particular the thyroid and mammary glands.²⁷ Only one RXT RCT (LOE-2, see Table 51-12 and its electronic version)¹⁴⁷ was evaluated which included RXT treatment alone, although β -RXT (twice weekly 4Gy, up to \leq 16Gy) monotherapy only eradicated 55% of symptoms and scar height by 11%. This improved considerably when surgical excision preceded the β -RXT and yielded a 67% success rate in preventing recurrences, rising to 75% if delivered with 48 hours of surgery. There was no advantage found in receiving preoperative β -RXT. Other authors (LOE-4)^{193,195} also found surgery and RXT more effective for keloid and HT scar management than RXT alone, especially if treatment was initiated up to 72 hours after excision with a single dose of 9Gy or greater.¹⁹⁵ Brachytherapy was preferred by Guix¹⁹³ for improved treatment selectivity and a lower degree of normal tissue irradiation than superficial x-rays or electron beam. In two non-randomized comparative dose evaluation studies (LOE-4),^{256,257} one assessed the benefits of receiving a 20Gy dose in 4 fractions either once a week, or twice a week.²⁵⁶ A positive response was defined as flattening of the lesion, relief of symptoms and restraint from further growth. When RXT was administered twice weekly, a successful response was recorded in 92% of lesions in comparison to 81% in those receiving weekly RXT. Alternately, Ogawa²⁵⁷ recommended that a traditional standardized protocol should be abandoned for a site-specific or scar characteristic protocol such as 10Gy in 2 fractions over 2 days for earlobe scars and 20Gy in four fractions over 4 days for keloid and intractable HT scars. A monotherapy case-series (LOE-4) study of 64 patients also reported 86 unresectable keloid scars has 97% significant regression 18 months post 37.5Gy RXT (received in 5 weekly fractions). Meanwhile the variable sites, individual and scar-specific propensity for recurrent disease limit the extent to which direct comparisons can be drawn when receiving such widespread therapy as irradiation. Twenty-seven additional polytherapy studies incorporating pre-RXT surgical excision provided positive level 2 (described previously),¹⁶⁵ level 4^{168,177,184,194,197,198,200-216,253} and level 5^{227,228} evidence, except one study of 'resistant keloids'.¹⁹⁹

5-FLUOROURACIL

5-Fluorouracil (5-FU) is a nucleotide (pyrimidine) analog with antimetabolite activity, which is a logical therapeutic modality for pathogenic scarring which has been shown to exist in a hypermetabolic state.²⁵⁸ The 5-FU is enzymatically converted intracellularly into its active substrate which is ultimately incorporated into DNA in place of uracil, where it inhibits DNA synthesis.⁸⁷ Cells proliferating rapidly, such as fibroblasts which are synthesizing increased amounts of DNA are preferentially targeted by 5-FU.¹⁵² *In-vitro*, both fibroblast proliferation and fibroblast-populated collagen lattices have demonstrated

a dose-related decline when treated with fluorouracil¹⁵², therefore it is believed to reduce postoperative scarring by suppressing fibroblast proliferation.^{149,259} Histopathological improvements have shown diminished hyalinization of collagen fibres, reduced vascularity prominence and flattening of dermal papillae *in-vivo*²⁶⁰. These characteristics of the drug as a chemotherapeutic agent have successfully broadened its use.

5-FU is frequently administered via intralesional injection (single or multiple doses), or at the time of surgery, the wound is exposed to 5-FU-soaked sponge pads for around 5 minutes before saline irrigation.^{191,260,261} The safety and efficacy of the 5-FU compound in surgery has been documented in long-term follow-ups with a multicenter study.²⁶² Side-effects are similar to other intralesionally administered drugs such as pain at the injection site, and short purpura formation and ulceration.^{149,261,263} Pigmentary disturbance (hyperpigmentation) can also occur, however this was reported not to be permanent and improved after discontinuation of treatment.^{87,263} When used post surgical excision, no wound dehiscence has been reported even when sutures were removed at 7 days.¹⁹¹

Clinically a number of studies exist utilizing 5-FU (see Table 51-13 and its electronic version). In Darzi's RCT (LOE-2, described previously),¹⁴⁷ scars statistically improved after receiving intralesional therapy with all treatment study arms, but no significant difference was determined for scar sections treated with 5-FU alone or in combination. Alternatively, a small non-randomized comparative study (LOE-4)¹⁴⁹ of 5 patients comparing various treatment regimes of 5-FU alone, 5-FU and ILS and 5-FU, ILS and PDL determined that the therapy was safe and effective for HT scars, not just keloids. In particular, scars that were most inflamed, red in colouration, firm and symptomatic responded more significantly to 5-FU mono- or polytherapy. Three case-series studies^{260,261,263} documented that the majority of scars improved by over 50%,²⁶¹ with half of patients observing 50% scar flattening²⁶³ and 95% of keloid scars reducing in volume after 5-FU therapy alone.²⁶⁰ Overall, no patients failed treatment and 5-FU was as effective as other keloid monotherapies.²⁶¹ The effects and recurrence rates correlated with the duration of the lesion and not the scar size^{260,263} Further polytherapy studies have acknowledged the positive therapeutic benefits of 5-FU with ILS (LOE-2: 2, LOE-4: 2),^{146,150,152,170} excision and 5-FU (LOE-4: 2)^{191,196} and 5-FU with multiple therapy components (LOE-2: 1, LOE-4: 1, LOE-5: 1).^{87,150,170}

INTERFERON

This promising method of scar management has originated from recent attempts to manipulate wound healing with various recombinant growth factors and interferons (IFN)¹⁹². This therapy focuses on interrupting the cell proliferation and activation of apoptotic pathways in raised scarring. Recent studies have demonstrated an inhibitory

5-Fluorouracil	LOE	Study Design	Evaluated Treatment Type	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Monotherapy</i>										
Manuskiatti ¹⁴⁵	2	RCT	PDL vs ILS vs 5-FU vs ILS & 5-FU vs untreated control	HT & K	10 patients (Fitzpatrick skin type I-IV) with HT and K sternotomy scars, ≥6 months old, excluded if previously treated	Scar height, erythema, pliability, overall scar appearance & histology	PDL/ILS (TA 20 mg/mL); 6 treatments, 4 week intervals 5-FU (50 mg/mL); 10 treatments, every 2-4 weeks ILS(TA 1 mg/mL) & 5-FU (45 mg/ml); 10 treatments, every 2-4 weeks	≤8 months (prospective)	+PDL +ILS +5-FU +ILS & 5-FU	Clinically and statistically all scars improved after ILS, ILS & 5-FU, 5-FU and PDL comparably. ILS, ILS & 5-FU and 5-FU alone resulted in faster resolution and better scar induration than the PDL treatment group. PDL produced the best treatment for scar texture and ILS lead to greater adverse reactions
Daroughreh ¹⁴⁶	2	RCT	ILS vs ILS & 5-FU	HT & K	40 patients (?ethnicity or skin type) with HT or K scars, ≥10mm long, excluded if received prior scar treatment in last 6 months or failed renal, liver or blood count tests, or pregnant	Scar erythema, symptoms, pliability, height, size & overall scar appearance	ILS (TA 40 mg/mL); 1/week for 8 weeks ILS (TA 40 mg/mL) & 5-FU (50 mg/mL); 1/week for 8 weeks	3 months (prospective)	+ILS & 5-FU	Both treatment groups demonstrated an acceptable improvement in nearly all parameters measured; this was more significant in the ILS & 5-FU group, and patients felt the polytherapy outcome was more acceptable.

Asilian ¹⁵⁰	2	RCT	ILS vs ILS & 5-FU vs ILS & 5-FU & PDL	HT & K 69 patients (?ethnicity or skin type) with HT or K scars ≥ 10 mm long, excluded patients who had received scar treatment in past 6 months, those pregnant, planning to conceive, or with renal, liver or blood count abnormalities	ILS (TA 10 mg/mL): 1/week for 8 weeks, 5-FU (40 mg/mL): 1/week for 8 weeks, PDL: at 0, 4 & 8 weeks	3 months (prospective)	+ILS & 5-FU & PDL > +ILS & 5-FU > ILS	All groups demonstrated improvements in nearly all measures but these were statistically more significant in the ILS & 5-FU and ILS & 5-FU & PDL groups. Overall efficacy of ILS & 5-FU was comparable to ILS & 5-FU & PDL, but ILS & 5-FU & PDL produced better results.
Manuskiatti ¹⁴⁵	2	RCT	PDL vs ILS vs 5-FU vs ILS & 5-FU vs untreated control	HT & K 10 patients (Fitzpatrick skin type I-IV) with HT and K sternotomy scars, ≥ 6 months old, excluded if previously treated	Scar height, erythema, pliability, overall scar appearance & histology PDL/ ILS (TA 20 mg/mL): 6 treatments, 4 week intervals 5-FU (50 mg/mL): 10 treatments, every 2-4 weeks ILS(TA 1 mg/mL) & 5-FU (45 mg/ mL): 10 treatments, every 2-4 weeks	≤ 8 months (prospective)	+PDL +ILS +5-FU +ILS & 5-FU	Clinically and statistically all scars improved after ILS, ILS & 5-FU, 5-FU and PDL comparably. ILS, ILS & 5-FU and 5-FU alone resulted in faster resolution and better scar induration than the PDL treatment group. PDL produced the best treatment for scar texture and ILS lead to greater adverse reactions

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGC, silicone gel sheet; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCs, intralesional cryosurgery; ILS, intralesional steroid; IL, intrallesional excision; ELExc, extralesional excision; EExc, extralesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

effect of IFNs, in particular IFN- α and IFN- γ on dermal fibroblast synthesis, collagen production and angiogenesis by reducing angiogenic factor concentrations.^{160,264} In may fibrotic disorders, local and systemic TGF- β have been implicated in the pathogenesis as fibrogenic cytokines. Keloid lesions are also known to have markedly depressed production levels of IFN- α , IFN- γ and TNF- β .²⁶⁵ It has been thought that IFN- $\alpha2\beta$ may benefit scar pathogenic features by antagonizing the effects of TGF- β and histamine.²⁶⁶ Short-term treatment of keloids with IFN- $\alpha2\beta$ has resulted in a selective and persistent keloidal fibroblast collagen normalization, glycosaminoglycans, and collagenase production and a clinical reduction in progressively enlarging keloids.^{267,268}

IFN compounds are normally administered intralesionally and by the nature of IFN treatment, a normal renal, hepatic and autoimmune function is required.^{160,192,268} Mild side effects attributed to the IFN are generalized flu-like symptoms, which occur in 74% of patients several hours after their first treatment but subside with subsequent treatments and no significant abnormalities in laboratory monitoring (serum, urinalysis or sediment) tests were observed during treatment.^{160,269,270} Intralesional injections are painful and 36% may require local anaesthetic²⁷⁰. Six monotherapy studies (LOE-2:1, LOE-4: 4, LOE-5:1, see Table 51-14 and its electronic version) were examined which included the cytokines TNF- α ,¹⁴⁴ IFN- $\alpha2\beta$,^{266,268} IFN- γ ^{270,271} and IFN- $\alpha2\alpha$ ²⁷² in therapeutic management of raised scars. The only RCT¹⁴⁴ (described previously) compared TNF- α to ILS. Both TNF- α and ILS improved scar appearance parameters after 8 weeks from baseline levels, but not to a significant level and TNF- α failed to perform as well as ILS. TNF- α did however, significantly reduce pruritus statistically after only two treatments administered in this programme. One case-controlled study²⁶⁸ evaluated the use of IFN- $\alpha2\beta$ injected intralesionally twice a week for 3 weeks compared to a placebo control. Follow-up was limited to 29 days and INF- $\alpha2\beta$ was found to be insignificant at reducing the height of mature keloid lesions. Alternatively, IFN- $\alpha2\beta$ significantly improved HT scar quality and volume after a high frequency treatment programme encompassing 76 injections over 6 months.²⁶⁶ Two small case-series^{270,271} additionally proved in favor of IFN- γ therapy. In one study, the majority of scars had complete symptomatic relief and objective changes after a month of therapy.²⁷⁰ Whereas in another,²⁷¹ after a 10-week treatment course all scars reduced in height and up to 50% in size, but the lack of follow-up after therapy completion may question the success. This is because Pittet²⁷⁰ found that 4 out of 7 patients had an increase in lesional area after completing IFN-g treatment.

When a small (n=9) RCT¹⁹² was completed to evaluate the use of INF-g post surgical excision, IFN therapy was found to be less effective than placebo treatment. Additionally, Davison¹⁶⁹ also found IFN- $\alpha2\beta$ to be less effective than post excisional ILS and the trial was stopped

prematurely because of the significantly high recurrence rates. This was in contrast to another comparative study¹⁷¹ which found IFN- $\alpha2\beta$ to be significantly better at preventing post surgical recurrence than ILS (19% in comparison to 58% recurrence), but treatment protocols were highly variable. Alternatively, if combined intralesional injections of IFN- $\alpha2\beta$ and ILS are administered statistically significant reductions in keloid height and volume are reported.¹⁶⁰

VERAPAMIL

Verapamil is a widely used calcium channel agonist, which can be used as an alternate intralesional therapy for HT and keloid scars. Calcium antagonists decrease the production of collagen in the extracellular matrix, stimulate the synthesis of collagenase and increase TGF- β activity.²⁷³⁻²⁷⁵ Depolymerization of actin filaments, altered cell shape and reduction of fibrous tissue production have also been shown to occur.^{161,276} Verapamil is a safe drug administered intralesionally and has been used topically in other fibrotic conditions to obtain successful results.^{222,277} It can be applied as a mono- or polytherapy to stabilize and prevent keloid scarring in susceptible individuals.^{92,161,221,222}

Only one parallel group comparative study (LOE-4, see Table 51-15)¹⁶¹ has evaluated the use of intralesional verapamil (1 mL of 2.5 mg/mL) against ILS in 54 patients with HT and keloid lesions. Scar improvements were assessed using the VSS and basic dimension measurements, but no blinding was described. A reduction in scar vascularity, pliability height and size was seen in both groups after 3 weeks, but changes were faster with ILS than verapamil. Outcomes were maintained up to 1 year, therefore verapamil may be a suitable alternative with less adverse side-effects to ILS in raised scarring. Three further studies (LOE-4)^{92,221,222} administered verapamil after surgical excision with positive results. Two years after treatment only 4 patients developed recurrences (n=2 keloid and n=2 HT) out of 22 receiving therapy.²²² When pressure therapy was also applied 55% of earlobe keloid scars were 'cured' after 6-28 months follow-up, with a positive trend to increased recurrence in previously treated scars.²²¹ If surgery was combined with verapamil (0.5-2 mL of 2.5 mg/mL) and SGS then various site and age matched keloids were 54% 'cured' after 18 months and recurrences were smaller in size and had a better consistency.⁹²

IMIQUIMOD

Imiquimod is a novel immune modulator that can be used to treat a variety of dermatologic conditions including basal cell carcinoma. The toll-like receptor agonist has a localized therapeutic response and is known to affect immune responses, which are both innate and cell-mediated, although the exact mechanism of imiquimod 5% cream is not fully understood.^{217,278} It has also been

TABLE 51-14 — Monotherapy and Polytherapy Published Clinical Trials: Interferon Treatment Modality

Interferon	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Monotherapy</i>										
Berman ¹⁴⁴	2	RCT	ILS vs TNF- α	K	20 patients (7ethnicity or skin type) with K scars ≥ 1 year old, ≤ 2 cm in length, extensive exclusion criteria including prior scar treatment in last 6 weeks	Scar erythema, symptoms, pigmentation, induration, volume & overall appearance	ILS (TA 20 mg/mL) or TNF- α : 2 treatments at 0 and 4 weeks	2 months (prospective)	+ILS (NS) +TNF- α	Both treatments improved several scar parameters at week 8, with ILS performing better than TNF- α although not significantly different compared to baseline. No statistical difference was apparent between groups, however TNF- α significantly reduced pruritus.
Broker ¹⁹²	2	RCT	Exc & IFN- γ vs Exc & placebo control	K	9 patients (7ethnicity or skin type) with ≥ 2 K lesions, extensive exclusion criteria	Scar size, height & overall scar appearance	Exc, IFN- γ : 10 treatments, 1/week	12-14 months (prospective)	-IFN- γ (NS)	There was no significant difference in scar size or height between the IFN- γ and the placebo control group at 3 months. Small sample size prevented further time point analysis. IFN- γ did not prevent reoccurrence of K scarring in this study.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel cushion; SGS, silicone gel sheet; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCs, intralesional steroid; IL, intralesional steroid; Exc, excision; ILExc, intralesional excision; ELExc, extrallesional excision; IPL, intense pulsed light; BM, betamethasone sodium phosphate; TA, triamcinolone acetonide; MP, methylprednisolone acetate; IFN, interferon; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

TABLE 51-15 — Monotherapy and Polytherapy Published Clinical Trials: Verapamil Treatment Modality

Verapamil	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Monotherapy</i>										
Shianthi ¹⁶¹	4	Comparative	ILS vs IL verapamil	HT & K	54 patients (ethnicity or skin type) with HT and K scars 2-10cm long, <5 years old, extensive exclusion criteria including a family history of K scarring	Scar pigmentation, vascularity, pliability, height & size	ILS (40 mg/mL) or IL verapamil (2.5 mg/mL); every 3 weeks up to ≤6 months	≤18 months (prospective)	+ILS (NS) > +IL verapamil (NS)	There was a reduction in scar vascularity, pliability, height and size seen in both treatment groups after 3 weeks, but changes were faster with ILS than IL verapamil. The outcomes were maintained at one year follow-ups after stopping treatment. IL verapamil has less adverse drug reactions and may be a suitable alternative to ILS in raised scarring.
D'Andrea ⁹²	4	Comparative	ELExc & SGS & IL verapamil vs Exc & SGS	K	44 patients (ethnicity or skin type) with various site K scars, no exclusion criteria stated	Scar size, thickness, texture & symptoms	ELExc, SGS; applied day 7-14 for 6-9 months, IL verapamil: day 0, 7, 14, 28 and during month 2	18 months (prospective)	+ELExc & SGS & IL verapamil (NS) > Exc & SGS	After 18 month reviews, K scars were cured in 54% of cases in the IL verapamil group compared to 18% in the second treatment group. Of the 36% of patients in the first group who saw reoccurrences, these were smaller in size and consistency. The authors conclude that verapamil hydrochloride is an effective preventative tool for K scars.
Lawrence ²²¹	4	Case-series	Exc & IL verapamil & pressure therapy	K	35 African American patients with 45 earlobe K scars, no exclusion criteria stated	Scar overall appearance/reoccurrence	Exc, IL verapamil: day 7-14 post-operatively & 1 month after Pressure earrings: continuously for ≥6 months	6-28 months (prospective)	+Exc & IL verapamil & pressure therapy (NS)	55% of K scars were cured by this treatment. There was a trend towards increased reoccurrence rates for previously treated K scars.
Copcu ²²²	4	Case-series	Exc & IL verapamil	K & HT	22 patients (ethnicity or skin type) with various K lesions ≤10mm wide and one HT scar, no exclusion criteria stated	Scar overall appearance, symptoms, patient satisfaction & histology	Exc with W-plasty or skin graft, IL verapamil: day 0, 7, 14, 28 and during month 2	≥ 2 years (prospective)	+Exc & IL verapamil (NS)	Two years after the treatment, 2 patients have keloid reoccurrences and 2 patients had HT scars. The authors suggest that surgical excision with W-plasty or skin grafting and IL verapamil may be a good alternative for the treatment of keloids.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGS, silicone gel sheet; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IP, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; IL, intralesional steroid; IL, intrallesional Exc, excision; ELExc, intralesional excision; ILver, IL verapamil; BM, betamethasone sodium phosphate; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

documented that imiquimod may be capable of enhancing local production of cytokines, interferons, TNF and interleukins, imparting an antifibrotic action to decrease collagen and glycosaminoglycan production.^{224,225} Imiquimod 5% cream can be applied as a polytherapy to prevent recurrences of keloids and HT scars postsurgical excision.¹⁰³ However local skin reactions do occur in 37% of cases, including erosion and erythema at the application site, this may require 1 week therapeutic break-period or occasionally some patients may be required to start every-other-day dosing.^{167,224,225} No monotherapy studies were located, but one non-randomized comparative study (LOE-4, see Table 51-16)¹⁶⁷ found topical imiquimod more beneficial than ILS after a shave excision procedure on earlobe keloids (2 of which were bilateral). Patients applied the cream daily for 8 hours for 8 weeks and after 6 months 75% of the imiquimod group were recurrence free, compared to 50% of the ILS scars. Patients in two additional positive case-series studies (LOE-4)^{217,225} applied imiquimod daily for 6-8 weeks and no evidence of recurrence was noted in any lesion after 6-12 months follow-up. The scars were asymptomatic and an excellent cosmetic results was achieved,²¹⁷ except hyperpigmentation in 64% of lesions.²²⁵ However, further studies (LOE-4:1, LOE-5:1)^{224,279} with similar regimes failed to demonstrate the efficacy of this particular combined therapy.

MITOMYCIN C

Mitomycin C is a chemotherapeutic and antineoplastic agent, which works by inhibiting DNA synthesis and fibroblast proliferation. It has previous been used for the successful management of laryngeal or tracheal stenosis¹⁰³. Mitomycin C alkylates and cross-links with DNA to inhibit DNA and protein synthesis. In in-vitro, fibroblasts treated with mitomycin C have a reduced DNA synthesis and density compared with controls.^{220,280} The inhibition of fibroblast proliferation by the therapy can decrease wound fibrosis when topically applied²⁸¹. In general, mitomycin C is well-tolerated even on new excision sites, but hyperpigmentation side-effects can be observed in rare cases.¹⁰³ One level 4 evidence comparative study (see Table 51-17)¹⁶⁶ evaluated the effectiveness of applying mitomycin C to one keloid out of two resected scar wound beds (n=15 patients) for 5 minutes at a concentration of 0.4 mg/mL prior to formal closure. All patients applied vitamin A and E cream to both wounds and one month after surgical excision both scars received ILS. The general scar appearance was monitored for signs of recurrence with no blinding and two patients were followed up by telephone rather than visually assessed. Overall, no statistically significant difference was observed between treatment groups. In three other small (n=28 in total) cases-series studies (LOE-4),^{219,220,226} mitomycin C proved a favorable polytherapy after surgical excision. A successful outcome and prevention rate of 80²²⁶- 90%²²⁰ was documented in keloid scars after a

14 month maximum follow-up. However, the terms by which a treatment is defined as successful or effective need to be better defined for comparative purposes in this complex patient group. For example, in Talmi's²¹⁹ study all patients were satisfied with the results after long-term follow-up (≤ 14 months) rated on a nonvalidated measure but complete keloid disappearance was only evident in 2 patients at 2 months.

Pressure

Pressure therapy has been a standard treatment for post-burn HT scars and is used as a frequent polytherapy for earlobe keloids. A wide range of pressure therapy devices exist, from fabric pressure garments often custom-designed for specific regions of the body, to the vast array of clips available for site-specific regions like the ear.^{85,174,282} The posterior auricular region is one of the most common and most difficult locations for pressure therapy that a keloid scar can develop. In this instance, a custom-made silicon ear mould can apply pressure homogeneously to the cartilaginous and lobular region. Wearing pressure garments can be uncomfortable, painful, hot and embarrassing, and as a consequence is challenging for the patient and subsequently low compliance is common.²⁸³

The application of constant scar pressure can potentially occlude capillaries and restrict oxygen flow to the affected lesion site, causing scar maturation to accelerate.⁸⁶ The localized hypoxia may also result in fibroblast degeneration and cell breakdown, which is beneficial in reducing recurrence of pathogenic scarring.^{223,284} In the absence of the superior surface pressure, the collagen fibres develop in a nonsystematic pattern and raised scarring can present²¹⁸. Pressure therapy devices should often, dependent on site be worn 24 hours a day for around a 12-18 months or until scar maturation occurs.¹⁷⁴ However, it is acknowledged that in some regions positive pressure splints can not be worn continuously (e.g., face) and in those instances compression therapy should aim to remain in place for 12 hours a day for a minimum 6-12 months.²⁸⁵ The exerted pressure should be at least 24 mm Hg, in order to exceed the inherent capillary pressure, but must not surpass 30 mm Hg to prevent peripheral circulation complications.^{86,168,286,287} Pressure adjuvant therapy often commences after wound re-epithelialization and suture removal at around 10-14 day²⁸⁴ and may reduce keloid scar formation by 70% when used consistently.⁸⁶ Side-effects are rare, but may include pressure ulcers.¹⁷⁴ Good patient education, including realistic expectations of compliance and success are key motivating factors for patient usage of pressure therapy.²⁸³ One RCT (LOE-2, Table 51-18 and its electronic version)⁹¹ was examined which evaluated pressure therapy alone against pressure therapy and SGS for the management of HT burn scars in two active treatment groups, for ethical reasons of withholding standard therapy no control group was included. This was a single blinded study with a good

(text continued on page 802)

TABLE 51-16—Monotherapy and Polytherapy Published Clinical Trials: Imiquimod Treatment Modality

Imiquimod	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Polytherapy</i>										
Martin-Garcia ¹⁶⁷	4	Comparative	Exc & imiquimod vs Exc & ILS	K	6 patients (Fitzpatrick skin type II-V) with bilateral earlobe K scars, excluded if pregnant, immunosuppressive, significant medical condition or previous treatment in last 3 months	Scar reoccurrence	Exc: parallel shave surgery, imiquimod cream applied daily for 8 hrs for 8 weeks to 1 st scar, ILS (TA 5 mg/mL); day 1, week 2, 4, 6, 8 to 2 nd scar	6 months (prospective)	+Exc & imiquimod (NS) > Exc & ILS	After 6 months 75% of the imiquimod group remained reoccurrence free. In comparison to the ILS group, 50% of the imiquimod treated scars remained clear of reoccurrence, while experiencing a re-growth in the ILS treated side. Local skin irritation secondary to imiquimod use required rest periods in 3 cases.
Cacao ²²⁴	4	Case-series	Exc & imiquimod	K	9 patients (various ethnicities) with stable trunk K lesions, excluded if active skin/systemic disease present, pregnant or using immunosuppressant drugs	Scar erythema, symptoms & size	Exc, imiquimod: daily from day 0 for 8 weeks	≤8 months (prospective)	-Exc & imiquimod (NS)	K scar reoccurred in 8 patients (7 after 12 weeks post surgery). Imiquimod 5% is not effective here in preventing reoccurrence of trunk K scars after surgical excision.
Stashower ²¹⁷	4	Case-series	Exc & imiquimod	K	4 patients (of various ethnicities) with 8 large earlobe keloids, excluded if received previous therapy or taken an immunosuppressive medication in last 6 months	Scar overall appearance, symptoms & size	Tangential shave Exc, imiquimod (5%); cream daily for 6 weeks	12 months (prospective)	+Exc & imiquimod (NS)	After 12 months no evidence of reoccurrence was noted in any lesion, the scars were asymptomatic and an excellent cosmetic result was achieved.

Berman ²²⁵	4	Case-series	Exc & imiquimod	K	12 patients (various ethnicities) with 13 K scars, ≥1 year old, excluded if previously treated in past 2 months, pregnancy, systemic or immune disorders	Scar erythema, edema, pigmentation, reoccurrence, symptoms & size	Exc, imiquimod: daily from day 0 for 8 weeks	6 months (prospective)	+Exc & imiquimod (NS)	No lesions reoccurred by 24 weeks (of the 11 evaluated). Hyperpigmentation side effects were high (64%). Reoccurrence rates of K scars treated with post-operative imiquimod here were lower than other published literature.
Malhotra ²²⁹	5	Case report	Exc & imiquimod	K	2 patients (Fitzpatrick skin type IV) with 3 presternal K scars	Scar reoccurrence	Exc: radio-frequency, imiquimod: cream applied daily overnight for 8 weeks	3 months (retrospective)	-Exc & imiquimod (NS)	No reoccurrences were seen while on imiquimod treatment, however, all K lesions reoccurred within 4 weeks of stopping the treatment.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGS, silicone gel sheet; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional cryosurgery; ILS, intralesional steroid; IL, intralesional; Exc, excision; ELExc, extralesional excision; ELEXc, extralesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate

TABLE 51-17 — Monotherapy and Polytherapy Published Clinical Trials: Mitomycin C Treatment Modality

Mitomycin C	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Polytherapy</i>										
Sanders ¹⁶⁶	4	Comparative	Exc & mitomycin C & vitamin A & C & ILS vs Exc & vitamin A & C & ILS	K	15 patients (majority African American descent) with ≥2 K scars in the head / neck region, no exclusion criteria stated	Scar overall appearance / reoccurrence	Exc: to 2 lesions (same patient), 1 wound treated with mitomycin C before skin closure, vitamin A&D ointment to each wound: 3/day for 7 days, ILS (TA 40 mg/mL): 1/month for ≤6 months	0-28 months (prospective)	-Exc & mitomycin C & vitamin A & C & ILS, +Exc & vitamin A & C & ILS (NS)	The study demonstrated no significant difference between K scars treated with Mitomycin C applied topically after excision in preventing re-occurrence in the same individual.
Talmi ²¹⁹	4	Case-series	Exc & mitomycin C	K	8 patients (?ethnicity or skin type) with various K scars, no exclusion criteria stated	Scar overall appearance, patient satisfaction & scar thickness	Exc & wound treated with single 5-FU treatment	≤14 months (prospective)	+Exc & mitomycin C (NS)	Mitomycin C following scar excision appears to be an effective treatment of K scars. All patients were satisfied with the results, although complete K disappearance was evident in only 2 patients at 2 months.
Stewart ²²⁰	4	Case-series	Exc & mitomycin C	K	10 patients (majority darker-skinned individuals) with head / neck K scars, no exclusion criteria stated	Scar overall appearance / reoccurrence	Exc & wound treated with single 5-FU treatment	≤14 months (retrospective)	+Exc & mitomycin C (NS)	Topical application of mitomycin C was found to be effective for the prevention of K scarring in the head and neck, with a success rate here of 90%.
Bailey ²²⁶	4	Case-series	Exc & mitomycin C	K	10 patients (various ethnicities) with a range of K scars, excluded if pregnant or planning to conceive	Scar overall appearance	Exc (shave-removed), mitomycin C: applied before skin closure (for 3 mins) & repeated after 3 weeks	6 months (prospective)	+Exc & mitomycin C (NS)	A satisfactory outcome was achieved in 80% of patients. This new treatment was effective in the majority of patients but further studies are needed to confirm the benefit.

RCT, randomized controlled trial, NS, not significant, +, positive, -, negative, SG, silicone gel, SGS, silicone gel sheet, SGC, silicone gel cushion, HT, hypertrophic, K, keloid, PDL, pulsed dye laser, IPL, intense pulsed light, SC, silicone cream, ?, no data found, CS, cryosurgery, ILCS, intralesional cryosurgery, IL, intralesional steroid, IL, intralesional, Exc, excision, ILExc, intralesional excision, ELEXC, extralesional excision, RXT, irradiation, 5-FU, 5-fluorouracil, IFN, interferon, MP, methylprednisolone acetate, TA, triamcinolone acetonide, BM, betamethasone sodium phosphate.

TABLE 51-18—Monotherapy and Polytherapy Published Clinical Trials: Pressure Treatment Modality

Pressure	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
<i>Monotherapy</i>										
Harte ⁹¹	2	RCT	Pressure therapy & SGS vs pressure therapy	HT	22 Caucasian patients with HT burn scars, excluded other scar types, presence of an infection or skin condition	Scar height, vascularity, pliability & pigmentation	Pressure therapy: pressure garment, SGS: applied under the garment for 23 hrs/day	6 months (prospective)	Pressure therapy & SGS = pressure therapy alone	No significant differences were established at 12 or 24 weeks between the two treatment groups, however both groups showed a general decrease in their group scar scores. Evidence here is inconclusive and a larger scale rCT is required.
<i>Polytherapy</i>										
Omranifard ¹⁴⁸	2	RCT	PDL vs ILS & pressure vs erbium laser	HT	120 patients (Fitzpatrick skin scale III) with HT scars ≥4cm long, <1 year old, excluded if received previous treatment within last 6 months	Scar pigmentation, vascularity, pliability & height	PDL/ILS (TA 5–10 mg/mL)/erbium:?: no. of treatments, every 4 weeks pressure therapy: garments	≤12 months (prospective)	+ILS & pressure < +PDL +erbium laser	All three groups significantly improved post treatment, but the results in the PDL and erbium laser treatment groups was significantly higher than the ILS & pressure group.
Harte ⁹¹	2	RCT	Pressure therapy & SGS vs pressure therapy	HT	22 Caucasian patients with HT burn scars, excluded other scar types, presence of an infection or skin condition	Scar height, vascularity, pliability & pigmentation	Pressure therapy: pressure garment, SGS: applied under the garment for 23 hrs/day	6 months (prospective)	Pressure therapy & SGS = pressure therapy alone	No significant differences were established at 12 or 24 weeks between the two treatment groups, however both groups showed a general decrease in their group scar scores. Evidence here is inconclusive and a larger scale rCT is required.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGS, silicone gel sheet; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCS, intralesional steroid; IL, intralesional; Exc, excision; ILExc, intralesional excision; EExc, extrallesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

description of the randomization technique. Pressure garments were tailor-made and worn for 23 hours a day, with silicone underneath dependent on therapy group. Scar assessment was completed using a validated form of the VSS and size measurements. No significant difference was established after 12 or 24 weeks of therapy.

Different types of polytherapy have been evaluated incorporating pressure therapy. The only additional RCT (LOE-2)¹⁴⁸ (described previously) supports the therapeutic role in combination with ILS, even though other modalities performed better. All level 4 evidence advocates the role of positive pressure treatment for the management of problematic scarring, for example after surgical excision alone,^{188,218} intralesional injections^{168,172} or a range of adjuvant therapies.^{85,86,168,174,176,177,201,221,223}

Others

Many other therapeutic options have been examined in the past twenty years in single and polytherapy studies, those that have been trialled as mono therapies are discussed individually here (Table 51-19 and its electronic version). Bleomycin is an antineoplastic agent, which has been used for other dermatologic conditions for many years, such as plantar warts. Bleomycin is not injected but instead dripped onto scars and the skin is then punctured to allow penetration through the dermis.^{133,288} In a comparative study (LOE-4),¹³³ bleomycin proved useful to therapeutically manage small lesions with similar results to CS and ILS but had significantly better results when treating large ($>100 \text{ mm}^2$) HT and keloid scars. Additionally, a case-series study (LOE-4)²⁸⁸ found equally positive results.

Calcipotriol has an anti-inflammatory influence, it actively stimulates keratinocyte differentiation, inhibits keratinocytes proliferation and suppresses the number of epidermal Langerhans cells and their antigen-presenting function.²⁸⁹⁻²⁹¹ One double-blinded RCT (LOE-2)²⁹¹ of 30 bilateral mammoplasty patients found that the application of topical calcipotriol to healing wounds did not prevent HT scar formation after 3 months therapy.

Research has demonstrated close links between tension levels and an increased scar tissue formation.^{183,292,293} Fibroblast mechanical tension induces signal transduction and cell proliferation, growth factor production and collagen synthesis.²⁹⁴ In particular longitudinal stretching, parallel to the axis of the wound stimulates the hypertrophic process.²⁹⁵ Atkinson (LOE-2)²⁹⁶ found that paper taping was effective at reducing scar tension and preventing the development of HT scarring when worn continuously for 12 weeks from day 4-6 postoperatively. This was a significant difference and those patients in the control group were 13 times more likely to develop raised scarring. However, this study was weakened by the large number of drop-outs and the lack of blinding for data collection, although quantitative ultrasound measurements were included. Other authors^{295,297} also found that control or elimination

of longitudinal stretching forces by long-term paper taping was an effective preventative treatment. Nevertheless, it must be noted that no untreated control scars developed hypertrophy in the Widgerow²⁹⁷ study either.

Occlusive dressings provide three main polytherapy components: scar support, hydration and light pressure therapy, all of which have been highlighted previously in the text.^{83,183,297} A number of studies have been examined which indicate that occlusive dressings alone provides equal,⁹⁶ better¹⁰⁷ or worse⁹⁷ results than similar SGS products. Philips (LOE-2)²⁹⁸ determined that hydration of keloids and HT scars by a hydrocolloid dressing resulted in statistically significant symptomatic improvement, but no change in physical scar parameters when compared to daily liquid moisturization. Although the study was small and no clear blinding or randomization was documented. Some evidence has reported that intralesional botulinum toxin (Botox) type A can relax muscle tension in a healing wound and could affect fibroblast cell cycle distribution in HT scars.²⁹⁹ Two studies (LOE-4)^{300,301} evaluated the effect of Botox type A. Three monthly injections were received and therapeutic satisfaction, erythema, symptoms and pliability were recorded. After 6 months, satisfaction was very high and all HT scar parameter were significantly improved, however no blinding was reported³⁰¹. Another smaller study (n=12)³⁰⁰ in keloid scars demonstrated peripheral regression in all lesions, decreased height and no recurrences after a year.

Tranilast (N-antranilic acid) is a selective inhibitor of collagen synthesis. This is available in an oral medication form but selective distribution into raised scar tissue is impossible. Therefore, when transdermal iontophoretic delivered tranilast was administered to HT and K scars, the results were more beneficial than oral treatment for relieving pain and itch³⁰². Pentoxifylline is a methylxanthine phosphodiesterase inhibitor and has been tested as a potential anti-fibrotic agent. It is reported to have a direct effect on inhibiting proliferation of burn scar fibroblasts and fibroblast-populated collagen lattice contraction^{303,304}. In clinical trials (LOE-4)³⁰⁴ it was noted that the extensibility and elasticity of scars can be increased with intralesional pentoxifylline.

Captopril has previously been demonstrated to be effective at preventing HT scar formation in animal studies by inhibiting angiotensin-converting enzyme in the skin, which could essentially suppress TGF-b1 and the release of interleukin-6. This can block fibroblast proliferation, collagen production and precipitate matrix metalloproteinase activity.³⁰⁵ When captopril 5% cream was applied to HT and keloid hand scars twice daily for 6 weeks, a 7mm reduction in scar height was noted and redness and itch were eliminated³⁰⁵. Other authors (LOE-2:1, LOE-4:5) have also examined and supported the use of scar massage¹²⁰, topical onion extract,^{73,162} additional vitamins A plus C¹⁶⁶, E⁷⁹ and other active extracts²⁹⁷ compounds as various forms of the multi-modal approach to scar management.

TABLE 51-19—Monotherapy and Polytherapy Published Clinical Trials: Other Treatment Modalities

Other	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Monotherapy										
Vander Veer ²⁹¹	2	RCT	Calcipotriol vs placebo	HT	30 female patients (?ethnicity or skin type) undergoing bilateral reduction mammoplasty, excluded if had a current/planned pregnancy in next year or post-operative complications (i.e. infection)	Scar overall appearance, thickness & biopsy sampling	Cream:10 days to 3 months post-operative, 2/day application	1 year (prospective)	-Calcipotriol (NS)	No significant difference was observed in the prevalence of HT scars treated with calcipotriol or placebo ointment. A strong association between keratinocytes activation and HT scar formation ($p=0.001$) was recorded.
Wigger-Alberti ¹⁰⁷	2	RCT	SGS vs poly-urethane dressing	HT	60 patients (?ethnicity or skin type) with HT scars $\geq 60\text{mm}$ long, extensive exclusion criteria including K scarring and other treatments in the last 2 months	Scar overall appearance, color, matte/shiny, contour, distortion & texture	SGS/dressing: 23-24 hrs/day for 3 months to half of scar	3 months (prospective)	+polyurethane dressing > +SGS	Both regimes demonstrated a significant reduction in the clinical HT scar signs over 3 months. However, the polyurethane dressing was significantly better at reducing the clinical signs at 4 and 8 week reviews and was tolerated more than the SGS.
Phillips ²⁹⁸	2	RCT	Hydrocolloid occlusive dressing vs moisturizer	HT & K	20 patients (?ethnicity or skin type) with existing long standing HT or K scars, no exclusion criteria stated	Scar size, volume, pigmentation, vascularity, pliability, height, symptoms & oxygen	Dressing: continuous for 8 weeks Moisturizer: 1/day application	3 months (prospective)	+Hydrocolloid occlusive dressing (NS) +Moisturizer (NS)	Itching significantly reduced ($p<0.03$), pain decreased ($p<0.08$) and pliability increased 10% for both treatment groups over 2 months. The authors proposed that an improved hydration may account for the symptomatic relief observed.

(Continued)

TABLE 51-19—Monotherapy and Polytherapy Published Clinical Trials: Other Treatment Modalities (Continued)

Other	LOE	Study Design	Evaluated Treatment	Scar Type	Participants	Primary outcome measure	Treatment regime	Assessment period	Outcome	Principal conclusions
Atkinson ²⁹⁶	2	RCT	Paper tape vs untreated control	HT	70(Caucasian) patients post caesarean section, excluded allergy sensitive to tape, developed post-operative wound complication, history of K scarring, had comorbidities or medication known to affect wound healing	Scar depth, size & volume	Tape: 12 weeks continuous treatment from day 4-6 post-operatively	6 months (prospective)	+Paper tape	Paper tape was an effective modality for the prevention of HT scarring by reducing scar tension. At 12 weeks there was a significant difference between treatment groups ($p=0.003$) and scar volume. Patients in the control group were 13 times more likely to develop a HT scar than the treatment group.
De Oliveira ⁹⁶	2	RCT	SGS vs placebo sheet vs untreated control	HT & K	26 patients (?ethnicity or skin type) with 41 HT or K scars, excluded if radiation or steroid therapy in previous 12 months, or lesion <3 months old	Scar size, coloured, induration & symptoms	Sheet: 24 hrs/day	4.5 months (prospective)	+SGS +placebo sheet	Significant reduction in parameters for silicone and control sheet groups compared to the control scars. No significant difference identified between silicone and control sheet groups.
Momenti ⁹⁷	2	RCT	SGS vs placebo sheet	HT	38 patients (?ethnicity or skin type) HT burn scars, excluded if wound infection, open wound or sensitivity to SGS	Scar pigmentation, vascularity, pliability & symptoms	Sheet:12-24 hrs/day	4 months (prospective)	+SGS	All scar parameters were significantly reduced in the SGS group in comparison to the control region after 4 months, except pain. For HT burn scars, SGS is an effective treatment.
Li-Tsang ¹²⁰	2	RCT	SGS & massage vs massage	HT	45 patients (Chinese ethnicity) with post-traumatic HT scars, no exclusion criteria stated	Scar thickness, pigmentation, height, vascularity, pliability & color	SGS:24hrs/day Massage: 15 mins/day for 6 months	6 months (prospective)	+SGS & massage > massage	Significant reductions in scar thickness at 2 and 6 months were noted in the SGS and massage group. Symptoms, pliability and pigmentation also improved with SGS and massage therapy.

<i>Polytherapy</i>									
Palmieri ⁷⁹	2	RCT	SGS vs SGC with added vitamin E	HT & K (?ethnicity or skin type) with HT and keloid scars, no exclusion criteria stated	Scar symptom, color, size & cosmetic appearance	Sheet:10 hrs/ night	2 months (prospective)	+SGC with vitamin E (NS)	SGC with added vitamin E scored better than simple SGS at both 1 and 2 month periods studied
Sawada ⁷⁵	2	RCT	SC with light dressing vs SC with occlusive dressing vs placebo with occlusive dressing	HT & K (?ethnicity or skin type) with HT or K scars, excluded if infected or ulcerated scars	Scar redness, elevation, hardness, itching & symptoms	Cream: 1-2 times/day	3-5 months (prospective)	+SC with occlusive dressing > SC with light dressing	Statistically significant improvement in the SC and occlusive dressing group compared to the SC and light dressing group, with an improvement in redness, tenderness, itching and hardness recorded.
Li-Tsang ¹²⁰	2	RCT	SGS & massage vs massage	HT	45 patients (Chinese ethnicity) with post-traumatic HT scars, no exclusion criteria stated	Scar thickness, pigmentation, height, vascularity, pliability & color	SGS:24hrs/ day Massage: 15mins/day for 6 months	+SGS & massage > massage	Significant reductions in scar thickness at 2 and 6 months were noted in the SGS and massage group. Symptoms, pliability and pigmentation also improved with SGS and massage therapy.

RCT, randomized controlled trial; NS, not significant; +, positive; -, negative; SG, silicone gel; SGS, silicone gel sheet; SGC, silicone gel cushion; HT, hypertrophic; K, keloid; PDL, pulsed dye laser; IPL, intense pulsed light; SC, silicone cream; ?, no data found; CS, cryosurgery; ILCs, intralesional cryosurgery; ILs, intralesional steroid; IL, intralesional; Exc, excision; ILExc, intralesional excision; ELExc, extrallesional excision; RXT, irradiation; 5-FU, 5-fluorouracil; IFN, interferon; MP, methylprednisolone acetate; TA, triamcinolone acetonide; BM, betamethasone sodium phosphate.

DISCUSSION

Keloid and hypertrophic scarring continue to be a challenge for healthcare providers. A wide range of potential treatment approaches and combination therapies have been proposed in the published literature with variable results. Despite the recent advances, a number of current therapeutic modalities for managing dermal scars can be ineffective, costly, and inconvenient, prove painful and have undesirable side-effects^{59,306}. There is therefore, a significant need for further RCT and quantitative systematic analysis of available scar therapies⁶⁰. Many studies examined to date appear to have been poorly designed thus making it difficult to derive conclusions regarding the reliability and transferability to daily clinical practice.

The vast majority of published research in the last twenty years, 116/173 (67%) studies have provided level 4 evidence and only 31 studies were LOE-2 and 10 studies were LOE-3. Treatment comparisons were difficult due to a number of study design flaws. The degree of scar heterogeneity in each single study was poorly controlled, with varying scar ages, types, various scar locations and inconsistencies in reported patient ethnicities^{113,147,166,177}.

Scarring is an individual process; no two scars present or develop the same, even in the same individual with the same exact scar type and age, therefore the extent to which these can be reliably compared is questionable. It is preferable that scar modulation modalities are compared within the same scar under similar external effects (e.g., skin tension and physiologic movement) in separate regions. Although it is acknowledged that this is the ideal and would be perhaps better suited to HT scars which are uniform by nature than keloid lesions. A quantitative assessment of scars using objective measurement tools will be of use in comparing different scars and treatment modalities. Recruitment of large patient numbers with a suitable level of homogeneity may take time especially in a single-site study. Hence, a multisite collaborative approach is likely to be of benefit and this may require significant additional resources and provision of adequate infrastructure³⁰⁷.

Despite the well-defined clinical characteristic differences between HT and keloid scarring, frequently there appears to be misdiagnosis and differences between studies of what is considered a keloid and a HT scar. It is therefore important that future studies would employ clear diagnostic guidelines in the assessment of raised dermal scarring in order to generate uniformity and homogeneity in case selection. Some scars however may be better defined as intermediate lesions as clinically they appear in between keloids and HT scars, this further exemplifies the need for development of an improved scar classification system^{55,60,61,308}.

The long-term follow-up of scar patients is essential, not only to simply determine the overall positive or negative treatment outcome but also to determine the effects

of stopping a treatment intervention. A criticism of many studies reported here was their short duration (less than 1 year) as early outcome measurement is likely to miss a late recurrence. Therefore, treatments evaluated as effective during these short-term studies needs to be viewed with caution. Some authors have acknowledged that when keloid scar therapy was stopped the lesions began to grow again²⁷⁹. Furthermore HT scars may take 2-5 years to mature^{27,60} and therefore even in a long-term follow-up trial, the question can be posed - whether the authors are evaluating the treatment or the natural scar evolution? Length of follow-up may also become more important in the future as healthcare providers look to potentially only fund treatments, which have proven and established long-term efficacy and cost-effectiveness.^{309,310}

In the literature reviewed, there is a need to standardize scar treatment protocols in order to evaluate each treatment at a baseline level. From which, new emerging therapy can be methodically trialled to establish the potential benefit to patients with scars non-compliant to currently available treatments.⁵⁷ Many studies also demonstrate a lack of randomization or they may state that they are randomized but do not provide sufficient details of the technique or the allocation of concealment^{102,144}. For example, the efficacy of silicone products was deemed unclear by the Cochrane Collaborative¹⁰⁵ because of poor study design and a high susceptibility to bias. Studies should recognize and relate their research findings to the Consolidated Standards of Reporting Trials (CONSORT)³¹¹ guidelines to enable transparency documentation of clinical research findings.

There were also a limited number of double-blinded studies for the management of keloid and HT scars. This may be caused by poor initial trial design, limited time, financial resources or a combination of both cannot be fully ascertained here. Placebo treatments are not impossible and could include intralesional saline injections, sham RXT or low-energy laser, which would not be expected to have any clinical effects.⁵⁵ Patient blinding is also important because for example in topical therapy studies, there is a psychological impetus to apply a believed 'active' cream or therapy to both sides or scars which can only be diminished with true placebo blinding. Throughout the normal continuum of tissue repair the resultant scar matures and evolves therefore quantitative analysis is empirically important due to the significance of the ill-defined treatment of raised skin scarring despite the range of therapeutic modalities and high recurrence rates.³¹² Assessments of efficacy need to be standardized and validated in the specific scar group they are being used to evaluate such as the MSS,⁴² VSS,¹¹⁴ Patient and Observer Scar Scale.³¹³ Subjective tools express an overall scar consensus, relying on the personal evaluation by the rater and often the patient. This personal perspective can be manipulated by prejudiced due to many external factors including feelings, beliefs and desires of the individual involved.³¹⁴ Hence it is critical in clinical

evaluation and especially research trials that quantifiable objective measurements are sort to validate treatment efficiency. True objective scientific evaluation encompasses biochemical and histological analysis involving invasive biopsy sampling which results in destruction of the scar under investigation.³¹⁵ Therefore this method has a limited application to the clinical scar population and hence non-invasive techniques are recognized as more

favorable to scar sufferers but can have the tendency to be less quantifiable than invasive methods.³¹⁶ At each stage of this advancement non-invasive objective assessment tools can be utilized to monitor erythema, vascularity, hypertrophy, contracture, flexibility and the overall scar dimensions. This repeated examination process is critical if modulatory therapies are to be appraised rigorously⁶² (Figure 51-7).

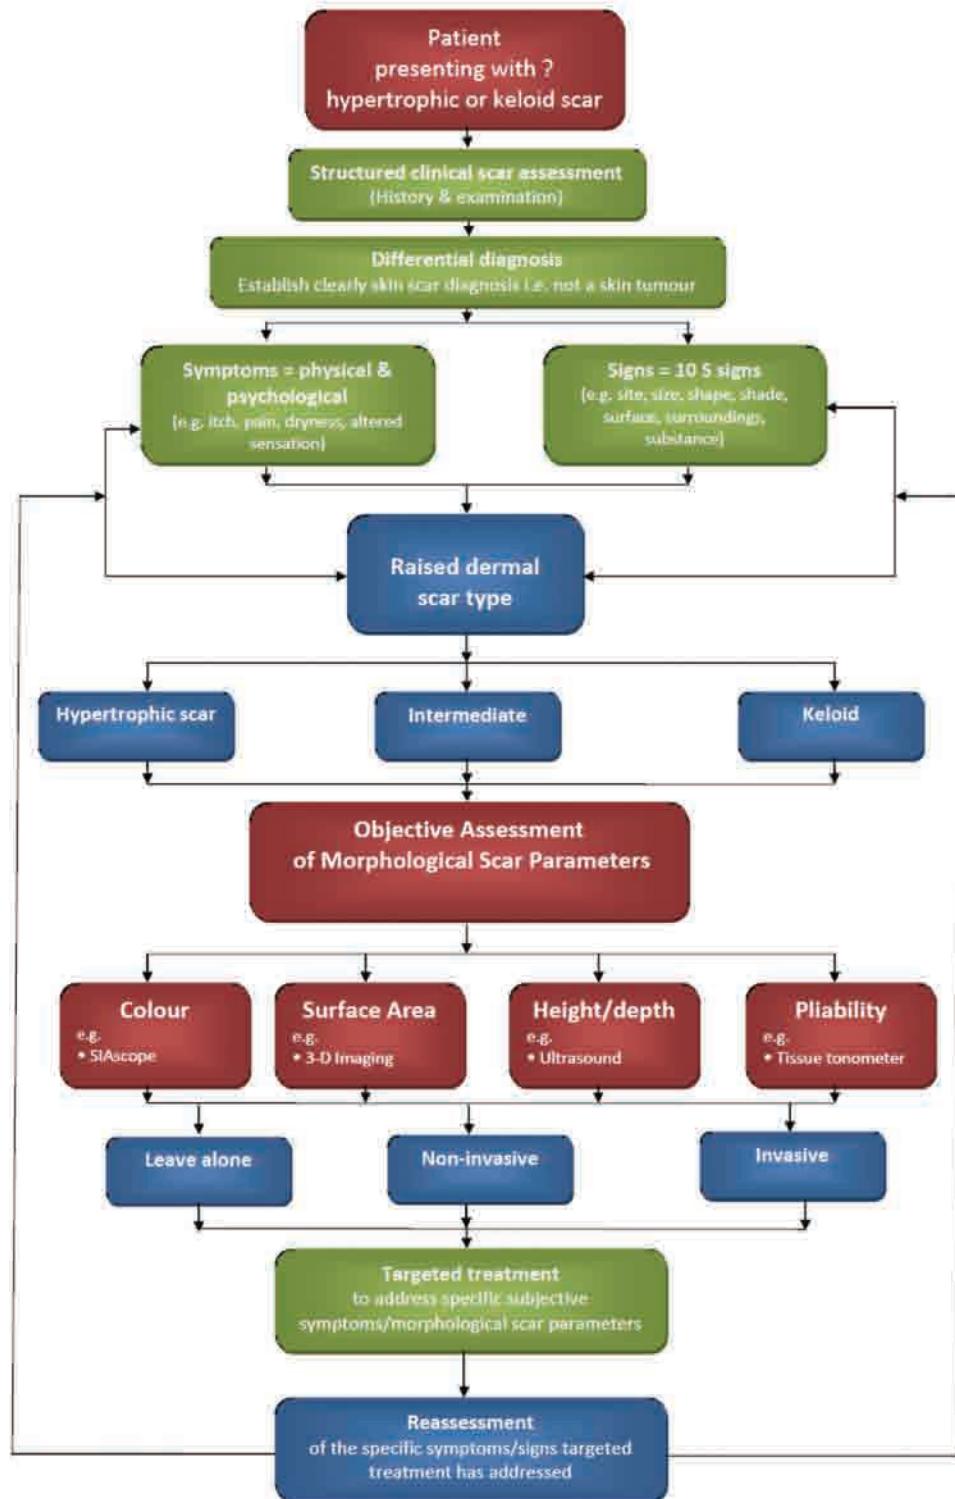

FIGURE 51-7 Flow-chart of the scar assessment process (as practised by the senior author).

In addition, studies evaluated here frequently assessed the outcome parameter of 'scar recurrence' but no clear definition of this subjective parameter was defined^{166,220}. Furthermore if recurrence is inevitable in some severe keloid lesions and the patient accepts this then perhaps a particular 'control' level should also be defined to characterize a 'successful' treatment.^{219,226} This may also relate to more specific therapeutic goals to be achieved depending on the requirements of the patient, for examples cosmesis, function or symptom management. These aspects have been previously suggested to be examined as independent endpoints by some authors.⁵⁵ This standardization of study design practices is essential to the development of quality studies, which can facilitate effective modality cross-comparisons and fundamentally enable meta-analyses to be completed. In the United Kingdom, the National Institute of Health Research (NIHR)³¹⁷ has set up a network of Research Design Services and Local Research Networks to assist clinicians and clinical researchers by providing access to key professional advice to strengthen the quality of new research undertaken and improve applications for government funding. The NIHR national databases may also assist in multi-center collaborations by effectively 'advertising' a study to other interested clinicians.

Advice Based on Current Understanding Scar Formation and Existing Literature

The control and modification of the inflammatory process post dermal injury may decrease raised scar formation. Several treatment modalities exist which can inhibit the inflammatory cascade at different levels, therefore a polytherapeutic approach may diminish scar formation.⁵⁸ However, it must be remembered that skin scarring is often a process, which requires long-term management. It is important that the patient understands the long-term nature and the duration of any treatment administered. In order to ensure compliance and adherence to any treatment regime, it is also important to assess the patient's psychological status before and during the treatment. The ability to commit to any treatment will determine potential response and prognosis and avoid disappointment in high expectation of scar eradication at an early stage (Table 51-20). Following examination of the data presented here, it seems that raised dermal lesions of small dimensions may benefit from intralesional therapy, primarily steroids that are administered via a full course of regular injections over a period of time (current advice is 4 weekly injections until full resolution unless contraindicated). If they fail to improve after a trial period of at least three to 6 months then surgery may be suitable. All surgery of raised dermal scars should be followed up and receive postsurgical adjuvant therapy. The role of neoadjuvant treatment is unclear. It would appear to be beneficial to offer ILS, SGS and pressure therapy post-surgery. Post-excisional radiation

TABLE 51-20

1. The presence of positive family history
2. Previous poor response
3. Multiply recurrent scar
4. Specific anatomical locations (e.g. sternum)
5. Large scar size
6. Irregular, non-geometric scar morphology
7. Prolonged active inflammation
8. Severe symptoms (e.g. tenderness, constant itching)
9. Psychological
10. Social history

appears to be more effective for larger, more severe and resistant lesions and laser therapy may benefit erythematous and symptomatic scars. Occlusive dressings or SGS should be applied early after surgical procedures to reduce hypertrophy and provide dermal support. If occlusive dressings are not used, paper taping may also be beneficial but this must stay in place as long as possible (minimum six weeks) to prevent the negative side-effects of disrupting the permeability barrier, increased transepidermal water loss which can potentially increase scarring⁸¹. There is limited study data for the inclusion of other therapeutic modalities such as IFN, verapamil and mitomycin C. All appear promising areas for further clinical research prior to regular clinical use. Rigorous high quality RCTs (LOE-1) are needed to evaluate these existing therapeutic options, which are currently in wide-scale use without underpinning evidence-base. Other well-designed trials such as large non-randomized controlled studies (LOE-2) and prospective cohort studies (LOE-2) can also significantly increase the quality of available literature.

CONCLUSION

There is a significant lack of existing high quality research for the evaluation of therapeutic management options undertaken in keloid and HT scarring. In the last 20 years, available literature is predominantly classified as level 4 evidence only. A combination of factors appears to have subsequently led to the low quality available research pool at present to base current and future treatment upon. Improved methodological and analytical reporting by authors, in conjunction with an increased compliance of trial reporting guidelines and developments in government health research support services may improve future study design quality.

However, future studies must primarily address the heterogeneity of scarring and the continuum of dermal scar types through an amalgamation and consensus approach. This will undoubtedly require a new sub-classification of both hypertrophic and keloid scars to be developed which bridge-the-gap between the genetic, morphologic, immunohistochemical and clinical characteristics widely observed.

Treatment of Acne (Non-Medical Interventions)

52

Sonal Choudhary, M.D., Michael Shelling, M.D., and Keyvan Nouri, M.D.

INTRODUCTION

Acne is a disease of the pilosebaceous unit characterized by development of both inflammatory and/or noninflammatory lesions that may ultimately result in scarring. The lesions may present as comedones, inflammatory papules, pustules, nodules, and cysts. Four factors are thought to contribute to this multifactorial disease: follicular hyperproliferation with subsequent follicular plugging; excess sebum production; the presence and activity of *Propionibacterium acnes*; and inflammatory response of the tissue. With its conspicuous cosmetic concerns and potential for scarring, acne may frequently have a profound psychological impact on the patient.

EPIDEMIOLOGY

Acne vulgaris is the most commonly occurring dermatologic disease worldwide. In the United States, 60-70% of the population is affected by acne at some point of life.¹ Persons of certain races are affected more than others. The Mediterranean region from Spain to Iran has high prevalence of cystic acne.² During adolescence, acne is more common in males than in females. In adulthood, acne vulgaris is more common in women than in men.³

Rarely, acne vulgaris may affect newborns in the first few weeks of life because of the presence of maternal hormones and the resultant excessive sebum production. The neonate may have small papules and impacted follicles, which may require topical retinoids for clearance; however, this transient condition usually resolves spontaneously.

ETIOLOGY AND DIAGNOSIS

The etiology of acne, as already mentioned, is multifactorial. Along with the four main factors believed to be involved in acne causation, there are new etiologic factors found to be contributory. All the factors are enumerated as below:

- Genetics- The inherited factors that lead to transfer of acne from one generation to the next is the propensity for follicular epidermal hyperproliferation and

subsequent plugging of the follicle.⁴ It is also believed that the size and number of sebaceous glands and their activity level appear to be inherited. The inheritance may not be evident in each generation and skipping of generations is commonly observed. An autosomal dominant pattern of inheritance is suggested, but the high prevalence of acne in general may limit the attribution to this genetic component.

- Retention hyperkeratosis- In individuals with acne, follicular epithelium produces cells at a very rapid rate and these cells are retained leading to plugging of follicles.⁵ It is believed that increased corneocyte cohesiveness also contributes to this accumulation of cells and follicular obstruction.
- Excessive sebum production- Hormones, especially androgens and other chemical mediators, play the key role in modulating sebum production and release.⁶ Around the time of adrenarche, follicular plugging begins to appear in patients with acne. The levels of adrenal androgen and dehydroepiandrosterone sulfate (DHEAS), in prepubertal girls can be correlated to the severity of acne.⁷ Despite normal levels of androgens, both males and females may still develop acne, for which a sebaceous gland hyper-responsiveness to androgens has been proposed.
- Peroxisome proliferator-activated receptors (PPAR) also partly regulate sebum production. Ottaviani et al. demonstrated the possible involvement of lipid peroxides, in particular squalene peroxides, in establishing an inflammatory process in acne.⁸

What is the mechanism by which *Propionibacterium acnes* causes acne?

Propionibacterium acnes (*P. acnes*) is a normal commensal bacteria of the skin, which colonizes the occluded pilosebaceous units. It breaks down the trapped sebum into free fatty acids and peptides triggering an inflammatory response mediated by proinflammatory mediators, which diffuse through the follicle wall. *P. acnes* is also known to activate toll-like-receptors (TLR) on monocytes and neutrophils which leads to the production of proinflammatory cytokines such as interleukins (IL)-12, IL-8 and

tumor necrosis factor (TNF).⁹ Alternatively, it is possible that some individuals are hypersensitive to *P. acnes* and develop an inflammatory response while others do not.¹⁰ Similar to a type IV hypersensitivity reaction, keratinocyte hyperproliferation and acne development seem to be initiated by up-regulation of interferon 1 alpha.¹¹ This is mainly because of the relative deficiency of linoleic acid caused by excess sebum and altered follicular barrier function. This results in production of cytokines that stimulates local endothelial cells, up-regulating inflammatory vascular markers such as E-selectin, vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1), and human leukocyte antigen-DR (HLA-DR) in the perifollicular vasculature of the pilosebaceous unit.

Molecular genetic studies have led to complete sequencing of *P. acnes* genome, which has shown to include lipases. It has been suggested that one function of the *P. acnes* lipase may be to aid colonization within the pilosebaceous follicle by promoting cell adherence to components such as oleic acid.¹² In addition, lipases may help *P. acnes* to breakdown sebum, heat shock proteins that lead to cytokine production, and inflammation. Additional *P. acnes* enzymes increase porphyrin production, which subsequently induces neutrophil chemokine production and accelerated oxidation of squalene in the sebum leading to comedogenesis.

The inflammatory cytokines act on their respective receptors through autocrine and paracrine mechanisms and amplify the signals that activate the activator protein (AP)-1 transcription factor. This further induces matrix metalloproteinase (MMP) genes, the products of which degrade and alter the dermal matrix.¹³ These MMPs include collagenases, gelatinases, stromelysins, and matrilysins.

CONCLUSION

P. acnes acts on sebum, releasing free fatty acids and peptides, which trigger inflammation in the follicle by means of several receptors and mediators.

What is the biofilm hypothesis and what is its importance in acne?

In the pathogenesis of *P. acnes*, a biofilm hypothesis has been proposed, which has suggested that bacteria residing within the follicles actually grow as a biofilm. These biofilms consist of an aggregate of bacterial microorganisms, which grow within an extracellular polysaccharide substance. Although *P. acnes* biofilms have not been observed directly in the pilosebaceous unit, it has been shown that *P. acnes* readily forms a biofilm in vitro as well as on various medical devices in vivo. In addition, sessile *P. acnes* demonstrate high levels of resistance, increased production of virulence factors, and quorum-sensing molecules which lend further

support to this hypothesis.¹⁴ The extracellular matrix consisting of lipoglycans and polysaccharides may provide a protective barrier against host defenses.¹⁵

CONCLUSION

Biofilm hypothesis has a role to play in acne development and while developing newer therapies of acne, this concept should be considered.

Do fats, chocolate and dirt increase acne?

Fatty acids are commonly thought to cause acne, and thus studies have been done to find their role in acne aggravation. Simopoulos et al.¹⁶ demonstrated that the ratio of omega-6 to omega-3 fatty acids in Western diets is commonly 10:1, while that in Japan is 4:1 and 2:1 in ancient civilizations. Omega-6 fats are proinflammatory mediators and are increased in inflammatory acne¹⁷ and high levels omega-3 fats have been shown to lower inflammatory markers.¹⁸

Chocolate consumption increases blood lipid levels and can supposedly lead to sebum production which is "less fluid" in consistency. This may be the reason for subsequent pilosebaceous follicle obstruction, follicle rupture, and inflammatory changes. Studies by Anderson and Grant¹⁹ and another by Anderson²⁰ have been conducted to understand the association between acne and cocoa intake. Unfortunately, these studies are limited by their lack of control groups and quantitative statistical analyses. Fulton et al.²¹ tried to overcome these limitations in their study but their findings could not conclusively establish an association.

Decrease in perspiration can reduce the growth of *P. acnes*.²² One small pilot study by Short et al. demonstrated a trend toward an increase in truncal acne lesion counts in the individuals from the exercising group.²³

The common misconception that dirt causes acne can cause people to wash too much or too often, which may actually worsen acne because of irritation of acne-prone skin. In addition, excessive washing can stimulate sebaceous glands to produce more oil resulting in more acne breakouts.

CONCLUSION

Although there have been a variety of hypothesis proposed, there is currently insufficient evidence to clearly demonstrate a role of chocolates and high fatty diets in the development of acne. Additionally, patients must be advised that there is a common misconception that dirt causes acne to develop. It is important to clarify this notion to prevent excessive or vigorous washing, which actually can worsen the irritation and even increase sebaceous gland production.

What is the role of IGFs and diets with high glycemic index in the development of acne?

Besides androgens, insulin like growth factors (IGF) that regulate the activity of the sebaceous glands may also contribute to acne formation.²⁴ Acne is proposed to be an IGF-1-mediated disease with smoking and diet believed to increase the insulin/IGF1-signalling. In human skin appendages, the strongest expression of IGF-1 protein was found in maturing sebocytes and suprabasal cells of sebaceous ducts.²⁵ A correlation between the mean facial sebum excretion rate and serum IGF-1 levels has been demonstrated in postadolescent acne patients.²⁶ Interestingly, metformin treatment and diets low in milk protein content and glycemic index seem to reduce this increased IGF-1 signaling. Persistent acne in adulthood with high IGF-1 levels may be considered as an indicator for increased risk of cancer, which may require appropriate dietary intervention as well as treatment with insulin-sensitizing agents.²⁴

Diets rich in carbohydrates with a high glycemic index have been implicated in aggravation of acne. This is mediated through the associated hyperglycemia, reactive hyperinsulinemia and increased formation of IGF-1. Conversely, diets with low glycemic load have shown to decrease serum IGF-1 levels and significantly improved acne in 12 weeks.²⁷ In addition, western diets in general have a high glycemic index. The low glycemic diets and lack of consumption of dairy products in 1200 Kitavan islanders of Papua New Guinea and 115 Aché hunter-gatherers of Paraguay are believed responsible for the absence of acne cases altogether in this population.²⁸ Skim milk consumption and acne have also been related and a strong association between intake of skimmed milk and acne was demonstrated in boys.²⁹ In fact, cow's milk has shown to contain high levels of IGF-1 even after pasteurization, homogenization and digestion. Due to the homology of the amino acid sequence between bovine and human IGF-1, the bovine IGF-1 can bind to human IGF-1 receptor and produce the same effects as human IGF-1.³⁰ Milk consumption increases circulating IGF-1 by 10-20% in adults and by 20-30% in children. In addition, it raises the ratio of IGF-1/IGF binding protein-3 making IGF-1 more bioavailable.

High saturated fat diets may also increase IGF-1 levels and low fat and high fiber diets decrease the concentration of IGF-1³¹ and androgens³² and increase concentration of sex hormone-binding globulin (SHBG).

CONCLUSION

Diets with increased glycemic index can cause increased activity of sebaceous glands by production of IGFs. There is some evidence that milk may increase acne.

SEARCH METHODOLOGY

The search methodology for compiling this chapter comprised of articles and reviews from Pubmed central,

Medscape, and emedicine online. For gathering information regarding procedures, multiple textbooks were referred.

MANAGEMENT

Chemical Peels:

Table 52-1 is an evidence based table summarizing the non-medical modalities used in management of acne. Table 52-2 presents a **Strength of Recommendation for these modalities**.

Are chemical peels effective in treatment of acne?

Chemical peels constitute nonlaser therapeutic options for superficial exfoliation. They aid in hastening the process of resolution of comedones by their transition to superficial epidermis, which otherwise takes between 2-6 weeks to resolve.³³ Chemical peels because epidermolysis of the stratum granulosum layer and the degree of this effect depends on the pH and the concentration of the product used.^{34,35} This results in improved elasticity of stratum corneum as new cells are produced and stimulate collagen production in superficial dermis.³⁵

The most commonly used chemical peel is glycolic acid, an alpha-hydroxy acid, which is available as a facial wash and can be used at home or in the office for procedures performed by the dermatologist. As discussed above, the patient's acne preferably should be of comedonal type and patients should not be on oral retinoids, as this may aggravate the irritation with the peels. In patients with no current medical acne regimen, appropriate topical antibiotic and /or topical retinoid should be supplemented. With the glycolic acid peel, the aim is to penetrate down to the stratum granulosum layer, indicated by "frosting" of the skin, achieved 2 and 10 minutes after application. This implies epidermolysis and detachment from the papillary dermis.^{36,37} The acid is then neutralized with a buffered bicarbonate solution or cool water to prevent any deeper peeling. Atzori et al. demonstrated the efficacy of the glycolic acid peel in a study by on 80 females undergoing 70% glycolic peels every 10 days for six or more treatments.³⁸ The most rapid improvement was observed in comedonal acne. In papulo-pustular forms, an average of six applications was necessary. Although nodular-cystic forms required eight to ten applications, a significant improvement of the coexisting postacne superficial scarring was noted. The procedure was well tolerated and patient compliance was excellent.

Salicylic acid peels are performed as in-office procedures with 20% to 30% concentration and for home use with concentration 0.5% to 10%.³⁹ Although the regimen is very similar to that used for glycolic acid, salicylic acid precipitates on the skin, leaving behind the white frost to

TABLE 52-1—Evidence Based Table for Various Non-Medical Interventions in the Treatment of Acne Vulgaris

Investigators	Objective	Methods	Results/Conclusions	Level of Evidence
Chemical Peels				
Ilknur et al ¹	To compare the therapeutic effects of glycolic acid (GA) peels and amino fruit acid (AFA) peels in patients with acne vulgaris	Single-blind, randomized, right-left comparison study, 24 patients received 12 serial peels (GA and AFA, at concentrations from the lowest to the highest) on the two halves of the face at 2-week intervals for 6 months	There was a statistically significant decrease in the number of non-inflamed lesions with GA following the first month and with AFA following the second month ($p < 0.05$). The decrease in the number of inflamed lesions was statistically significant with GA at the end of the fifth and sixth months and with AFA only at the end of the fifth month ($p < 0.05$). When the two applications were compared with each other, there was not a statistically significant difference in terms of non-inflamed and inflamed lesions ($p > 0.05$). Compared to a GA peel, an AFA peel was less irritating and better tolerated.	2B (due to single blinding-low quality RCT)
Kessler et al ²	To compare the efficacy of alpha- and beta-hydroxy acid chemical peels in the treatment of mild to moderately severe facial acne vulgaris.	Twenty patients were recruited in this split-face, double-blind, randomized, controlled study. An alpha-hydroxy acid (30% glycolic acid) was applied to one-half of the face and a beta-hydroxy acid peel (30% salicylic acid) was applied contralaterally every 2 weeks for a total of six treatments. A blinded evaluator performed quantitative assessment of papules and pustules.	Both the chemical peels were significantly effective by the second treatment ($p < .05$) and there were no significant differences in effectiveness between the two peels. At 2 months post-treatment, the salicylic acid peel had sustained effectiveness. More adverse events were reported with the glycolic acid peel after the initial treatment.	1B
Microdermabrasion				
Lloyd JR ³	To evaluate the use of microdermabrasion for the treatment of acne	Twenty-five patients with grade II-III acne received eight microdermabrasion treatments at weekly intervals. All patients were under dermatologic care and were maintained on their acne medications throughout the study.	Thirty eight percent (9/24) of the 24 patients who completed the study demonstrated excellent results, 34% (8/24) good results, 17% (4/24) fair results, and 12% (3/24) poor results. Ninety-six percent (23/24) of patients were pleased with their peer results and would recommend this procedure to others.	2B
Karimipour et al ⁴	To review the relevant literature and to evaluate the clinical efficacy of microdermabrasion in skin care.	Used an evidence-based approach	Role of microdermabrasion in acne is very limited.	2A
532 nm KTP Laser				
Baugh and Kucaba ⁵	To study the safety and efficacy of the potassium titanyl phosphate (KTP) 532 nm pulsed laser for the treatment of acne vulgaris.	Twenty-six subjects, clinically evaluated with moderate facial acne, were enrolled in this single-center prospective trial. The entire facial area for each subject was divided in half and randomly designated as either a treatment or a control side. Each subject was treated with four laser exposures using a KTP 532 nm laser with continuous contact cooling.	Primary outcome analysis in the Michaësson acne severity score demonstrated a mean 34.9% ($p = .011$) and 20.7% ($p = .25$) reduction at the 1-week and 4-week post-final treatments, respectively. Subjective investigator evaluations of overall percent satisfaction indicated that all patients demonstrated a minimum 50% overall satisfaction in treatment outcomes at the 4-week follow-up period. No side effects were encountered.	2B

(Continued)

585 nm Pulsed Dye Laser			
Leheta ⁶	To evaluate the role of the pulsed dye laser in the treatment of acne in comparison with other topical therapeutic modalities.	Forty-five patients were randomly divided into three groups: group A received treatment with pulsed dye laser therapy every 2 weeks, group B received topical preparations and group C was subjected to chemical peeling using trichloroacetic acid 25%.	At 12 weeks of treatment, there was a significant improvement of the lesions within each group with the best results seen in group A; however, no significant difference was detected between the three treatment protocols after the treatment period. Remission in the follow-up period was significantly higher in the first group.
Karsai et al ⁷	To assess the efficacy of an adjuvant PDL treatment when combined with a proven topical treatment [fixed-combination clindamycin 1%-benzoyl peroxide 5% hydrating gel (C/BPO)].	Eighty patients (38 males and 42 females) were randomized in a 1:2 ratio to receive C/BPO alone or in combination with PDL treatment (wavelength 585 nm, energy fluence 3 J cm(-2), pulse duration 0.35 ms, spot size 7 mm).	Both groups showed a significant improvement during observation [Investigator's Static Global Assessment (ISGA) 27.1% (C/BPO) and 24.6% (C/BPO + laser), total lesion count 9.2% and 9.0%, inflammatory lesion count 36.3% and 36.9%, Dermatology Life Quality Index (DLQI) 54.5% and 42.5%], but there was no significant or otherwise appreciable difference between treatment modalities as far as the extent of improvement was concerned. Patients with more severe findings at baseline had a greater benefit from either therapy regimen.
Jung et al ⁸	To compare the efficacy and safety of PDL and of combined 585/1,064-nm laser treatment for mild to moderate facial acne in a randomized, prospective, split-face, double-blind study.	Sixteen participants with mild to moderate acne were treated with a single pass of a combined 585/1,064-nm laser on half of the face and PDL on the other half during each treatment session. Patients underwent three treatment sessions at 2-week intervals and were followed up at 8 and 12 weeks after treatment commencement.	At the final visit, inflammatory acne lesions were reduced by 86% on the PDL sides and by 89% on the 585/1,064-nm laser sides. Noninflammatory acne lesions showed corresponding reductions of 69% and 64%, respectively. A significant difference between the two treatments was observed for noninflammatory acne lesions at the eighth week. Histopathologic examinations showed that both treatments decreased inflammation and interleukin-8 expression and increased transforming growth factor beta expression.
Seaton et al ⁹	To compare the efficacy and tolerability of such PDL treatment with sham treatment in patients with facial inflammatory acne in a double-blind, randomized controlled trial.	Forty-one adults with mild-to-moderate facial inflammatory acne. We randomly assigned patients to PDL (n=31) or sham treatment (n=10). Treatment was given at baseline and patients were seen after 2, 4, 8, and 12 weeks.	After 12 weeks, acne severity (measured by Leeds revised grading system) was reduced from 3.8 (SD 1.5) to 1.9 (1.5) in the PDL group and 3.6 (1.8) to 3.5 (1.9) in the sham group ($p=0.007$). Treatment was well tolerated. Total lesion counts fell by 53% in PDL patients and 9% in controls ($p=0.023$), and inflammatory lesion counts reduced by 49% in PDL patients and 10% in controls ($p=0.024$).
Orninger et al. ¹⁰	To evaluate the clinical efficacy of pulsed dye laser therapy in the treatment of acne in a randomized, single-blind, controlled, split-face clinical trial.	Forty patients aged 13 years or older with facial acne received 1 or 2 nonpurpuric pulsed dye laser treatments to half of the face (fluence of 3 J/cm ²), serial blinded clinical assessments (lesion counts), and grading of acne severity using standardized bilateral serial photographs.	After 12 weeks, there were no significant differences between laser-treated and untreated skin for changes in mean papule counts (-4.2 vs. -2.2 ; $P=.08$), mean pustule counts (0 vs. -1.0 ; $P=.12$), or mean comedone counts (2.9 vs. 1.6 ; $P=.63$). Grading of serial photographs confirmed the clinical assessments, showing no significant mean differences in Leeds scores (range, 1-12) for treated skin (3.98 [0.32] at baseline and 3.94 [0.27] at week 12) compared with untreated skin (3.83 [0.32] at baseline and 3.79 [0.28] at week 12) ($P>.99$).

TABLE 52-1—Evidence Based Table for Various Non-Medical Interventions in the Treatment of Acne Vulgaris (Continued)

Investigators	Objective	Methods	Results/Conclusions	Level of Evidence
Visible Light				
Papageorgiou et al. ¹¹	To evaluate the use of blue light (peak at 415 nm) and a mixed blue and red light (peaks at 415 and 660 nm) in the treatment of acne vulgaris in a	One hundred and seven patients with mild to moderate acne vulgaris were randomized into four treatment groups: blue light, mixed blue and red light, cool white light and 5% benzoyl peroxide cream. Subjects in the phototherapy groups used portable light sources and irradiation was carried out daily for 15 min.	After 12 weeks of active treatment a mean improvement of 76% (95% confidence interval 66-87) in inflammatory lesions was achieved by the combined blue-red light phototherapy; this was significantly superior to that achieved by blue light (at weeks 4 and 8 but not week 12), benzoyl peroxide (at weeks 8 and 12) or white light (at each assessment). The final mean improvement in comedones by using blue-red light was 58% (95% confidence interval 45-71), again better than that achieved by the other active treatments used, although the differences did not reach significant levels.	1B
Goldberg and Russell ¹²	To assess the efficacy of this combination phototherapy	Twenty-four subjects, Fitzpatrick skin types II-V, with mild to severe symmetric facial acne vulgaris were recruited for the study. Subjects were well matched at baseline in terms of both age and duration of acne. Subjects were treated over eight sessions, two per week 3 days apart, alternating between 415 nm blue light (20 minutes/session, 48 J/cm ²) and 633 nm red light (20 minutes/session, 96 J/cm ²) from a light-emitting diode (LED)-based therapy system. Patients received a mild microdermabrasion before each session.	At the 4-week follow-up, the mean lesion count reduction was significant at 46% ($p=0.001$). At the 12-week follow-up, the mean lesion count reduction was also significant at 81% ($p=0.001$). Side effects were minimal and transitory. Comedones did not respond as well as inflammatory lesions.	2B
Na and Su ¹³	To assess the efficacy of red light phototherapy with a portable device in acne vulgaris in a split-face randomized-controlled single-blinded trial	Twenty-eight volunteers with mild-to-moderate acne were enrolled. The right or left side of the face was randomized to treatment side and phototherapy was performed for 15 minutes twice a day for 8 weeks.	The percent improvement in noninflammatory and inflammatory lesion counts of the treated side was significant compared to the control side ($p<.005$). Visual Analog Scale decreased from 3.9 to 1.9 on the treatment side and the difference between the treatment and control sides was significant at week 8 ($p<.005$), suggesting that red light has the potential for being used as a single treatment for acne.	2B
1450 nm Diode Laser				
Jih et al ¹⁴	To evaluate the dose response of a 1450-nm diode laser for treatment of facial acne, sebum production, and acne scarring utilizing two laser fluences and to determine long-term remission after laser treatment.	Twenty patients (Fitzpatrick skin phototypes II-V) received 3 treatments using the 1450 nm diode laser (3-4 week intervals). Split face comparisons were performed by randomizing patients to one of two fluences (14 or 16 J/cm ²) on the right or left side of the face.	Percentage reductions in mean acne lesion counts from baseline were 42.9% (14 J/cm ²) and 33.9% (16 J/cm ²) after one treatment and 75.1% (14 J/cm ²) and 70.6% (16 J/cm ²) after 3 treatments. There was persistent reduction of 76.1% (14 J/cm ²) and 70.5% (16 J/cm ²) at the 12-month follow-up ($P < .01$). Both objective and subjective improvements in acne scarring and sebum production were noted. Treatment-related pain was well tolerated, and adverse effects were limited to transient erythema and edema at treatment sites.	1B

Photodynamic Therapy	Riddle et al ¹⁵	A non-critical review is presented of a PubMed search for studies examining PDT in the treatment of acne vulgaris.	The authors found 21 clinical trials and case series of various designs. Eight studies employed a split-face design comparing photosensitizer to placebo, no treatment or another photosensitizer. Two trials used three test spots and one control spot per patient. Three studies utilized control subjects receiving no photosensitizer with or without light therapy. All 21 studies reported a reduction in inflammatory lesions and/or a significant improvement in acne. The light sources utilized included blue light, pulsed-dye laser (PDL), intense pulsed light (IPL) and red light. Studies comparing the use of PDT to light therapy alone demonstrated greater improvement in treatment groups pretreated with a photosensitizer.	2A
Orringer et al ¹⁶	To examine the efficacy of PDT using 5-aminolevulinic acid (ALA) and pulsed dye laser therapy in the treatment of acne in a randomized, controlled, split-face, single-blind clinical trial.	Forty-four patients with facial acne were randomized to receive three pulsed dye laser treatments to one side of the face after a 60-90 min ALA application time, while the contralateral side remained untreated and served as a control.	Global acne severity ratings improved bilaterally with the improvement noted to be statistically significantly greater in treated skin than in untreated skin. Erythematous macules (remnants of previously active inflammatory lesions) decreased in number in treated skin when compared with control skin and there was a transient but significant decrease in inflammatory papules in treated skin when compared with untreated skin. There were no other statistically significant differences between treated and untreated sides of the face in terms of counts of any subtype of acne lesion. Thirty percent of patients were deemed responders to this treatment with respect to improvement in their inflammatory lesion counts, while only 7% of patients responded in terms of noninflammatory lesion counts.	1B
Hörfelt et al ¹⁷	To investigate the efficacy and tolerability of MAL-PDT for treatment of moderate inflammatory facial acne in a blinded, prospective, randomized, placebo-controlled multicentre study.	Thirty patients aged 15-28 years with moderate to severe acne were enrolled. Each side of each patient's face was randomly assigned to treatment with MAL (160 mg/g) or placebo cream, applied for 3 h prior to illumination. A second treatment was given 2 weeks later.	A statistically significant greater reduction in the total inflammatory lesion count with MAL-PDT compared with placebo PDT at week 12 was observed; median reduction 54% [95% confidence interval (CI) 35-64%] vs. 20% (95% CI 8-50%), P = 0.0006. MAL-PDT was associated with more pain than placebo PDT, although intensity varied across centers and was reduced with repeated treatment. Local adverse events were consistent with this treatment modality.	1B

(Continued)

TABLE 52-1—Evidence Based Table for Various Non-Medical Interventions in the Treatment of Acne Vulgaris (Continued)

Investigators	Objective	Methods	Results/Conclusions	Level of Evidence
Wiegell and Wulf ¹⁸	To evaluate the efficacy and tolerability of methyl aminolevulinic-based photodynamic therapy (MAL-PDT) in patients with moderate to severe facial acne vulgaris in a randomized, controlled and investigator-blinded trial.	Twenty-one patients were assigned to the treatment group and 15 patients to the control group. The treatment group received two MAL-PDT treatments, 2 weeks apart. Both groups were evaluated 4, 8 and 12 weeks after treatment.	Twelve weeks after treatment the treatment group showed a 68% reduction from baseline in inflammatory lesions vs. no change in the control group ($P=0.0023$). There was no reduction in number of noninflammatory lesions after treatment. All patients experienced moderate to severe pain during treatment and developed severe erythema, pustular eruptions and epithelial exfoliation. Seven patients did not receive the second treatment due to adverse effects.	1B

1450 nm diode laser	B
Photodynamic therapy	A (consistent results seen in high quality studies)

the areas applied. In addition, salicylic acid is a volatile compound and leaves no active agent after 4 minutes of topical application.⁴⁰ Unlike glycolic acid, the patient does not require buffering and the topical application can be visually quantified by the doctor based upon the amount of the white precipitate to achieve the desired effect.

There have been many studies evaluating the efficacy of these peels in different populations and skin types^{41–44}. In addition, studies have been conducted to compare glycolic and salicylic acid peels, but such studies are few in number. A recent, split-faced, double-blind trial compared a 30% concentration of each compound on 20 individuals every other week for 3 months.⁴⁵ There was a decrease of acne lesions in the salicylic acid group, which persisted 2 months after the last peel, whereas patients in the glycolic acid group displayed new acne lesions after discontinuation of peeling. However, this difference in lesion counts was small and not statistically significant, and patients did not seem to favor salicylic acid over glycolic acid.

Application of sunscreen and strict protection from the sun is essential with any chemical peel and should be explained to the patients very clearly.

CONCLUSION

Both glycolic and salicylic acid peels appear to be effective in achieving superficial epidermolysis, which leads to an improvement in a variety of different forms of acne as seen in the treatment of a number of different patient populations and skin types.

Microdermabrasion

How is microdermabrasion helpful in management of acne?

Microdermabrasion involves propelling polyester or nylon bristles or an element (e.g., aluminum oxide crystals) onto the face at various speeds, then vacuuming off the

debris using a specialized wand or handpiece. The vacuum suction can be operated at various pressures, allowing the operator to control both particle speed and suction at the skin surface. Common complications include eye irritation, which ranges from chemosis and tearing to photophobia to punctate keratitis if crystals adhere to the corneal epithelium.⁴⁶ Microdermabrasion was originally shown to be beneficial in patients in acne.^{47–49} More recently, microdermabrasion has been combined as a pretreatment with aminolevulinic acid (ALA) photodynamic therapy (PDT) or chemical peels to get better results.⁵⁰ Removing the superficial stratum corneum allows greater penetration of ALA, and PDT seems to have greater improvement in comedonal and even inflammatory acne lesions. Wang et al. compared the efficacy, safety, and pain associated with the treatment of inflammatory facial acne with the 1,450 nm laser alone versus microdermabrasion plus the 1,450 nm laser, in a randomized split face trial. Although laser alone and microdermabrasion plus laser significantly reduced the total number of acne lesions, this small pilot study with 20 patients did not demonstrate increased clinical efficacy or decreased associated pain with the addition of microdermabrasion to treatment with the 1,450 nm laser.

CONCLUSION

Microdermabrasion can be used as an adjuvant for enhancement of efficacy of PDT for treatment of acne scars.

Lasers and Light Devices

How do laser and light devices help in management of acne?

The increase of bacterial resistance and the adverse effects and lack of response to usual therapies has led to the investigation of new therapeutic alternatives such as the laser and light-based devices. The main potential targets for light sources are the infundibulum, the sebaceous glands, *P. acnes* and the inflammatory response. The laser and light devices can help reduce/clear acne broadly by either or both of the two mechanisms of action:

- The shorter wavelengths such as the 532 nm, 585 nm and 595 nm pulsed dye laser (PDL) are absorbed by the porphyrins contained in the *P. acnes* and cause thermal damage leading to bacterial destruction.⁵¹ Different studies have shown results in favor of and against this theory, with various degrees of clearance achieved with their use in treating acne.
- The longer wavelength lasers such as 1450 nm diode laser and photodynamic therapy focus on decreasing the size of sebaceous glands by their deeper penetration into the skin. The shrunken sebaceous glands result in decreased sebum production and improvement of acne.

532 nm Potassium titanyl phosphate (KTP) laser

The optical penetrance of green light at 500-532 nm has been shown to be greater than that of blue light in studies probably because of its innate characteristic of activating bacterial porphyrins.⁵² In a study with 175 patients with mild to severe acne, three groups of patients were used to compare three treatments for acne: first group received laser treatment with 532 nm alone, second group received laser treatment with topical and cleansing agents used after completing 6 sessions of laser treatments and third group was treated with topical and cleansing agents concurrently with laser therapy.⁵³ Six weekly laser sessions were used with 30- to 40-millisecond pulse duration and 6 to 12 J/cm² of energy with continuous contact cooling. Although decrease in lesion counts and clearance rates of 60-70% were achieved in first group, 90% of patients in the third group demonstrated 80-95% improvements in their inflammatory lesions. Of the third group, more than 50% of the patients were able to maintain their outcomes for up to 4 months without any further treatments.

In another later study with 26 patients with moderate to severe acne, the safety and efficacy of 532 nm KTP laser for treatment of acne was studied.⁵⁴ In this split face study, one side of the face for each patient served as the treatment half and the other side as a control. Four laser exposures with 532 nm laser were given to these patients and results

were assessed at 1 and 4 weeks postfinal treatment. A mean score of 34.9% and 20.7% reduction was noted at 1- and 4-week respectively, calculated using Michaësson acne severity score. No side effects occurred. These findings indicated that KTP 532 nm laser is safe and effective for treating acne.

585 nm Pulsed Dye laser (PDL)

The PDL emits a beam of visible coherent light and targets oxyhemoglobin in microvessels. Traditionally used to treat vascular lesions of the skin, PDL can cause significant discomfort and purpura that is generally transient, but may persist for long in certain cases. In addition, it carries a higher risk of hyperpigmentation especially in patients with darker skin types, requiring extra caution. PDL can target inflammatory component of acne by using hemoglobin as the chromophore. Moreover, it seems to induce release of antiinflammatory molecules by stimulating T-cells.⁵⁵ Use of low fluence induces production of procollagen secondary to heating of the perivascular dermis, a process that may help reduce acne scarring, comedo formation, and maturation of follicular wall.^{56,57} PDL has been studied for treating scars and shown to be very efficacious.^{58,59} In a recent study, treatment of acne in comparison with other topical therapeutic modalities was evaluated in 45 patients with mild to moderate acne.⁶⁰ Patients were randomly divided into three groups: group A received treatment with pulsed dye laser therapy every 2 weeks, group B received topical preparations and group C was subjected to chemical peeling using trichloroacetic acid 25%. At 12 weeks of treatment, there was a significant improvement of the lesions within each group with the best results seen in group A; however, no significant difference was detected between the three treatment protocols after the treatment period. Remission in the follow-up period was significantly higher in the first group.

Seaton et al. compared the efficacy and tolerability of PDL treatment in 41 adults with mild-to-moderate facial inflammatory acne in a double-blind, randomized-controlled trial 41 adults with were enrolled.⁶¹ Patients were randomly assigned to PDL or sham treatment. Treatment was given at baseline and patients were seen after 2, 4, 8, and 12 weeks. After 12 weeks, acne severity was reduced from 3.8 to 1.9 in the PDL group and 3.6 to 3.5 in the sham group ($p=0.007$). Treatment was well tolerated. Total lesion counts fell by 53% in PDL patients and 9% in controls ($p=0.023$), and inflammatory lesion counts reduced by 49% in PDL patients and 10% in controls ($p=0.024$). The most rapid improvements were seen in the first 4 weeks after treatment. This suggests that PDL therapy improves inflammatory facial acne 12 weeks after one treatment with no serious adverse effects.

On the other hand, Orringer and colleagues conducted a split face, single-blind, randomized-controlled trial to

assess the efficacy of 585 nm PDL with 350- μ s pulse duration, 7 mm spot size and 3-J/cm² energy.⁵¹ The treated halves had significant reduction in papules from baseline to week 12, but the untreated sides also showed reduction, thus resulting in an overall statistically insignificant difference. In addition, despite the consideration of the large dropout rates from the study, the authors concluded that PDL was not very efficacious in treating acne.

595 nm Pulsed Dye Laser

In a study by Yoon et al. 595 nm PDL was shown to be useful for reducing acne associated erythema in 20 patients using two successive sessions with a 595-nm PDL at 4-week intervals.⁶² A total of 90% of acne erythema patients achieved clinical improvement. Lesion counts decreased 24.9% after the first treatment ($p<0.05$) and by 57.6% (versus baseline) after the second treatment ($p<0.05$). Significant improvements were also noted in mean Leeds scores, erythema indexes, and skin elasticities after each treatment. Treatment-related pain was well-tolerated and adverse effects were limited to transient erythema and edema at treatment sites.

The 595-nm pulsed dye laser (VBeam; Candela Corp.) has also been used in conjunction with the 1450-nm diode laser (Smoothbeam; Candela Corp., Wayland, MA) to treat both acne vulgaris and postinflammatory erythema resulting from acne. Glaich et al. in a noncontrolled study of 15 patients, demonstrated that the lesions counts dropped by a mean of 52%, 63%, and 84% after 1, 2, and 3 treatments, respectively ($p<0.01$).⁶³ In addition to improvements in acne and acne scarring, significant improvement in postinflammatory erythema was also noted and may be attributed to the selective photothermolysis of vessels by the pulsed dye laser.

UV radiation

Although no controlled studies have been conducted, UVB resulted in nontherapeutic minor effects.⁶⁴ Short-term improvement may be seen, probably because of the anti-inflammatory effects of UV radiation. However, UV radiation generates squalene peroxide from the sebum lipid, squalene, which in animal models has been shown to be comedogenic.^{65,66} In addition, UV radiation's carcinogenic abilities cannot be ignored.

Visible light

Na and Su assessed the efficacy of red light phototherapy with a portable device in acne vulgaris in a split-face randomized-controlled single-blinded trial on 28 volunteers with mild-to-moderate acne.⁶⁷ The right or left side of the face was randomized to treatment side and phototherapy was performed for 15 minutes twice a day

for 8 weeks. The percent improvement in noninflammatory and inflammatory lesion counts of the treated side was significant compared to the control side ($p<.005$). Visual Analog Scale decreased from 3.9 to 1.9 on the treatment side and the difference between the treatment and control sides was significant at week 8 ($p<.005$), suggesting that red light has the potential for being used as a single treatment for acne.

De Arruda et al. evaluated the efficacy and safety of blue light treatment versus topical benzoyl peroxide 5% formulation in patients with acne grades II and III by enrolling 60 volunteers with facial acne.⁶⁸ Thirty of them were irradiated with blue light (8 times, twice a week) and the other thirty were treated with topical benzoyl peroxide 5% formulation, auto-applied twice a day, every day. The improvement achieved by the blue light was the same as the one with benzoyl peroxide, regardless of the type of lesion ($p=0.05$). The side effects were less frequent in the group treated with blue light. Gold et al. in a multicenter clinical evaluation evaluated the safety and efficacy of a new blue light source in the treatment of mild to moderate inflammatory acne vulgaris in comparison to topical 1% clindamycin solution.⁶⁹ Blue light therapy reduced inflammatory acne vulgaris lesions by an average of 34%, compared to 14% for topical 1% clindamycin solution.

In a study, blue light (peak at 415 nm) and a mixed blue and red light (peaks at 415 and 660 nm) were evaluated in the treatment of acne vulgaris.⁷⁰ One hundred and seven patients with mild to moderate acne vulgaris were randomized into four treatment groups: blue light, mixed blue, and red light, cool white light and 5% benzoyl peroxide cream. After 12 weeks of active treatment, a mean improvement of 76% (95% confidence interval [CI] of 66-87%) in inflammatory lesions was achieved by the combined blue-red light phototherapy which was significantly superior to that achieved by blue light (at weeks 4 and 8 but not week 12), benzoyl peroxide (at weeks 8 and 12) or white light (at each assessment). The final mean improvement in comedones by using blue-red light was 58% (95% CI of 45-71%), again better than that achieved by the other active treatments used, although the differences did not reach significant levels. This study suggested that phototherapy with mixed blue-red light, probably by combining antibacterial and anti-inflammatory action, is an effective means of treating acne vulgaris of mild to moderate severity with no significant short-term adverse effects.

Another study alternated blue and red light treatments in 24 subjects with Fitzpatrick skin types II-V and mild to severe symmetric facial acne vulgaris. They used eight sessions, two per week 3 days apart alternating between 415 nm blue light (20 minutes/session, 48 J/cm²) and 633 nm red light (20 minutes/session, 96 J/cm²) from a light-emitting diode (LED)-based therapy system.⁷¹ Of the twenty-two patients who completed the trial, the mean lesion count reduction was significant at 46% ($p=0.001$). At the 12-week follow-up, the mean lesion count reduction was

also significant at 81% ($p=0.001$). Severe acne responded best, while inflammatory lesions responded better than comedones. Besides, the treatments were free of pain and other side effects.

1450 nm diode lasers

The 1450 nm laser with dynamic cooling device is FDA-approved for the treatment of acne. The 1450 nm laser targets the water in the upper dermis, remodels the underlying collagen and improves facial and periorbital rhytides. The improvement in acne lesions was noticed when some patients received facial rejuvenation with this laser⁷² and is possibly caused by thermal damage caused to the sebaceous glands arresting their sebaceous output in a temporary manner.⁷³

Paithankar et al. used four sessions of 1450 nm laser 3 weeks apart on 27 patients and showed a significant clearance of inflammatory acne that lasted 6 months. Erythema was reported as the most common side-effect and hyperpigmentation was experienced in 3 patients.⁷⁴ Jih et al. evaluated the dose response of a 1450-nm diode laser for treatment of facial acne, sebum production, and acne scarring utilizing two laser fluences and to determine long-term remission after laser treatment.⁷⁵ Twenty patients (Fitzpatrick skin phototypes II-VI) received 3 treatments using the 1450 nm diode laser (3-4 week intervals). Split face comparisons were performed by randomizing patients to one of two fluences (14 or 16 J/cm²) on the right or left side of the face. Percentage reductions in mean acne lesion counts from baseline were 42.9% (14 J/cm²) and 33.9% (16 J/cm²) after one treatment and 75.1% (14 J/cm²) and 70.6% (16 J/cm²) after 3 treatments. There was persistent reduction of 76.1% (14 J/cm²) and 70.5% (16 J/cm²) at the 12-month follow-up ($P < .01$). Both objective and subjective improvements in acne scarring and sebum production were noted. Treatment-related pain was well tolerated, and adverse effects were limited to transient erythema and edema at treatment sites.

Although 1450 nm diode laser has been shown to be effective in treating acne, the pain associated with the treatment is a limiting factor. For the same efficacy, higher fluences with single pass have been demonstrated to be associated with more pain as compared to a double pass lower fluence protocol.⁷⁶ However, this doubled the treatment times. A new laser which possesses a spot size four-fold larger than the previous lasers reduced the treatment times more than fourfold. Bernstein studied this new laser and demonstrated that the Allen Smith acne scores decreased from 2.7 pre-treatment to 2.0 post-treatment and lesion counts decreased from an average of 34.4 pre-treatment to 16.1, 2 months post-treatment.⁷⁷ Pain ratings on a 1 to 10 scale averaged 4.9. All subjects rated their skin as less oily at the follow-up period.

In another recent study, Laubach et al. aimed to study the mechanism of action of the 1450 nm diode laser in acne

reduction and its effects on sebum excretion rate (SER).⁷⁸ No significant reduction in SER was observed on all treatment sites ($P > 0.05$) on the nose. Reduction in the absolute SER was observed for both test and control sites on the forehead, reaching significance on the treatment site ($P = 0.04$) and marginal significance on the control site ($P = 0.08$).

1540 nm Er:glass laser

In a study with 2-year follow-up, Angel et al. evaluated the efficacy of 1540 nm Er:glass laser with four treatments at 4-week intervals in 25 patients with acne severity greater than 3 on the Burton scale. In this group, the mean percent reduction was 71%, 79%, and 73% at 6-month, 1-year and 2-year follow-up respectively.⁷⁹ No side effects were reported. All patients commented that their skin was less prone to oiliness. Biopsies taken after treatment showed progressive rarefaction and miniaturization of sebaceous glands and pilosebaceous follicles without morphologic damage to epidermal and dermal structures.

Kassir et al. performed another study on the 1540 nm Er:glass laser with an active cooling contact device for 4 treatment sessions at 2 weeks intervals on 20 patients with inflammatory acne and observed a lesion count reduction of 70% with follow-up evaluations at 1 and 3 months without any side-effects.⁸⁰

Randomized-control trials (RCTs) are required to assess the role of 1,540 nm Er:glass laser in acne and provide a higher level of evidence.

Photopneumatic technology

Photopneumatic technology (Isolaz™, Aesthera Inc., Pleasanton, CA) combines vacuum pressure with a broadband light source device has been designed to attack multiple targets for the effective treatment of acne. The vacuum draws the target tissue into the treatment tip of the device, raising the sebaceous glands and opening the pores to empty the trapped sebum and necrotic cell. This decreases the proliferation of *P. acnes*.

Gold and Biron demonstrated reduction in inflammatory lesion counts for at least 3 months after the final treatment in 11 subjects.⁸¹ They received 4 treatments at 3 week intervals and were seen after at 1 and 3 months. At 3 months, reductions in lesion counts were significant for inflammatory ($P = .0137$) and noninflammatory ($P = .0383$) lesions. Mean scores between visits consistently dropped sharply from their immediate post-treatment values for pain, erythema, and edema. Nine out of the eleven subjects were moderately satisfied to very satisfied with treatment.

Another study with 20 patients with mild to severe acne was performed to determine the clinical efficacy and side-effect profile of photopneumatic therapy for the treatment of facial acne vulgaris. These patients received four successive treatments at 2-week intervals with a

combined photopneumatic device.⁸² Modest reduction in acne lesion counts and global clinical improvement was seen in the majority of patients. Best clinical improvement was noted in patients with severe acne. Side effects were mild and limited to transient erythema and rare purpura. Most patients experienced worsening of acne early in the treatment course.

As this is a relatively new modality being explored, good quality RCTs are still awaited to provide better evidence of the usefulness of photopneumatic technology in acne therapy.

Intense pulsed light (IPL)

Intense pulsed light or flash lamps are high energy light sources that emit a broad spectrum of wavelengths in the visible and near-infrared spectrum. IPL has been used in photodynamic therapy for acne as the light source, but IPL alone for treating acne has not been studied enough. In a split face study with 30 female patients with mild-moderate acne, benzoyl peroxide (BP) gel was applied to one side of the face and also treated with the PR filter (acne filter) of the IPL.⁸³ On the other side, only benzoyl peroxide was used. Although all patients experienced the reduction of inflammatory lesion counts in both sides of face, there was no significant difference between IPL-treated and untreated sides of the face for mean papule plus pustule counts 3 weeks after three sessions. Reduction in redness was better observed on the side that was treated with the IPL.

In another study involving IPL, 3 treatments were compared. Adapalene alone, IPL combined with adapalene and PDT with methyl aminolevulinic acid (MAL), and IPL plus adapalene.⁸⁴ There were no significant differences in the treatment results with any of the 3 treatments.

Recently, IPL was compared with PDL concerning efficacy and safety, in a study by Choi et al. with 20 patients with facial acne. Treatment was performed 4 times at 2-week intervals.⁸⁵ Numbers of total acne lesions decreased following both treatments. For inflammatory lesions such as papules, pustules and nodules, IPL-treated sides showed an earlier and more profound improvement than PDL-treated sides. However, at 8 weeks after the 4th treatment, a rebound aggravation of acne was observed on IPL-treated sides. On the contrary, PDL produced gradual improvements during the treatment sessions and these improvements lasted 8 weeks after the 4th treatment. Noninflammatory lesions as open and closed comedones also showed improvement following both treatments and PDL-treated sides showed better improvement as the study proceeded. Histopathologic examinations showed amelioration in inflammatory reactions and an increase in TGF-beta expression after both treatments, which were more prominent for PDL-treated sides.

The paucity of studies with IPL for use in treating acne makes it an uncertain option for acne management.

Photodynamic therapy (PDT)

Photodynamic therapy works on the principle of a multistep process which involves uptake of a photosensitizer agent by target cells more than healthy cells followed by exposure of this part of the body to light source. This activates the photosensitizer leading to repairable (local changes to redox state of cell) and irreparable (cell death) changes to cells. The main toxic agents produced in this process are singlet oxygen or reactive oxygen species that oxidize biologic molecules. The oxidative stress induces stress proteins such as heat shock and glucose-regulated proteins.^{86,87}

P. acnes produces endogenous porphyrins, predominantly coproporphyrin III. This absorbs mainly visible light in the range of 400 to 415 nm.^{88,89} The emission maximum for coproporphyrin is at 623 nm.⁸⁹ Studies have shown that irradiation of the affected acne skin with UV (390 nm), violet (405 nm), blue (415 nm), green (470 nm), white (full spectrum) and red (660 nm) improves the state of the skin to varying degrees depending on the wavelength and the dose of the light.⁹⁰⁻⁹¹ Though the blue and the violet wavelengths have the most effective activation of *P. acnes* porphyrin, they have poor penetration depth in the skin.^{90,91,70} In this regard, the green light is also a good choice, but the red light has deeper penetration into the tissues even if it is less effective in activating porphyrins. Red light has wound healing properties as well, since it induces the release of proinflammatory cytokines from macrophages, which in turn stimulate fibroblast proliferation and growth factor production.^{92,93}

The photodynamic killing of bacteria can be enhanced by modification of sebaceous gland apparatus with exogenous inductive agents such as aminolevulinic acid (ALA) which is the photosensitizer. Photodynamic therapy with 5-aminolevulinic acid and recently methyl aminolevulinate (MAL) has been shown to be a safe and effective modality for the treatment of acne vulgaris.⁹⁴ Consensus guidelines suggest that 30 to 60 minutes is sufficient 5-aminolevulinic acid contact time before photoactivation with blue light, red light, yellow light, broadband light, halogen, or pulsed dye laser devices. An average of three treatments can yield significant long-term improvement. Photosensitizers activated by visible and near-infrared (NIR) laser irradiation, which have deep penetration within the tissue, are preferred.

In a recent study, the effect of PDT with ALA and red light (550-700 nm) was studied on comedo formation using the Cyanoacrylate follicular biopsy (CFB), a noninvasive procedure proposed as the most reliable modality of studying follicular casts.⁹⁵ In 10 patients with mild-to-moderate facial and/or chest/back acne resistant to conventional therapies, ALA PDT at 2-week intervals in 3 sessions was given. Four weeks after their last PDT session, the patients showed an average global score reduction of 50%. CFBs demonstrated a reduction in the total area, the average area and the density of macrocomedones suggesting that ALA-PDT does exert an action on the comedogenic phase of acne.

In another study, PDT with an intralesional injection of ALA (ILI-PDT) was studied for its efficacy and safety in patients with recalcitrant localized acne.⁹⁶ In 10 patients of Fitzpatrick III and IV, ILI-PDT showed a statistical superiority in effect after the first and second PDT compared to conventional PDT. In addition, ILI-PDT can reduce the total number of PDT sessions and can cut down the overall cost. Generalized erythema and exfoliation were not reported after ILI-PDT. Focal treatment in the ILI group may account for such findings, but as most PDT side effects are associated with the epidermal damage, it is natural to expect less irritation with an ILI method in which ALA is delivered directly to the dermis.

ALA is a hydrophilic molecule and thus has limited penetration through cellular membranes and into the interstitial space of tissues. Methyl aminolevulinate (MAL) is an ester of ALA with enhanced lipophilicity. MAL is de-esterified into ALA by intracellular enzymes. MAL should be expected to penetrate more easily and deeper into the targeted lesion⁹⁷ and studies have demonstrated that MAL is more selective towards abnormal skin than ALA.⁹⁸

Wiegell and Wulf compared the treatment effects and tolerability of ALA-PDT versus MAL-PDT in the treatment of acne vulgaris in a controlled randomized investigator-blinded trial on 15 patients.⁹⁹ There was a 59% decrease in inflammatory lesions at 12 weeks after treatment with no significant differences in effectiveness between the two treatments. All patients experienced moderate to severe pain during illumination and developed erythema, pustular eruptions, and epithelial exfoliation after treatment, which were more severe and uniform in the ALA-PDT-treated area.

Twenty percent ALA may have phototoxic side effects which can limit its use. The 5-ALA concentration can be lowered by a factor of 40 by changing the vehicle of 5-ALA from a moisturizing cream to liposome encapsulation. de Leeuw et al. assessed the efficacy and the safety of PDT using 5-ALA 0.5% in liposomal spray and intense pulsed light (IPL) in combination with topical peeling agents (Li-PDT-PC) in acne vulgaris.¹⁰⁰ After a mean of 7.8 months and 5.7 treatments, the mean total number of lesions reduced from 34.6 lesions to 11.0 lesions, resulting in a mean improvement of 68.2%. Side effects were minimal.

Indocyanine green (ICG), often used as a diagnostic dye, has its maximum absorption between 650 and 800 nm.¹⁰¹ It has been used a photosensitizer, and combined with diode laser irradiation has been applied for acne treatment. This is based on the principle of selective photothermolysis of sebaceous glands.

Studies have shown that multiple treatments with a combination of ICG and NIR irradiation reduced inflammation and improved the state of the skin for a month without any side effects.¹⁰² In a study with 22 patients with facial or back acne, ICG application and NIR laser-diode light (803 or 809 nm) irradiation were performed.¹⁰³ One mg/mL solution of ICG was applied for 5 or 15 minutes to the cleaned skin site. Untreated, only stained, and only

light irradiated skin areas served as controls. For soft acne treatment, the low-intensity (803 nm, 10-50 mW/cm², 5-10 minutes) or the medium-intensity (809 nm, 150-190 mW/cm², 15 minutes) protocols were used. The observations during 1-2 months showed that soft acne treatment decreased the number of active elements, reduced erythema and inflammation, and considerably improved the skin state without side effects. At high power densities (up to 200 W/cm²), ICG-stained acne inflammatory elements were destroyed for light exposures of 0.5 seconds.

Different incubation times may yield variable outcomes. This idea was studied recently where incubation times of 30 minutes and 3 hours were compared in PDT with intense pulsed light for inflammatory acne.¹⁰⁴ The 20 Korean patients enrolled in the study were randomized into 2 groups: short incubation with ALA plus IPL (30 minutes) or long incubation with ALA plus IPL (3 hours) on one side of face and IPL alone on the other side of the face for 3 monthly sessions. All the patients showed significant improvement after 3 treatments, but the degree of improvement was highest in the group with ALA-PDT plus 3 hour incubation. All groups showed reduction in sebum secretion after the 3 sessions but the differences among the groups did not show significance. Mild side effects such as transient erythema and mild edema were reported.

Radiofrequency

Radiofrequency (RF) has been used for nonablative skin rejuvenation and is believed to work on the principle of heat-induced skin remodeling and tightening.^{105,106} There have been three types of radiofrequency devices in use: monopolar, bipolar, and tripolar. Unfortunately, the role of radiofrequency in management of acne has not been studied well and not defined, except that it has been shown to lower sebum secretion.¹⁰⁷ A study was conducted in which IPL, combination of RF and IPL, and blue light in photodynamic therapy were studied for acne vulgaris. Twenty-two patients with moderate to severe acne vulgaris were randomly assigned to receive ALA-PDT with photoactivation by intense pulsed light (IPL, 600-850 nm), a combination of IPL (580-980 nm) and bipolar radiofrequency (RF) energies, or blue light (417 nm).¹⁰⁸ Each patient received 3 ALA-PDT sessions at 2-week intervals. At 1 month and 3 months, median lesion count reduction percentages were highest with IPL activation and lowest with blue light activation, although the differences did not reach statistical significance. ALA-PDT with activation by IPL appears to provide greater, longer-lasting, and more consistent improvement than either RF-IPL or blue light activation in the treatment of moderate to severe acne vulgaris.

A series of 4 case reports were published by Braun who used the combination of radiofrequency and blue light for acne treatment.¹⁰⁹ He suggested that this combination provided a method of treating acne that was rapid, caused no downtime, pain, erythema, peeling; safe in all

skin types, caused skin tightening and not associated with bacterial resistance. This combination could be used as an option for treating cystic acne but more data and research needs to be available for considering them more effective. Observational studies using a combination of IPL (400 to 980 nm) and radiofrequency have shown improvement in patients with moderate acne, but the effect of RF is not clear, as IPL being an effective treatment by itself may have overshadowed it.^{110,111}

Larger studies with good design can aid in placing Radiofrequency in the treatment spectrum of acne.

CONCLUSION

Evidence suggests that shorter wavelengths such as 532 nm, 585 nm and 595 nm PDL are absorbed by the porphyrins in *P. acnes* and cause thermal damage leading to bacterial destruction. The longer wavelength lasers such as 1450 nm diode laser and PDT focus on decreasing the size of sebaceous glands by their deeper penetration into the skin. Radiofrequency may have a role in reducing sebum secretion and thus help reduce acne.

Botox

Does Botox have a role in management of acne?

Botulinum toxin A (BTX-A) or BOTOX® is currently FDA-approved for the treatment of blepharospasm and strabismus associated with dystonias (including benign

essential blepharospasm or cranial nerve VII disorders) in patients aged 12 years or older and for the treatment of cervical dystonia in adults. Myobloc (botulinum toxin type B) is currently FDA-approved for the treatment of cervical dystonia. However, the most prevalent and popular use of Botox is for cosmetic purposes and is an off-label use.¹¹²

The property of botulinum toxin that led to the idea of its role in acne treatment is the different pathways that may be utilized by BTX-A in inhibiting formation of acne. These are mainly 3 pathways:

- BTX inhibits sebum production by sebaceous glands through cholinergic inhibition. Botulinum toxins block acetylcholine release, causing a chemical denervation. Neurotransmission at the neuromuscular junction involves the release of acetylcholine from the presynaptic nerve terminal. Acetylcholine (Ach) release requires docking and binding of the neurotransmitter vesicles to the presynaptic membrane. This is also the mechanism by which it acts a muscle relaxant and helps improve wrinkles and facial lines. Decreased sebum production reduces the growth of *P. acnes*.
- BTX also inhibits sweat production from the sweat glands. Reduction in perspiration improves acne by decreasing the *P. acnes* growth.¹¹³ This may help in acne reduction.
- Keratinocytes occlude the follicles and play a role in causing acne. Migration of keratinocytes is inhibited by high-dose stimulation of nicotinic ACh receptors and by inhibiting the release of Ach, BTX can indirectly increase the migration of keratinocytes and reduce follicular occlusion.¹¹⁴

What We Know

- Acne is a disease of pilosebaceous unit with multifactorial etiology characterized by comedones, papules, pustules, nodules and cysts- inflammatory and/or noninflammatory lesions, which commonly result in scarring.
- 60-70% of the population of USA is affected by acne at some time in their lives.
- Acne has multifactorial etiology with four major factors: follicular hyperproliferation, subsequent follicular plugging, excess sebum production, and the activity of *P. acnes* causing inflammatory response of the tissue.
- The newer etiologic factors demonstrated to be contributory in acne development include a genetic component, retention hyperkeratosis, hormones (androgens, IGF etc.), inflammatory activity of *P. acnes* via toll-like receptors, *P. acnes* lipase activity, diet (western diets and chocolate).
- Increase of bacterial resistance has led to investigation of new therapeutic options.
- Chemical peels constitute a nonlaser therapeutic option for superficial exfoliation and aid in hastening the process of resolution of comedones by their transition to superficial epidermis.
- Shorter wavelengths such as 532 nm, 585 nm, and 595 nm pulsed dye laser are absorbed by the porphyrins in *P. acnes* and cause thermal damage leading to bacterial destruction.
- The longer wavelength lasers such as 1450 nm diode laser and photodynamic therapy focus on decreasing the size of sebaceous glands by their deeper penetration into the skin.
- Radiofrequency has been shown to reduce sebum secretion and thus help reduce acne.
- Botox is a new modality for acne. It works by inhibiting sebum production of sebaceous glands through cholinergic inhibition, inhibits sweat production, thereby decreasing growth of *P. acnes* and also by indirectly increasing the migration of keratinocytes which may reduce follicular occlusion.
- *P. acnes* vaccine that consists of cell-wall anchored sialidase of *P. acnes* has shown in-vivo protective immunity in animal models.

It is still in its very early stages to comment and conclude about the use of BTX in acne therapy, although a potential role can be foreseen.

Future Directions

P. acnes vaccines

P. acnes vaccine is an interesting concept and has been developed for *P. acnes*-associated inflammatory acne. It consists of a cell-wall anchored sialidase of *P. acnes* or killed whole organism of *P. acnes*. Intranasal immunization of mice with this vaccine provided in-vivo protective immunity against *P. acnes* challenge. In addition, it decreased the *P. acnes*-induced elevation of cytokine production.¹¹⁵ The antibodies elicited by inactivated *P. acnes* attenuated IL-8 production in human sebocytes but no effect was seen on *P. acnes* growth.¹¹⁶ Besides, there was reduced ear swelling and decreased release of proinflammatory macrophage inflammatory protein (MIP-2) cytokine. This study in the murine model suggests that antibodies against *P. acnes* that exhibit antiinflammatory properties yield clinical improvement, though they may lack antimicrobial effect.

CONCLUSIONS

Medical treatments of acne – traditional and new therapies are great modalities for acne management, but with the development of bacterial resistance to these drugs, alternative treatments are being explored. Some of these have proven to be better than the existing therapies while others are still under research and show potential as treatments for acne. In addition, some of these newer modalities have demonstrated great results when used in combination with topical medications. With experience and a thorough understanding of all the available nonmedical interventions, the doctor and patient can decide upon the best course of action for treating acne.

Sick Building Syndrome: Cutaneous Manifestations

53

Berndt Stenberg, M.D., Ph.D.

INTRODUCTION

During the past 40 years, health problems related to indoor air quality (IAQ) have received increasing attention. “Sick” buildings were reported in the 1950s but have become a recognized occupational health problem since the 1970s.^{1,2} In 1982, a World Health Organization (WHO) expert group produced a definition of “Sick building syndrome” (SBS).¹ This definition, based mainly on reports from the Scandinavian countries and the United States, is still in widespread use and includes a list of general, mucosal, and skin symptoms and signs (Table 53-1).

This definition, however, does not relate to an accepted clinical syndrome but is rather a list of symptoms often experienced by individuals working or residing in buildings with indoor climate problems. Consequently, the concept of SBS has been given a different meaning by various investigators; for example, Anglo-American investigators often exclude skin symptoms.³ Criteria for the definition of SBS have been suggested. These include specific symptoms and signs plus odor or taste sensations reported by a threshold number of occupants of the building. The cause must not be exposure to a single agent.⁴ These criteria, however have never been validated.

The term “sick building syndrome” has been widely criticized,^{5,6} mainly because it implies a cause or attribution of the symptoms. SBS is commonly separated from “building related illnesses” (BRI), which comprises established illnesses where the indoor environment factor causing the symptoms is often well known, such as hypersensitivity pneumonitis, humidifier fever and Legionnaire’s disease.³ Another suggested terminology, which has come into use

gradually is “specific building-related illnesses” as opposed to “nonspecific building-related illnesses” which includes SBS.⁷

The cause of or rather risk factors for SBS have been reviewed^{8–11} and the syndrome is generally described as having a multifactor background. Consistent risk factors reported are the female gender, atopy, psychosocial stress, low outdoor airflow rate, and indoor chemical exposure.^{8–11}

There are other environmental syndromes described that are closely connected to SBS. Carbonless copy paper (CCP) has been used since the 1940s, extensively so during the 1970s to 1990s. Skin, mucosal, and general symptoms have been reported when CCP is handled intensively and especially in small, badly ventilated areas.^{12–13} Reports of symptoms related to CCP are currently very sparse.

Since the 1980s, a phenomenon known as multiple chemical sensitivities (MCS) has attracted great interest and there are numerous related publications. Cullen¹⁴ has defined MCS as “an acquired disorder characterized by recurrent symptoms, referable to multiple organ systems, occurring in response to demonstrable exposure to many chemically unrelated compounds at doses far below those established in the general population to cause harmful effects. No single widely accepted test of physiologic function can be shown to correlate with symptoms”. A range of similar major diagnostic features have been suggested. The current knowledge of MCS has been extensively reviewed in a textbook,¹⁵ in which it is stated “reference to rash is frequent, but presence of visible rash is less common”.

A phenomenon known as “low humidity occupational dermatoses,” with symptoms predominately associate with the skin, has been reported. In this case, the common exposure factor was a relative humidity at the lower end of the comfort range, around 35%. The problem was solved when the relative humidity was raised to 45–50%. The skin symptoms reported were pruritus and urticaria on covered areas and a scaling dermatitis on the face, scalp, and ears.^{16,17} Similar findings have been reported in patients living and working in air-conditioned houses when air humidity has been drastically reduced.¹⁸ Increased prevalence of dryness of the skin, eyes, nose, and throat has also been reported in clean rooms with moderate humidity.¹⁹

Because of the nonspecific nature of many symptoms reported in the office environment, it is often suggested that psychologic factors are responsible. They may even

TABLE 53-1—Common Symptoms Reported by Occupants of Buildings with Indoor Air Quality Problems (WHO)

Sensation of dry mucous membranes and skin
Erythema and itching
Eye, nose and throat irritation
High frequency of airway infections, and cough
Hoarseness, wheezing, and non-specific hypersensitivity
Mental fatigue and headache
Nausea and dizziness

be used as an excuse for incomplete investigations.²⁰ In a textbook on occupational dermatology, SBS is described as follows: "SBS...refers to epidemics of subjective symptoms (itching and burning sensations) without any clinically visible signs, which occur in the work environment. This situation can be related, for instance, to low relative humidity but may also represent a mass psychogenic illness."²¹ Experience gained from the investigation of 19 episodes of probable mass psychogenic illness (MPI) by the National Institute for Occupational Safety and Health (NIOSH) has been summarized.²² Although some symptoms typical of MPI are common to SBS, skin symptoms were not reported in these episodes. Signs suggestive of MPI, such as sudden onset of relatively severe symptoms, conversion symptoms, and recurrences in affected individuals when they congregate, make it possible to separate this phenomenon from real indoor air problems.²²

EPIDEMIOLOGY

The prevalence of SBS is not known, simply because there is no agreed definition of the syndrome. Most epidemiologic studies are cross-sectional and use questionnaires to record the prevalence of symptoms or combinations of symptoms compatible with the WHO list. Most studies look at selected populations while a few are general population studies. Some studies record "building-related" symptoms while others report symptoms independent of attribution. It has been shown that a considerable bias in attribution can result from the information given when collecting the data. In a Danish study, the prevalence rates of symptoms were similar, but reporting of work-relatedness and home-relatedness differed considerably between two study groups to which different information was given. If the information letter focused more on the workplace than the home, the subjects were more likely to report that their symptoms were work-related. Likewise, the subjects reported more home-related symptoms if focus was on the environment at home.²³

Work-related skin symptoms in office buildings in the UK (1984) have been reported with a prevalence ranging from 6–16% (dry skin), 2–3% (rash) and 3–7% (itchy skin) in buildings with different ventilation systems.²⁴ Swedish data (1993) from a random sample of office workers reported the prevalence of symptoms perceived every week independent of attribution.²⁵ Women reported higher prevalence than men (Table 53-2). A combination of at least one general, one mucosal (eye, nose, throat) and one skin symptom was perceived by 4% of men and 12% of women.

In a Japanese survey (2004) of newly built private homes, symptoms that occurred commonly or mainly in the home were recorded.²⁶ Skin symptoms (itching, dry, flushed, and erupted skin) were more prevalent in women (18%) than in men (11%). The German ProKlimA project (2004), involving 14 office buildings, reported at least one fairly or very annoying skin symptom (raw skin, irritated skin,

TABLE 53-2—Prevalence (%) of Symptoms Perceived Every week Among Men and Women in Office Work.²⁵

Symptom	Men (%)	Women (%)
Dry facial skin	8.1	24.4
Flushed facial skin	4.6	8.5
Itching/stinging/tight or burning sensations of facial skin	3.0	8.1
Scaling/itching scalp or ears	8.6	9.9

dry skin, red skin, itching skin, flaky skin, rash, spotty skin, or brittle nails) in 25% of the participants.²⁷ SBS, defined as at least two sub-scales (organ systems) having at least three items (symptoms) that were "a minor annoyance" or worse, was experienced by 44% of women and 26% of men.²⁸ In a Norwegian study (2003) of 32 office buildings without previously recognized indoor air problems,²⁹ the prevalence of facial skin symptoms perceived every week was very similar to the Swedish figures.²⁵ Dry skin was perceived by 8% of men and 22% of women, itching/scaling by 9% and 13%, flushing by 2% and 6% and a burning sensation by 2% and 7% respectively. Swedish population data (2006) from the general population³⁰ show prevalence of skin symptoms (independent of attribution) of the same magnitude but somewhat lower than in a population of office workers.²⁵ Dry facial skin was perceived every week by 8% of men and 18% of women, flushed facial skin by 4% and 5%, facial sensory skin symptoms by 2% and 3% and body itching without any rash by 3% and 5% respectively. There is seasonal variation in SBS symptom reports³¹ and most studies on indoor climate and symptoms are performed during the cold season when symptoms are most prevalent.

Because of the nonspecific nature of SBS symptoms, epidemiologic studies have an in-built weakness. One can assume that a certain proportion of reported SBS symptoms are associated with IAQ problems, otherwise the linear relationship between symptom reports and ventilation rates could not have been established. On the other hand, it is likely that an unknown proportion of reported symptoms have causes other than IAQ. This latter proportion leads to a misclassification in prevalence studies and risk assessment studies in which the health outcome is established using questionnaires. If this misclassification is independent of the factors/characteristics (for example gender, age, psychosocial stress, ventilation and volatile organic compound levels) in relation to which the outcome is analyzed, then this misclassification will cause a lower precision in the estimates but will not bias the results. If the health outcomes could have been defined more specifically for IAQ problems, then the associations found would have been even stronger than those reported. In questionnaire studies, alternative causes for the symptoms are difficult to rule out. However, in most risk assessment studies atopy or atopic dermatitis have been adjusted for.⁹

In most studies, either the work environment or the home environment has been investigated. However, in a few studies, there have been attempts to include both environments. In some work-place investigations, surrogate variables for the home environment have been used instead of actual measurements in individuals' dwellings. One common surrogate variable for ventilation rate is the presence of condensation on windows during winter time in cold or temperate climates.^{9,32}

CLINICAL COURSE/PROGNOSIS

While some reviews have stated that SBS is characterized and even defined by the relief of symptoms when the affected person leaves the building,³³ others have pointed out the gradual onset and long duration of the symptoms even in early descriptions of the syndrome.^{8,34} In fact, there are no studies supporting the statement that SBS symptoms always resolve immediately after exposure ceases. There is however, evidence for long-lasting symptoms in a study showing slowly decreasing mucosal hyperreactivity, years after working in a school with moisture problems.³⁵ A follow-up study of the prevalence of work-related SBS symptoms among office workers, reported a decrease in symptom prevalence soon after moving to a building with an improved ventilation system. Three years later, however, nearly half of the symptom prevalence remained.³⁶ In the first follow-up study of SBS patients who had previously been referred to hospital, it was shown that symptoms decreased over time. Nearly half of the patients claimed that symptoms were more or less unchanged after 7 years or more, despite actions taken to mitigate them.³⁷ In the same study the most prevalent environmental factors triggering skin symptoms were: the use of public transport, using photocopiers or printers, fluorescent lamp exposure and going to shopping malls.³⁷ Due to reported long-lasting symptoms in SBS patients triggered by other environmental factors, some authors consider that persistent SBS symptoms represent multiple chemical sensitivity (MCS).³⁸ The similarities between SBS and MCS have been pointed out in a recent textbook.³⁹

SKIN SYMPTOMS AND SIGNS

Clinical studies of SBS are sparse and it is sometimes stated that there are no clinical signs.^{21,33} One Swedish study is of particular interest, as it focuses on reactions in children and because it is one of the studies upon which the WHO list of SBS symptoms was based (Lindvall T, personal communication). During clinical examination, dry and erythematous skin on the face and extremities was more frequently found among children in day care centers with IAQ problems compared to control buildings.⁴⁰ Skin reactions in patients referred to a dermatology department because of symptoms perceived in buildings with indoor climate problems have been reported. Facial erythema,

rosacea, scaling of the scalp, ears and face, urticaria and "itching folliculitis" were common work-related findings.⁴¹ In the follow-up study of patients mentioned above,³⁷ the most common skin symptoms noted during the primary investigation in the hospital clinic were facial erythema and body itching. At follow-up, facial erythema was the dominant skin symptom. These two latter studies are the only ones where patients have been clinically examined and where alternative causes and diagnoses have been ruled out, for example by patch testing.

Skin reactions related to the indoor environment have been reviewed in a textbook,⁴² in which findings from the German ProKlimA study are noted. Questionnaire-reported symptoms were compared to medical observations and measurements of skin sebum content and the hydration of the stratum corneum. Individuals with low levels of sebaceous secretion and/or low stratum corneum hydration reported significantly more skin complaints.⁴³ In a case-referent study of SBS, two personal factors were significant risk indicators after adjustment for atopy: photosensitive skin and a strong "stinger test" reaction.³² As the study was cross-sectional, it was not possible to determine which came first, the SBS symptoms or the "stinger" reactivity.

RESEARCH QUESTIONS AND ANSWERS

What is the definition of SBS? How is SBS diagnosed? Are there cutaneous manifestations in SBS? If yes, what are the manifestations and are these manifestations specific to SBS?

There is no agreed clinical definition of SBS. There are, however, a number of operational definitions of SBS and SBS symptoms used in epidemiologic studies. SBS cannot

be positively diagnosed based on clinical criteria. Building-related symptoms are diagnosed when a temporal relationship to spending time in a certain building is verified and when alternative explanations are ruled out.

There are cutaneous manifestations in SBS. Epidemiologic studies highlight perceived dry and erythematous facial skin as the dominant building-related symptoms, and the few clinical reports available refer to facial erythema as a typical finding.

The reported skin symptoms and signs are not specific to SBS. The few clinical tests that have been conducted on individuals with symptoms (sebum content, stratum corneum hydration and the "stinger test") have not been validated against other conditions and cannot be used for diagnosing building-related skin symptoms.

CONCLUSION

Sick building syndrome relates to a list of symptoms experienced by some individuals who spend time in buildings with IAQ problems; it is not a defined syndrome. There are a number of skin manifestations associated with other "SBS symptoms." Dry facial skin and facial erythema are the symptoms most often reported as "building-related". Dry facial skin may not only indicate exposure to low relative air humidity but also to polluted air. The symptoms are nonspecific and common in the general population. Even if building-related symptoms often abate soon after affected persons leave the building, the symptoms may become long-standing or chronic in some individuals.

Our review of reported skin reactions related to indoor climate factors indicates that the suggested "primary SBS symptoms", (i.e., perceived dryness of the skin and erythema) can trigger or aggravate a clinically observable disease in a number of predisposed individuals. In addition, skin signs may be more diverse than previously recognized. Moreover, the findings seen in clinical practice may reflect the impact of physical, chemical, and psychosocial factors interacting in a complex way.

There is a need for both epidemiologic and clinical studies to develop our understanding of skin reactions related to indoor air quality and of how skin symptoms and signs are connected to other SBS symptoms. Before questionnaire-based studies can be improved with more specific questions than those currently used, there is an urgent need for extensive case studies, which thoroughly examine subjects working or living in buildings with defined IAQ problems. This approach could establish whether there are core symptoms common to different IAQ problems and if there are symptoms specific to certain exposures. Risk assessment studies should also, as far as possible, include investigations of indoor environments where people spend most of their time (i.e., their work-places and their homes).

What We Know

- There is an association between low outdoor air flow rates and SBS symptoms.
- There is an association between psychosocial stress and SBS symptoms.
- SBS symptoms are more prevalent in women than in men.

III

Risk Factor Analysis

Risk Factors for Nonmelanoma Skin Cancer

Athanassios Kyrgidis, M.D., D.D.S., M.Sc.

Nonmelanoma skin cancer is the most common cancer in Caucasians. Cutaneous squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) constitute nearly all non-melanoma skin cancers, the incidence of which tumors is rising.¹⁻³ Population-based studies demonstrate an increase in the incidence of nonmelanoma skin cancer among young women and men.^{2,4}

SCC has an incidence of 16 per 100,000 people in central Europe and of 356 per 100,000 sun-exposed Caucasians in the United States.⁵ Accounting for approximately 20% of cutaneous malignancies, squamous cell carcinoma (SCC) is the second leading cause of skin cancer in Caucasians.⁶ Cutaneous squamous cell carcinoma has significant adverse public health effects because of high medical costs and, in advanced or aggressive cases, compromised quality of life from devastating aesthetic and psychosocial sequelae, functional impairment, and other serious consequences.^{1,6-7}

The reported incidence of BCC varies among different countries from approximately 50 cases per 100,000 person-years in Finland,⁸ to 150 cases in UK⁹ and 935 in Australia respectively,¹⁰ while a recent prospective cohort study concluded that actual BCC tumor burden is much greater in the population than is apparent from normal incidence rates.¹⁰

The head and neck region is the most common skin location of nonmelanoma skin cancer development; up to 85% of basal cell carcinomas develop in the head and neck region.^{5,11}

A biomarker, or biologic marker, is in general a substance used as an indicator of a biologic condition. It is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention. A risk factor is a variable associated with an increased risk of disease or infection. Risk factors are correlational and not necessarily causal, because correlation does not imply causation.¹²

In the last decade, new discoveries in cancer research generally and in nonmelanoma skin cancer research more specifically are targeted in finding new biomarkers of potential prognostic value, and in better understanding the pathophysiologic processes of the disease, to improve current therapies or introduce novel treatment

approaches.¹³ Human cells, in order to transform to cancer cells need to: (1) provide growth signals and obtain growth self-sufficiency, (2) ignore growth inhibitory signals, (3) avoid apoptosis, (4) replicate without limit, (5) sustain angiogenesis, and (6) invade and proliferate.¹⁴ While these are true for most cancers including nonmelanoma skin cancer; with regard to BCC, it is rather unlikely that (5) and (6) occur. The reason for that could be the low to nonexistent metastatic potential of BCC and the fact that the majority of tumors ulcerate in the center, thereby suggesting a limited ability to provoke and sustain angiogenetic molecular signalling.²

In this chapter, we describe risk factors for nonmelanoma skin cancer development, recurrence following treatment with curative intent, second primary nonmelanoma skin cancer tumors and metastasis of SCC tumors. In order for the chapter to be more comprehensive and practical for clinicians, it is structured along clinically relevant questions to which we provide evidence-based answers. These questions are:

1. Which patients are more likely to develop nonmelanoma skin cancer?
2. Are there any clinico-epidemiologic factors that predispose to nonmelanoma skin cancer development?
3. Are patients with prolonged Ultra Violet (UV) radiation exposure at higher risk of developing nonmelanoma skin cancer?
4. Are all patients equally prone to nonmelanoma skin cancer development when exposed to UV radiation?
5. Is UV exposure the only significant risk factor for nonmelanoma skin cancer development? Are there any genetic factors that predispose to nonmelanoma skin cancer development?
6. Which patients are more likely to develop second primary nonmelanoma skin cancer?
7. Which of those patients treated for nonmelanoma skin cancer are more likely to experience a recurrence?
8. Are there patients in higher risk for nonmelanoma skin cancer metastasis?
9. Does BCC metastasize? Are there patients in higher risk for BCC metastasis?

WHICH PATIENTS ARE MORE LIKELY TO DEVELOP NONMELANOMA SKIN CANCER?

Are There Any Clinico-Epidemiologic Factors that Predispose to NMSC Development?

Sex-Related Factors

Large epidemiologic studies concluded that age-standardized incidence rates of people with new histopathologically confirmed NMSC are on the rise.² These incidence rates for nonmelanoma skin cancer are reported to be higher in men,^{9,15} (Table 54-1). Of note, the mortality rate from nonmelanoma skin cancer is reportedly two-fold in men than in women.¹⁶

Age-Related Factors

Incidence rates are reported to be higher in the elderly.^{9,15} Epidemiologic studies have reported an increase in the incidence of nonmelanoma skin cancer in ages 30-39.^{9,4,17} A 27-year long prospective cohort study demonstrated a disproportionate increase in basal cell carcinoma in young women.⁴ Another single-center cohort study reported a significant trend towards superficial clinical type of BCC in younger patients. However, there is some inconsistency in the literature with regard to the latter argument.²

Dietary Factors

Reports from Australia state significantly reduced odds ratio for NMSC with higher category dietary fat intake using both case-control and cohort study designs.^{2,18} A recent cohort study, concluded that dietary fats are not associated with BCC occurrence¹⁹ in consistence with recently published results stating lack of efficacy of antioxidant supplements from a randomized clinical trial. (NCT00272428).²⁰

However, in participants of the Nambour Skin Cancer Prevention Trial with a history of skin cancer, total fat intake was associated with increased numbers of SCC tumors comparing the highest to lowest tertile.¹⁹ The same trial demonstrated a decreased risk of SCC tumors for high intakes of green leafy vegetables and an increased risk for high intake of unmodified dairy products.²¹ High meat and fat-consuming patterns were positively associated with development of SCC tumors after adjustment for confounders and even more strongly associated in participants with a skin cancer history (see Table 54-1).²²

In a random sampling case control study from the Southeastern Arizona Skin Cancer Registry, increased levels of arachidonic acid in red blood cell membranes were associated with increased risk of SCC and this association remained significant when controls with actinic

keratosis precursor lesions were excluded. SCC risk was highest among the upper quartile of arachidonic acid content in red blood cell membranes. In contrast, increasing proportions of palmitic acid and palmitoleic acid in red blood cell membranes were associated with reduced SCC risk (see Table 54-1).²³

BODY MASS INDEX

No significant association was found between any of the anthropometric measures or indices and risk of NMSC after controlling for potential confounding factors including sun exposure. Short-term weight gain has been suggested to increase the risk of developing NMSC in the female population.²

Drug-Related Factors

A randomized clinical trial (RCT) reported a weak and inconsistent chemopreventive effect of non-steroid anti-inflammatory drugs (NSAIDs) on NMSC development (see Table 54-1).²⁴ Significant positive associations were observed between total alcohol intake and risk of BCC in cohort studies.² A case-control study found that history of regular tea consumption was weakly associated with increased BCC risk after adjustment for age and sex, but the study could have been susceptible to recall bias and to confounding by potential unknown cancer risk factors associated with tea consumption.² Oppositely, having ever consumed tea regularly was reported to be associated with a significantly lower risk of SCC.²⁵ A randomized clinical trial proved that selenium supplementation is ineffective in preventing basal cell carcinoma. In the same trial after a 10-year follow up period, selenium supplementation was associated with statistically significantly elevated risk of squamous cell carcinoma and of nonmelanoma skin cancer.²⁶ Beta carotene supplementation had no effect on the incidence of a first nonmelanoma skin cancer after adjusting for age and randomized aspirin assignment.²⁷

Recently, FDA security files revealed that some new hypnotics may increase nonmelanoma skin cancer risk. However, currently available evidence only derives from rodent experimental models.²⁸

A meta-analysis of case-control and cohort studies demonstrated that Vitamin D supplementation did not confer any preventive benefit with regard to NMSC development. However, no clear pharmacogenomic benefit from Vitamin D supplementation was reported for patients bearing specific mutations in the vitamin D receptor (VDR) gene (FokI and BsmI polymorphisms).²⁹ In contrast, the VDR Bsm1 BB genotype was significantly associated with an increased SCC risk. An unfavorable pharmacogenomic interaction between the VDR Bsm1 polymorphism and total vitamin D intake was observed for SCC, where the highest risk was reported in women with the BB genotype

Comp Q: Decrease size please check ok as set

and high vitamin D intake (see Table 54-1).³⁰ Thus, vitamin D supplementation is to date of no value in the prevention NMSC.

A number of ongoing trials study the preventive actions of a series of retinoids in NMSC. However the risk of a new SCC in was significantly increased in the isotretinoin group compared with placebo.³¹

Demographic Factors

In contrast to the Caucasian population, squamous cell carcinoma is the most common nonmelanomatous skin tumor in the African-American population.³² According to the public perception of UVR-induced skin cancer, populations or occupations with higher UVR exposure are anticipated to express higher risk for NMSC. Indeed, there are large-scale epidemiologic studies, which have found that the incidence rate of nonmelanoma skin cancer increased from the northern to the southern states.²

Occupational Factors

Elevated risks for NMSC have been reported among groundskeepers, gardeners, garage and service station-related occupations and to a limited extent among food industry occupations. Women in health services occupations were also reported to exhibit elevated risk for nonmelanoma skin cancer development.² In addition, constitutional susceptibility was reported to be an independent risk factor for BCC. On the contrary, epidemiologic studies reported the incidence rate for BCC to be higher in urban than in rural regions. Farmers, forestry workers, and fishermen demonstrated low incidence of BCC, whereas occupations with high level of education or compulsory health check-ups as well as medical care occupations appeared to have an increased incidence of BCC. The authors did not comment on whether this reversed risk could be attributed to regular follow-up or patients' self-reporting.² Results for the HELIOS-I multicenter case control study reported that concerning nonmelanoma skin cancer as a whole (both histologic types), miners and quarrymen, secondary education teachers, and masons registered exhibit excess risk, regardless of exposure to solar radiation and skin type. Frequency of BCC proved higher among railway engine drivers and firemen, specialized farmers and salesmen, in addition to miners and quarrymen and secondary education teachers. The occupations that registered a higher risk of SCC (though not of BCC) were those involving direct contact with livestock, construction workers, stationary engine and related equipment operators and masons (see Table 54-1).³³

Chronic exposure of radiologists to ionizing radiation at low to moderate levels was reported able to increase the risk of BCC but not of SCC, and this risk may be related to pigmentation characteristics.²

Immunocompromised Patients, Transplant Recipients and Irradiation Treated Patients

The remarkable improvement in immunosuppressive therapy and surgical procedures for organ transplantation observed since the first successful kidney transplant was achieved in 1954, now allows many organ types including kidney, heart, liver, lung, skin, cornea and bone marrow to be successfully transplanted.^{3,4-36} The survival of patients has increased substantially and it has also become clear with time that recipients present a higher risk of cardiovascular disease, infection and cancer.^{34,37} Renal transplant recipients (RTRs) submitted to lifelong immunosuppression, constitute the most important group of patients with long-term survival to have provided important information on the increased susceptibility to cancer. The cumulative risk of tumor development, which includes skin cancers, lymphomas and kaposi's sarcoma is reported to be 14% in the first 10 years after transplantation and increases to 40% at 20 years compared to 6% in the general population.³⁷ Half of the tumors are nonmelanoma skin cancers, predominantly squamous cell carcinomas, in contrast to the normal population where basal cell carcinomas prevail. The rapidly growing numerous NMSC, at multiple sun-exposed body sites in RTRs, are more aggressive and present increased metastatic potential resulting in substantial morbidity with increased mortality.^{34,37}

A retrospective cohort study of 926 kidney transplant recipients reported a 9.7% incidence of nonmelanoma skin cancer lesions with a median time of development of a first nonmelanoma skin cancer lesion of 4 years. Reported risk factors for nonmelanoma skin cancer among kidney transplant recipients include older men (>45 years), a history of post-transplant warts and longer duration of residence in a northern climate.³⁵ Another study estimated the relative risk of nonmelanoma skin cancer among liver transplant recipients to be twenty-fold as compared to sex- and age-matched population (see Table 54-1).³⁶

Patients who undergo radiation therapy also exhibit elevated risk for NMSC development.² Among participants of the Childhood Cancer Survivor Study the median age of occurrence was 31 years (range, 7 to 46 years). Location of nonmelanoma skin cancer included head and neck (43%), back (24%), chest (22%), abdomen and pelvis (5%), extremity (3%), and unknown (4%). Ninety percent of patients had previously received radiation therapy (RT); 90% of tumors occurred within the RT field. RT was associated with a 6.3-fold increase in NMSC risk (see Table 54-1).³⁸ Of note, a retrospective cohort study reported that BCC in irradiated scalp had a more aggressive behavior that might oblige for a more extended surgical resection.²

Infection-Related Factors

Cutaneous human papilloma virus (HPV) may be associated with the development of nonmelanoma skin cancer, as

suggested by reports of HPV DNA in nonmelanoma skin cancer tumors. HPV DNA was detected in various skin lesions including basal cell carcinomas, actinic keratoses, and SCC.³⁷

Human papilloma virus DNA is reported to be commonly expressed in superficial layers of BCC lesions, but is not necessarily present throughout tumors.² A population-based case-control study that detected HPV antibodies reported no difference in HPV seropositivity between BCC patients and controls.²

When SCC is concerned, most reports did not point to any significant association with HPV infection.³⁹ However, Karagas et al. detected HPV antibodies more frequently in SCC patients than in control subjects. Among different HPV types, seropositivity to HPV types in genus beta, particularly HPV 5, was associated with SCC risk (see Table 54-1). Individuals with tumors on chronically sun-exposed sites were more likely to be seropositive for beta HPV types than individuals with SCC at other anatomic sites.⁴⁰

Are Patients With Prolonged UV Exposure at Higher Risk of Developing NMSC? (Ultra Violet Radiation Related Factors)

Extrinsic skin aging or ‘photoaging’, as opposed to intrinsic skin aging, is the result of exposure to external factors, mainly ultraviolet irradiation.⁴¹ It appears that photoaging is predisposing to NMSC development: Photoexposed skin areas account for 92.6% of NMSC tumors. A positive association between sensitivity to sunburn and increased risk for NMSC development has been reported for NMSC of the head but not for NMSC of the trunk. Patients reported to having red hair; green, hazel, or blue eyes; a tendency to sunburn; and north European ancestry were reported to have elevated risk for NMSC development. Keratotic skin lesions were reported to be associated with NMSC and have been proposed as a potential prognostic criterion for identifying those organ-transplant recipients with an increased risk for skin cancer development, who should be offered more intensive skin surveillance.² The lifetime number of blistering sunburns was also found to be positively associated with NMSC risk.² Skin type 1 patients were reported to be more prone to development of NMSC.⁴² Men who as teenagers had been outdoors on a daily basis were reported to have elevated risk for NMSC when compared to men who as teenagers had been outdoors less than once a week. Living in a residential area with high solar exposure as an adult was also found associated with an increased risk for NMSC, whereas living in such a region only during childhood was not found to increase NMSC risk.² Sunbathing was reported to be associated with a five-fold increased risk of truncal BCC but not with BCC histology⁴³ (see Table 54-1). Higher sun exposure while wearing a bathing suit was reported to be an independent risk factor for NMSC.⁴³⁻⁴⁴ Repeated exposure to tanning beds might also

be a contributory factor.⁴⁵ Sunscreen treatment was not reported to be associated with early or late first occurrence of NMSC. Multivariate hazard models of follow-up data from the Nambour Skin Cancer Prevention Trial revealed a trend towards a lower risk of subsequent NMSC tumors among a sunscreen intervention group.² Randomized-controlled trials concluded that regular application of sunscreen has no clear benefit in reducing risk for NMSC development (see Table 54-1).³⁴

It appears that the total amount of UV dose is associated with different forms of NMSC. A cohort study found the BCC to SCC ratio to be increased in participants who received low and medium UV doses while it was reduced for those who received very high UV doses. A very high UV dose was also associated with the doubling of the total number of tumors per person and a significantly increased risk of having SCC (see Table 54-1).⁴⁶ These results suggest that the association between risk and UV exposure is less dose-responsive in BCC than in SCC.

Are All Patients Equally Prone to NMSC Development if Exposed to UV Radiation? Which are the Predisposing Factors for Such a Patient to Develop NMSC? (Factors related to defective host response to ultraviolet radiation)

DNA-Repair

Exposure to UVR, specifically UVB, induces covalent bonds in DNA between adjacent pyrimidines, generating photoproducts such as cyclopyrimidine dimers (TT) and pyrimidine lesions, which are mutagenic if not repaired. Polymorphisms in the melanocortin 1 receptor (MC1R, locus 16q24.3) have been shown to be strongly associated with skin type.⁴⁷ Variant alleles have also been found to be strongly associated with red hair and experimentally assessed UVR sensitivity.

A nested case-control study suggested that MC1R gene variants were an important independent risk factor for nonmelanoma skin cancer. Information on MC1R status was reported to contribute up to a 3.3-fold increase in BCC risk (see Table 54-1).⁴⁷⁻⁴⁸ Specific SNPs at the tyrosinase (TYR, locus 11q1 4-q21) gene was reported to be associated with increased risk for SCC development⁴⁹ while two other SNPs, in the oculocutaneous albinism type II (OCA2, locus 16q24.3, 15q11. 2-q12) and in the agouti signalling protein (ASIP, locus 20q11.2) have been associated with increased BCC risk. The haplotypes rs4911414[T] and rs1015362[G] near the ASIP gene was also associated with higher SCC risk.⁴⁹

CpG sites are regions of DNA where a cytosine (C) nucleotide occurs next to a guanine (G) nucleotide in the linear sequence of bases along its length. Cytosine (C) to Thymidine (T) transitions at CpG sites adjacent to

pyrimidine-pyrimidine (PyPy) sequences were reported to be more prevalent in tumors from UV-exposed than UV-shielded body areas. CpG-mutations at non-PyPy sequences were reported to be more prevalent in tumors which received cumulative ionizing radiation (IR) dose higher than 1 Gy compared to those who received cumulative dose lower than 0.2 Gy. These data could be of potential use in determining the specific risk for BCC development among different persons or different body sites of a person when exposed to IR.²

A haplotype near agouti signalling protein (ASIP, locus 20q11.2) known to affect a similar spectrum of pigmentation traits as the MC1R variants was recently found to confer significant risk of BCC (OR = 1.33, p<0.001)⁵⁰ (see Table 54-1). Nevertheless, the ASIP polymorphism is not uniformly reported to be associated with BCC.⁴⁸ The results concerning MC1R and ASIP polymorphisms, were reported to be independent of the subjects' pigmentation characteristics⁴⁸ thus adding value to their potential use as biomarkers. Another polymorphism in tyrosinase (TYR, 11q1 4-q21) encoding the R402Q amino acid substitution, which was previously shown to affect eye color and tanning response, was also found to confer risk of BCC (see Table 54-1).⁵⁰

DNA repair capacity (DRC) was measured in the subjects' peripheral blood lymphocytes by using a host-cell reactivation assay that measures cellular activation of a reporter gene irradiated with UV light. Elderly BCC patients were reported to demonstrate a higher DRC compared to younger BCC patients and non-BCC controls. The effects of age, family history of skin cancer, and current sun exposure may confound such results and therefore DRC measurement is unlikely to become a useful routine predictor before the latter confounding associations are clarified.² Overall, there was a statistical significant 16% reduction in DRC in nonmelanoma skin cancer patients compared to controls. DRC below the controls' median value was associated with increased risk significantly for BCC but borderline for SCC after adjustment for age, sex, and other assay-related covariates (see Table 54-1).⁵¹ Because the association between risk and UV exposure is less dose-responsive in BCC than in SCC, suboptimal DRC may play a more important role in the etiology of BCC when the level of UV-induced DNA damage is low. Wang et al. observed that patients who had a BCC or single and nonaggressive nonmelanoma skin cancer tended to have the lowest DRC. Likewise, they observed the highest frequencies of UV-induced chromosomal aberrations in BCC patients, suggesting a major role of suboptimal DRC in the etiology of single nonmelanoma skin cancer. When the level of UV-induced DNA damage was high or accumulated because of chronic exposure to sunlight as seen in SCC, the DRC may be up-regulated; however such an adaptive increase in DRC in response to damage to DNA appeared to be overwhelmed by high levels of UV-induced damage, thus being associated with a high risk of SCC.⁵¹

Nucleotide excision repair (NER) is instrumental in removing DNA lesions caused by ultraviolet (UV) radiation,

the dominant risk factor for nonmelanoma skin cancer. Studies have examined polymorphisms in genes associated with DNA repair and identified significant associations with both xeroderma pigmentosum complementation group D (XPD, locus 19q13.2-3, also known as ERCC2) and x-ray complementing defective in Chinese hamster 3 (XRCC3, locus 14q32.3) genes, but not with any of five common haplotypes of excision repair complementing defective in Chinese hamster 1 (XRCC1, locus 19q13.2-q13.3) gene.² Another study reported the XRCC1 Arg194Trp het genotype to confer an increased risk for SCC development and the XRCC1 Arg399Gln var/var genotype to confer a reduced risk for SCC development.⁵² The variant allele for susceptibility to breast cancer T241M (C>T) polymorphism in the XRCC3 gene was associated with a decreased BCC risk⁵³ (see Table 54-1). The XRCC3 18085T (241Met) allele and its associated haplotype were significantly inversely associated with the risks of SCC and BCC (see Table 54-1). The XRCC3 4552C allele along with its associated haplotype and the XRCC2 30833A allele were significantly associated with increased BCC risk.⁵⁴

Another study supported the hypothesis that alleles of several polymorphisms in the chromosomal region 19q13.2-3, encompassing the genes retinoic acid-induced gene 1 (RAI, locus 19q13.2) and XPD, are associated with occurrence of basal cell carcinoma in Caucasian Americans.⁵⁵ Some authors have indicated that a specific haplotype partly defined by the alleles of three single nucleotide polymorphisms, RAI intron1(G), RAI exon6(T), and XPD exon 6(C), is associated with a protective gene variant in a region spanning from XPD to XRCC1⁵⁵ (see Table 54-1). Other authors suggested a role of the double-strand break (DSB) repair complex in BCC development. Genotyping of 19q13.2-3 and 14q32.3 regions to scrutinize for protective haplotypes could be of value in determining follow up strategy (see Table 54-1).

The A23G polymorphism present in xeroderma pigmentosum gene (XPA, locus 9q22.3) was associated with an increased risk of BCC and this polymorphism appeared to be a determining polymorphism in XPA that alters cancer susceptibility. A case control study investigated the effect of the A allele of the XPA gene adjusted for age, gender, pigmentation factors and severe sunburns in Caucasians. Using GG as the reference allele, the A allele was less frequent among cases of BCC and SCC⁵⁶ than controls. Risk from three or more severe sunburns was reported elevated only for those with the GG genotype. These results only exhibit a trend because they were significant at the 0.10 alpha level.² Men but not women homozygous for the C-allele for E185Q (G>C) polymorphism in the p95 protein encoding gene of the MRE11/RAD50 complex (also reported as Nijmegen breakage syndrome, NBS1, locus 8q21) showed an increased BCC risk. In men, the age and nationality adjusted odds ratio for the CC (XRCC3)/CC (NBS1) genotype was almost nine-fold compared to the TT (XRCC3)/GG (NBS1) genotype.⁵³ Moreover, the risk of multiple BCC was significantly

lower among variant allele carriers than in non-carriers (see Table 54-1).⁵³ Overall, these findings could allow for identification of patients with high risk to develop second primary BCC, should genotyping be used as a standard procedure. The same associations imply that BCC patients have a reduced capacity to repair UV-induced DNA lesions and are therefore more susceptible to UV-induced DNA damage in comparison to the general population.

Chemical Detoxication

Unlike UVB, UVA may have effects that are more indirect in DNA through ROS. UVR is also a local immunosuppressant for skin, giving rise to the suggestion that this may compromise local antitumor activity. The functional V16A polymorphism in the manganese superoxide dismutase gene (MNSOD, locus 6q25.3) was not found to be associated with skin cancer risk. Similarly, the polymorphisms C677T and A1298C in the methylenetetrahydrofolate reductase gene (MTHFR, locus 1p36.3) and the polymorphisms Fok1, Bsm1 and Cdx2 in the vitamin D receptor gene (VDR, locus 12q12-q14) did not point to any clinically significant association with increased nonmelanoma skin cancer risk in a nested case-control study.²

Associations between polymorphisms in the cytochrome p450 (CYP) and glutathione S transferase (GST) supergene families and BCC risk have been proposed.² Genes in both these families are involved in detoxification of various mutagens, while some GST members also detoxify the products of oxidative stress. Studies have shown that polymorphisms in glutathione s-transferase mu-1 (GSTM1, locus 1p13.3), GLUTATHIONE glutathione s-transferase theta-1 (GSTT1, locus 22q11.2) and cytochrome p450 subfamily II D polypeptide 6 (CYP2D6, locus 22q13.1) genes are associated with patients who present with multiple BCC. Another GST family member, glutathione s-transferase mu-3 (GSTM3, locus 1p13.3) was also found to be associated with multiple BCC⁵⁷ (see Table 54-1), thus, it could be of value in detecting multiple BCC patients. NAD(P)H dehydrogenase quinone 1 (NQO1, locus 16q22.1) gene null, GSTM1 B and GSTT1 null, and CYP2D6 EM polymorphisms have been reported to be associated with multiple BCC, although quantitative effects analysis showed that predisposition to many BCC is determined by an unknown number of further loci. The relative influence of NQO1 null was studied in a multivariate model adjusted for GSTM1 B, GSTT1 null, CYP2D6 EM, GSTM3, cytochrome p450 subfamily I polypeptide 1 (CYP1A1, locus 15q22-q24) gene and MC1R. NQO1 null and MC1R asp294/asp294 were reported to be associated with multiple BCC, and the association with CYP2D6 EM approached significance. Male gender, skin type 1, CYP2D6 EM and VDR TT genotypes were reported to be associated with more BCC per year with univariate analysis⁴² (see Table 54-1). Different factors mediate the numbers of BCC

per year in males and females and the univariate contributions of variables to risk were modest.⁴²

Allele GSTP1*A was associated with a higher risk of nonmelanoma skin cancer. Homozygosity for allele GSTP1 Val (105) was associated with reduced risk for NMSC development (see Table 54-1). Analysis of interactions between allelic variants showed a significant association between combined GSTM1 and CYP1A1 Val (462) genotypes, where individuals homozygous for the risk allele GSTM1 null and carrying also the allele CYP1A1 Val (462), showed a higher risk of developing nonmelanoma skin cancer.⁵⁸

Immunologic Effects

Exposure to UVR results in a cascade of events including a T-lymphocyte-mediated immunosuppression. DNA damage and the UVR-induced transformation of cis-urocanic acid (cUCA), can result in altered expression of several cytokines including tumor necrosis factor (TNF) TNF-alpha, interleukin (IL) IL-10, IL-1 α and β , IL-3, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor, and nerve growth factor which results in an alteration from a T helper 1 to a suppressive T helper 2 response, thereby inhibiting the ability of antigen-presenting cells (APC) to induce antitumor immunity.² Of note, higher levels of cUCA were detected in SCC biopsies (44% of total UCA) compared to samples of BCC and that of healthy photoexposed skin (30%).⁵⁹ On the other hand, BCC situated on the head and neck was reported to over express certain Th2 cytokines, namely IL-4 and IL-5 and TNF-alpha.⁶⁰

Immunosuppressed transplant patients are reported to have a considerably higher risk for BCC, demonstrating a critical role for the immune system in BCC development.² It has been reported that the TNF allele (locus 6p21.3) haplotype a 2-b4-d5 statistically significantly influenced BCC numbers (mean BCC number, 8.1 vs. 3.7 in other allele combinations) in patients with multiple BCC (Table 54-2). A single base pair polymorphism at position -308 in the promoter region of the TNF-alpha gene associated with an enhanced secretion of TNF-alpha has been identified in humans. Mononuclear cells from patients with a previous BCC demonstrated a significantly increased release of TNF-alpha upon stimulation with lipopolysaccharide compared to mononuclear cells from age-matched control subjects.² TNF-alpha GG genotype was associated with more BCC per year.⁴² Additionally, HLA-DR4 (locus 6p21.3) was reported to be associated with multiple BCC, however authors concluded that HLA-system might only play a minor role in the development of multiple BCC. Furthermore, GSTM1 and GSTT1 genotypes have been shown to influence the inflammatory response following UVR exposure, a finding possibly reflecting the link between oxidative stress and immune function.² Overall there is sufficient evidence to support that immunologic status plays some role in the development of NMSC but to date limited biomarkers could be of prognostic value (see Table 54-2).

Is UV Exposure the Only Significant Risk Factor for NMSC Development? Are there Any Genetic Factors that Predispose to NMSC Development? (Factors Related to Genomic Instability in NMSC)

Cell Cycle – Growth Self Sufficiency

The mouse double minute two homolog (MDM2 gene, locus 12q14.3-q15) oncoprotein promotes cell survival and cell cycle progression by inhibiting the p53 tumor suppressor protein. Recent results suggest that the MDM2 SNP 309 polymorphism alone affects neither the risk nor the age at onset of NMSC. Thyroid autoantigen 70-KD G22P 1 (Ku70 gene, locus 22q11-q13) and x-ray repair complementing defective in Chinese hamster 5 (Ku80 gene, locus 2q35, also known as XRCC5) protein levels were found to be significantly increased in BCC as compared tonormal skin. A direct correlation was found between Ku70 and Ku80 protein levels and expression of the proliferation markers Ki-67/MIB-1 (locus 10q2 5-pter) in basal cell carcinoma. DNA-binding activity was increased in BCC tumor samples as compared to matched control skin samples that were histopathologically negative for cancer.² The percentages of expression for Ki-67, CD31 and epidermal growth factor receptor (EGFR) were significantly higher in the recurrent tumors than in the nonrecurrent ones (Table 54-3). Expression of Ki-67 and CD31 was 271.57 +/- 17.91 and 58.1 +/- 9.37 for the recurrent group and 187.08 +/- 21.48 and 23.9 +/- 5.45 for nonrecurrent group respectively (Table 54-3). Expression of epidermal growth factor receptor (EGFR gene, locus 7p12.3-p12.1) was reported to be positive in basal cell carcinoma cells.⁶¹ Other studies found that the interaction term, glutathione s-transferase p-1 (GSTP1, locus 11q13) Val105/Val105 with cyclin D1 (CCND1, locus 11q13) AA, was associated with tumor numbers in total and multiple concurrent tumors but not with single tumors in BCC patients (see Table 54-2).⁶² In a stepwise model including GSTP1 Val105/Val105, CCND1 AA and their interaction terms as well as GSTM1, GSTT1 and CYP2D6 genotypes, skin type 1 and gender, the combination of genotypes was the best predictor of BCC numbers in patients with multiple BCC (Table 54-2).⁶² Increased expression of the oncogene ERBB3 encoding the tyrosine kinase-type cell surface receptor HER3 (HER3, locus 12q13) was associated with hyperproliferative tumor stages and HER3 expression was suggested to reflect an increased malignant potential in cutaneous lesions.²

Insensitivity to Anti-Growth Signals

Basal cell carcinomas were essentially a molecular 'black box' until some 12 years ago, when identification of a genetic flaw in a rare subset of patients who have a great propensity to develop basal cell carcinomas pointed to

aberrant Hedgehog signalling. Over-expression of sonic hedgehog (SHH, locus 7q36) gene in transgenic human skin (in mice) was reported to induce features of BCC. Furthermore, SHH-activating mutations have also been described in sporadic BCC. High-IR tumors harboured more p53 (locus 17p13.1) and patched drosophila homolog 1 (PTCH, locus 9q22.3) abnormalities compared to low-IR tumors. Therefore, alteration of both genes is likely to play a role in radiation-induced basal cell carcinogenesis. PTCH is the human homologue of the Drosophila-patched (ptc) gene encoding Ptc protein which is a receptor for the diffusible morphogen hedgehog (SHH). Ptc negatively regulates SHH signaling through inhibition of a transmembrane protein Smoothened (Smo). The SHH signaling pathway is highly conserved in different species including humans, where it is involved in determining cell fate and organogenesis.² The WNT genes are a family of highly conserved developmental control genes which encode secreted glycoproteins that are involved in short-range signaling during embryonic patterning. Responses to oncogenic SHH signaling in skin are dependent on canonical Wnt/beta3-catenin signaling, which might be a potential pharmacologic target for BCC.⁶³

Nevoid basal cell carcinoma syndrome (NBCCS) is linked to chromosome 9q22, which harbours the PTCH gene where inactivating germline mutations have been found in BCC tissue. Somatic PTCH mutations have also been described in sporadic BCC. In accordance with a tumor suppressor mechanism for PTCH, loss of the wild-type allele has been demonstrated in BCC from both NBCCS patients and patients with sporadic tumors. Deletions at the PTCH locus were more frequent in tumors with high irradiation exposure. A recent case control study provided indications that azathioprine exposure may be associated with PTCH mutations in post-transplant patients. This might be particularly true in tumors from non-sun-exposed skin.⁶⁴ Dysregulation of the PTCH pathway is thought to be a critical event in BCC development.²

It is believed that cyclins form complexes that phosphorylate retinoblastoma protein (Rb), promoting cell-cycle progression. Rb appears to be the S-phase entrance molecular gate keeper which normally blocks progression and is inactivated via phosphorylation.¹³ The cyclin dependent kinase N2A gene (CDKN2A, locus 9p21) encoding p16 protein may play a role in the pathogenesis of human skin BCC in view of increased p16 mRNA and expressed protein within tumor cells.⁶⁵

Avoidance of Apoptosis/Defective Apoptosis

The tumor suppressor gene (TSG) p53, involved in genome surveillance through the regulation of cell proliferation and death, is frequently inactivated in NMSC, with up to 70% of tumors displaying mutations in the conserved region of one p53 allele. Hitherto, p53-deletion frequencies demonstrated no IR-dose associations. A very common

polymorphism of p53 is that of codon 72, which codes either for a proline (P72) or an arginine (R72). The two alleles differ in their biologic properties: P72 is a stronger inducer of p21, while R72 induces 5–10 times more apoptosis. It is not known, however, whether this polymorphism influences genomic stability.² The influence of p53 codon 72 polymorphism on cancer risk has been studied for different types of cancer with mixed and inconsistent results.¹³ No significant association was reported between p53 genotype and BCC. The germline Arg72Pro polymorphism alters the protein's biochemical functions, and may confer individual susceptibility to skin cancer. Compared to the Arg/Arg genotype, the Pro/Pro genotype was reported to be associated with BCC risk, while no association was observed between the polymorphism and SCC risk⁴⁴ (see Table 54-1). It has been suggested that p53 mutation is a crucial but late event in BCC progression, an event also pertinent for other cancers.¹³ Therefore, p53 mutations could only be biomarkers of limited value.

Several p53 codon mutations have been linked to nonmelanoma skin cancer (particularly SCC) development in renal transplant patients.³⁷ The same study reported no differences in p53 codon 72 polymorphisms and XPD gene polymorphisms between renal transplant patients with skin tumors and control individuals of the same Northern European Caucasian population.³⁷ Other authors did not find any significant association either between p53 polymorphism, that of codon 72, codes either for a proline (P72) or an arginine (R72) and basal cell carcinoma (BCC), squamous cell carcinoma (SCC), or both combined.⁶⁶

An interesting observation concerns the oncogene B-cell leukemia 2 (Bcl-2, locus 18q21.3) protein expression; Bcl-2 was found to be expressed in BCC but not in SCC. The authors concluded that Bcl-2 overexpression in BCC supports the observation that these tumor cells are derived from basal keratinocytes. On the contrary, in SCC, lack of Bcl-2 expression indicates that origin of tumor cells could be from more differentiated suprabasal keratinocytes.⁶⁷

The Family with sequence similarity 82, Member A2; (FAM82A2, locus 15q15.1, also known as protein tyrosine phosphatase-interacting protein 51: PTPIP51 Family with sequence similarity 82, Member C and FAM82C) is thought to be involved in a mitochondria/cytochrome c-mediated apoptosis pathway. The FAM82A2 protein was reported to be overexpressed in both BCC and SCC tumors. FAM82A2 was also detected in the peritumoral tissue,⁶⁸ thus the protein may play a crucial role in keratinocyte proliferation and escape from apoptotic signaling.

Limitless Replicative Potential of Cells

Increased DNA content is a basic feature in cancer cells, allowing for more mutations and greater genomic instability. Aneuploidy indicates widespread DNA changes as a result of genomic instability. It is known that the assessment of the DNA content of cells can be accomplished with

the use of a flow cytometer technique.¹³ Nuclear morphometry is an alternative method of quantitatively evaluating nuclear DNA content. With regard to BCC, nuclear morphometry could not distinguish between primary and recurring tumors.² Cheretis et al.⁶⁹ in a recent publication argue that nuclear morphometry when evaluated through computer-assisted algorithms, may be a useful adjunct to histopathologic and demographic markers in order to detect which BCC tumors are going to recur. A case control study reported presence of aneuploidy in 78% of primary BCC in patients who experienced recurrences compared to only 32% of primary BCC in the control group.⁷⁰ The authors concluded that aneuploidy is a risk factor for recurrences, which should be useful in clinical practice (see Table 54-3).

Sustain Angiogenesis

In BCC tumors, vascular endothelial growth factor (VEGF, locus 6p.12) was expressed by tumor epithelial cells, predominantly at the invasive tumor front and its expression was significantly greater than in adjacent skin. More widespread VEGF expression was found in cases of SCC, and it was significantly associated with the degree of tumor differentiation.⁷¹

BCCs with high chemokine, CXC motif, receptor 4 (CXCR4, locus 2q21) expression had concomitantly higher micro-vessel density, as compared with those with low CXCR4 expression. Chu et al. found that Chemokine, CXC motif, ligand 12 (CXCL12, locus 10q11.1, also known as stromal cell-derived factor-1, SDF-1) induced angiogenic activity in human BCC cells, both *in vitro* and *in vivo*. CXCL12 significantly upregulated several angiogenesis-associated genes such as interferon-alpha-inducible protein 27, interleukin (IL)-6, bone morphogenetic protein (BMP)-6, suppressor of cytokine signaling 2 (SOCS2) and cyclo-oxygenase 2 (COX)-2 in human BCC cells. Among them, IL-6 was the earliest and highest up-regulated gene whose induction was observed within 6 hours of the commencement of CXCL12–CXCR4 interaction.⁷² Despite the fact that BCC is not widely regarded as a tumor with high vascularity (cause for that is the necrosis/ulceration in the center of the tumor) it appears that BCC tumor cells exhibit alterations in angiogenesis signaling. Further research is warranted in this field.

Invade and Proliferate

Cadherins are cell adhesion molecules thought to play a vital role in cell–cell adhesion. Loss or down-regulation of their expression has been implicated in neoplasia. In gastrointestinal cancers, a significant reduction in cadherin expression has been documented as the dysplasia to adenocarcinoma sequence progresses.¹³ Similarly, few existing studies demonstrated that normal skin and skin showing mild and moderate solar elastosis strongly

expressed membranous E-cadherin and beta-catenin. E-cadherin expression was progressively reduced in the epidermis of skin with severe solar elastosis through solar keratosis to SCC. The same phenomenon was observed for beta-catenin starting from solar keratosis.⁷³ Suppression of E-cadherin expression and loss of its function fundamentally modified squamous cell carcinoma progression by activating a highly invasive, aggressive tumor phenotype, whereas maintenance of E-cadherin prevented invasion and limited tumor progression in vitro.⁷⁴

Basal Cell Carcinoma, Susceptibility to [Number], BCC [Number] Gene Family

The primary environmental risk factor for BCC is sun exposure, but genetics also has a substantial role. Some of the sequence variants that confer susceptibility seem to operate through their association with fair-pigmentation traits (common among Europeans), resulting in reduced protection from the damaging effects of ultraviolet (UV) radiation as described in section 4.8.1.3. Other sequence variants have no obvious role in pigmentation or UV susceptibility but instead seem to operate in the contexts of tumor growth and differentiation of the basal layers of the skin, as earlier described in section 4.8.1.4. During 2009, specific loci in the human genome have been renamed to exhibit their association with BCC development. Susceptibility to basal cell carcinoma is now considered a genetically heterogeneous trait. Loci associated with susceptibility have been identified on chromosomes 1p36 (BCC1), 1q42 (BCC2), 5p15 (BCC3), 12q13 (BCC4), 9p21 (BCC5), and 7q32 (BCC6) (see Table 54-1).

Which Patients Are More Likely to Develop Second Primary NonMelanoma Skin Cancer?

The risk of developing a subsequent nonmelanoma skin cancer in people who have developed a first nonmelanoma skin cancer is not well defined.³⁴ Marcil et al. in their meta-analysis concluded that the 3-year cumulative risk was 44% (increased) for BCC after an index BCC, 18% (increased) for SCC after an index SCC, 6% (reduced) for SCC after an index BCC, and 47.25% for a nonmelanoma skin cancer after an index nonmelanoma skin cancer.⁷⁵

Other authors reported that up to 39% of patients initially referred with BCC either presented with multiple primary lesions or experienced a subsequent tumor within 2 years. Multivariate analysis models showed older age, multiple tumors, and male sex as significant prognostic factors for second primary NMSC.⁷⁶ (see Table 54-2). A statistically significant decrease in size of the second primary NMSC when it was compared to the first primary NMSC has also been reported. The authors did not comment on whether the latter was an effect of closer surveillance.² History of

previous NMSC was reported to confer increased risk for second tumor development compared to the overall population, in a study which included over 4,000 NMSC patients⁷⁷ (Table 54-2). Some aforementioned single nucleotide polymorphisms (SNPs) or their combinations (haplotypes) have been associated with increased or reduced risk for second primary NMSC development (Table 54-2). Another study reported that patients with history of both BCC and SCC were less likely to develop a further BCC during the 5 years after initial presentation when compared to the group of patients with history of BCC only.⁷⁸

Tumor Site

Some authors reported higher risk for second primary BCC in certain tumor locations. Patients with truncal BCC were reported to have augmented predisposition to multiple tumors. Other authors did not find any relation between tumor site and second primary. Anatomic distribution of BCC is consistent with general levels of sun exposure across body sites,² thus site selectiveness is probably confounded by photoaging. On the other hand, the proportion of patients with truncal BCC could have genetic risk factors that predispose to BCC development.

Which of Those Patients Treated for NMSC are More Likely to Experience a Recurrence?

BCC Recurrence

The 5-year recurrence rates were reported to be 3.3% for primary and 7.3% for recurrent basal cell carcinomas (Table 54-3).⁷⁹ The use of different statistical methods to report the recurrence rates mainly accounts for the discrepancy among the various studies. Some authors suggested that life-table analysis provides the best approximation of the true recurrence rates.⁷⁹ Histologic markers for recurrence do not exist to date. Of note, margin involvement could be related to peripheral healthy tissue sacrifice.² Nuclear morphometry and few aforementioned biomarkers could have some value to predict risk for BCC recurrence (Table 54-3).

SCC Recurrence

In contrast to BCC, SCC has the potential to metastasize and thus disease recurrence cannot be confined to local recurrence alone but also concerns regional recurrence or even metastasis. Last year, an RCT⁵ reported specific risk factors, which were associated with SCC tumor recurrence, namely tumor thickness in mm and presence of desmoplastic growth (Table 54-3). A retrospective cohort study reported scar carcinoma, history of burn in the tumor site, presence of chronic sinus tract/ulcer, tumor size >2 cm, nodal disease, poorly differentiated versus moderately

and well differentiated and well differentiated versus moderately and poorly differentiated as significant risk factors to predict local, regional, or metastatic recurrence (Table 54-3).⁸⁰

Are There Patients in Higher Risk for Nonmelanoma Skin Cancer Metastasis?

Histologic diagnosis (differentiation, tumor thickness, depth of invasion, perineural involvement), size (horizontal dimension/diameter) and immune status of the patients all have a role in predicting the risk of metastasis.⁶ However, no specific relative risks have been attributed to the majority of these risk factors by appropriately conducted clinical trials.

In the RCT by Brantsch et al.⁵ tumor thickness, tumor horizontal size, immunosuppression, and tumor location in the ear were reported as statistically significant risk factors for metastasis of SCC (Table 54-3). Of note, tumor thickness and size are the main variables measured by the widely applied TNM staging system. Tumor location in the ear and genitalia have long been associated with increased risk for SCC metastasis.

A retrospective cohort study concluded that locally advanced tumors are at risk of lymph node metastasis. Increased risk was associated to previous lesions at tumor site. TNM stage, T4 classified tumors have worse prognosis.⁸¹ Of note in the latter study lymph node recurrences in N0 patients, once treated, did not affect survival. The authors reported that their results did not support indication for elective lymphadenectomy or sentinel node mapping.⁸¹

Does BCC Metastasize? Are There Patients in Higher Risk for BCC Metastasis?

NMSC Progenitor Stem Cells

A previously published hypothesis argues that there is a relationship between BCCs and the cells of the stem cells of the hair follicle. The results of a case control study showed that neural cell adhesion molecule (NCAM) immunoreactivity was present in 31 of 34 patients with BCCs, but not in patients with SCC or controls. This pattern corresponds to the expression patterns of the outer hair root sheath of the vellus hair follicle.⁸² Similar to embryonic hair follicles, human BCC cells showed increased levels of cytoplasmic and nuclear beta-catenin and expressed early hair follicle lineage markers.⁶³ Another case-control study concluded that BCC tumor cells likely originate from the more mature nestin-negative/K15-positive/CD34-negative outer-root sheath cells, while SCC cells likely originate from the nestin-negative/K15-positive/CD34-negative keratinocytes of the basal cell layer in the epidermis.⁸³

Monoclonal Origin

It was argued that distinct BCC arising in the same patients could be of monoclonal origin. The authors supported their hypothesis via X-inactivation and loss of heterozygosity (LOH) studies at the 9q22.3 region. However, currently available evidence does not support the argument that BCC metastasizes. No well-designed studies have documented BCC tumors to discontinuously spread to anatomically distinct body sites far beyond their point of origin. Limited existing case reports could be subject to second primary development bias.²

Methods

We systematically searched the literature for studies assessing the incidence, the probability of recurrence and/or second primary tumor development, the genetic basis of host response to UV DNA damage, the effect of UV on generation of reactive oxygen species (ROS) and their detoxification, UV-induced skin immunity modifications, and the role of genomic instability with focus on the potential use of these biomarkers to the treatment and prognosis of NMSC patients.

The following databases were electronically searched to identify eligible studies to be included in this chapter.

- Cochrane Database of Systematic Reviews to September 2009
- Cochrane Central Register of Controlled Trials (Clinical Trials)
- MEDLINE from 1950 to September 2009.
- OMIM to October 2009.
- EMBASE from 1980 to September 2009.

The search strategy included any of the following medical subject headings (MeSH) and/or terms: “skin”, “skin neoplasms”, “acanthoma”, “SCC”, “Carcinoma, Squamous Cell”, “Neoplasms, Squamous Cell”, “epithelioma”, “Skin Diseases, Viral”, “Skin Diseases, Papulosquamous”, “BCC”, “basal cell carcinoma”, “basal cell cancer”, “neoplasms, basal cell”, “nodular BCC”, “nevroid BCC”, “basal cell nevus syndrome”, “Gorlin syndrome”, “rodent ulcer”, “basal cell epithelioma”, “basalioma”, and “nonmelanoma skin cancer”.

These terms then were combined with the MeSH terms “epidemiology,” “histology,” “second primary,” “multiple tumor”, “recurrence”, “Neoplasm Metastasis”, “tumor site”, “risk factor,” “clinical”, “demographic” and “gene”, “DNA Repair”, “DNA Repair Enzymes”, “DNA Repair-Deficiency Disorders”, “Risk Factors”, “Genomic Instability”.

The search strategy used to locate randomized controlled trials (RCTs) included search terms 1–29 as given in the Cochrane Reviewers’ Handbook⁸⁴, Appendix 5b.2. Since the search strategy with the relevant search terms was expected to result in an inadequate number of RCTs, we also included nonrandomized studies. For studies identified that are of nonrandomized design, case-control and

cohort studies, the quality of these was assessed using an appropriately modified version of the Newcastle-Ottawa Scale (NOS),⁸⁵ whereby the selection of the cases and controls, the comparability and exposure was assessed.

Articles were excluded if they were case reports or reviews, if the article focused only on treatment or diagnosis, or if the article did not reference NMSC cases. Articles published in languages other than English were evaluated from their English abstract when available. Data about patient age, sex, tumors, risk factors, and potential follow-up were abstracted. To be eligible, a published study must have explicitly stated the probability of developing a certain outcome under the influence of one or more risk factors. Only studies conferring statistically significant results were selected for tabular presentation.

The initial Medline search strategy resulted in 78,326 articles that included the “skin neoplasms” term. This number was reduced to 56,826 when the Mesh term “melanoma” was inserted preceded by “NOT” option. When the remainder terms were used, a total of 528 articles were collected. The article abstracts were reviewed, and 108 articles, which matched the search intent criteria, were obtained for review. An additional 11 articles were identified within the citations of articles reviewed.

For studies, which reported on chromosomal locations and gene names, the information was inputted in the OMIM database and OMIM nomenclature was obtained for use in this chapter.

CONCLUSIONS AND FUTURE PERSPECTIVE

Socioeconomic Burden of the Disease and Risk Factor Utility

While the incidence of nonmelanoma skin cancer increases in both the United States and Europe, limited data exist about the financial burden generated by the disease. Studies from Canada⁸⁶ and the United States⁸⁷ reported the cost of treating a single primary nonmelanoma skin cancer to range from US\$ 471 up to \$ 3,460, depending on the treatment modality of choice. Nonmelanoma skin cancer was reported to rank fifth among all cancers when annual mean Medicare payment was examined. More specifically, nonmelanoma skin cancer followed lung, prostate, colon, and breast cancer and preceded leukemia, non-Hodgkin’s lymphoma, ovarian, pancreatic, stomach cancers and melanoma.⁸⁸ The authors proposed that in addition to classifying cancers by number of cases and number of deaths, the financial impact of treatment could also be used to prioritize different malignancies. Such a scheme would rank nonmelanoma skin cancer far higher than would death statistics. In light of its already high and rising incidence, the cost of nonmelanoma skin cancer care to Medicare is likely to increase.

Apart from the burden generated for the treatment of the disease, those that are diseased suffer further

socioeconomic consequences, mainly being less concerned about their general health, feel shame about their appearance, and losing time from work or caring for others.⁹¹

The estimated increase of the socioeconomic consequences of NMSC might be attenuated should preventive strategies be applied to high risk populations. Deployment of risk factors is essential to characterize high risk populations. Deployment of currently available biomarkers to facilitate earlier diagnosis in high-risk patients is anticipated to reduce treatment costs too. To maintain the cost-effective management of nonmelanoma skin cancer, the current low per-patient cost of its management should be maintained. In this regard, treatment modalities like simple surgical excision, Mohs micrographic surgery, irradiation therapy and imiquimod chemotherapy, need to be evaluated with regard to their risk for recurrence. A recent randomized clinical trial concluded that Mohs micrographic surgery is more efficient for the treatment of recurrent BCC when compared to surgical excision. When, primary BCC was concerned, the same study concluded that both treatment modalities were similarly efficient but surgical excision was less costly.⁸⁹ Another randomized clinical trial comparing MMS to surgical excision is currently recruiting participants in Europe (NCT00699829). Surgery and radiotherapy appear to be the most effective treatments, the best results being obtained with surgery.⁹⁰ Topical imiquimod could become a useful treatment for superficial and low-risk BCCs and would allow dermatologists to concentrate on the high-risk BCCs, but long-term results comparing topical imiquimod with excisional surgery are still required.⁹⁰ Vigilant selections of patients to be treated with each modality, based on evidence-based risk factors is a requisite.

Risk Factors for NMSC: Future Perspective

To facilitate earlier diagnosis, a currently recruiting study is held at the University of Texas, MD Anderson Cancer Center, in which a spectral diagnosis probe is used to detect cutaneous malignancies (NCT00476905).

Since patients with Basal Nevus Syndrome (NBCCS) and kidney transplant recipients are at higher risk of developing new BCC tumors, new trials for the prevention of BCC have logically focused on them. Celecoxib versus placebo twice daily for 2 years has been supplemented to a subset of patients (NCT00023621). The results of the study are pending. In patients with NBCCS, the efficacy and safety of a systemic hedgehog pathway antagonist (GDC-0449) are studied in an ongoing trial (NCT00957229). Another study stratifies patients with high risk for BCC according to disease type (xeroderma pigmentosum vs nevoid basal cell carcinoma syndrome) and tests the effectiveness of isotretinoin in preventing or slowing the growth of skin cancer (NCT00025012).

In kidney transplant recipients, an ongoing clinical trial (NCT00089180) studies T4N5 liposomal lotions ability in

preventing the recurrence of nonmelanoma skin cancer. The use of acitretin versus placebo in preventing skin cancers in patients with previously treated skin cancers who have undergone organ transplantation is under study (NCT00003611). Another possible preventive treatment is that of PDT With Metvix® 160 mg/g cream which is studied in organ transplant recipients with nonmelanoma skin cancer (NCT00472459). Results are pending.

A randomized phase II trial to study the effectiveness of a low-fat, balanced diet to prevent disease progression in patients with nonmelanoma skin cancer is also ongoing. (NCT00003097) Acitretin (NCT00644384) and eflornithine (NCT00005884) are two new agents under trial for the prevention of nonmelanoma skin cancer. Ongoing RCTs aim to determine the chemopreventive efficacy in patients at high risk for nonmelanoma skin cancer, or patients who have previously received treatment for nonmelanoma skin cancer. NCT00847912 is a clinical trial aimed to examine if 5-fluorouracil (5-FU) skin cream can prevent the growth of new skin cancers on the face and ears. The cost of trying to prevent skin cancer will be compared to the usual cost of treating skin cancer. Patients who have been treated for two or more skin cancers within the past 5 years are being enrolled.

While there are some randomized clinical trials on prevention of nonmelanoma skin cancer, most of them are targeted at preventive regimens rather than risk factors. This is commonsensical, keeping in mind that the expenditure of an RCT is large and funds are mainly drawn from the drug industry.⁹² It is not unusual for such studies to be prematurely terminated; as a study to determine the efficacy of topical tretinoin cream for the prevention of nonmelanoma skin cancer was terminated 6 months early because of an excessive number of deaths in the tretinoin-treated group. (NCT00007631).⁹³ Importantly, no study to date reports the cost-effectiveness or preventive strategies to reduce the economic burden of nonmelanoma skin cancer. Since a key role of clinical trials is to improve efficiency and reduce health costs,⁹² one could anticipate that new clinical trials would be designed to evaluate the prognostic significance of a number of risk factors.

Pharmacogenomics is the branch of pharmacology which deals with the influence of genetic variation on drug response in patients, by correlating gene expression or single-nucleotide polymorphisms with a drug's efficacy or toxicity. Pharmacogenomics aims to develop rational means to optimize drug therapy, with respect to the patients' genotype, thus to ensure maximum efficacy with minimal adverse effects. Such approaches promise the advent of "personalized medicine"; in which drugs and drug combinations are optimized for each individual's unique genetic makeup. The VDR gene is such an example when SCC tumors are concerned. Vitamin D supplementation maybe inexpensive, but RCTs reported no benefit for the general population.

Despite spending much time and effort for developing biomarkers, to date no biomarker could be of use in identifying which patients are going to develop a second primary nonmelanoma skin cancer or which treated nonmelanoma skin cancer tumors are going to recur; such information would be of importance for reducing follow-up and treatment cost. On the other hand, conventional clinical and demographic prognostic factors for nonmelanoma skin cancer have long been reported (Tables 54-2 and 54-3). Clearly, exposure to UVR is an important initiating factor in skin cancer, although the exact connection between nonmelanoma skin cancer risk and nature, extent, and timing of exposure, remains poorly understood. Excluding PCTH mutations, data so far suggest that risk of NMSC is likely to result from the combined effect of many genes, each with a relatively weak individual contribution. Presumably, the effect of genomic instability results in dysregulation of expression of key TSG or oncogenes. Whether these alterations could be of prognostic value for the clinical practice is not clear to date. Certain genomic alterations have been associated with increased or reduced risk for NMSC (Table 54-1), with a second primary NMSC (Table 54-2) or with a recurrent tumor (Table 54-3). However, use of these biomarkers in everyday practice should be supported by further studies, mainly for its cost-effectiveness. Such studies also add to the currently available knowledge regarding NMSC aetiopathogenesis providing further justification for their expenditure.

Several SNPs predisposing to NMSC development have been described previously in the manuscript. Basic medical research is expected to contribute a large number of associations between risk for NMSC development and various genes. In the future, microarray analyses of a person's DNA sequences may be the most cost-effective way to predict risk for NMSC development. Evidence reviewed herein suggests that there may be more research targeted in BCC when compared to SCC. In this regard, six distinct genes signifying susceptibility to BCC have been named after their risk predicting capacity within 2009; their number is expected to rise. The reason for that may be the longer life expectancy of BCC patients, the greater cumulative incidence of the disease, and the more homogenic differentiating profile of BCC cancer cells when compared to SCC cancer cells. While for BCC development the genetic hallmark is abrogation of the PTCH-sonic hedgehog pathway, little is known about the causal alterations of SCCs. However, the complexity of the genetic alterations (numerical and structural aberration profiles) in SCCs argues for several levels of genomic instability involved in the generation and progression of skin cancer.

CONCLUSIONS

Given the continuously rising life expectancies of new born children⁹⁴ and the previously reported role of skinaging in nonmelanoma skin cancer development, it is anticipated that the number of patients who experience

a nonmelanoma skin cancer will also rise. The incidence of nonmelanoma skin cancer is increasing year by year and the number of immunocompromised patients who exhibit a higher risk is on the increase.³⁴ Furthermore, the usually reported patient incidence rates of BCC and SCC substantially underestimate the burden of nonmelanoma skin cancer in the population when compared to tumor-incidence rates.⁹⁵ A study in US Veteran's concluded that nonmelanoma skin cancer is being diagnosed at a younger age and more commonly on the extremities than in the past.⁹⁶ Thus, more research targeted on nonmelanoma skin cancer is justified. New approaches in early identification of nodal metastases, treatment, and prevention of local recurrences, and second primary malignancies are warranted.

Existing demographic and clinical risk predictors for nonmelanoma skin cancer derived from open uncontrolled studies which are mainly unmatched and retrospective.

Not enough information exists on the possible value of these factors regarding the characterization of high risk populations (see Table 54-1). Furthermore, the predictive value of available biomarkers in the development of second primary or recurrent tumors is also uncertain (Tables 54-2, 54-3). Limited existing data presented in this chapter suggest that demographic and clinical risk factors are of the same or more likely higher predictive value when compared to biomarkers. Moreover, they are indisputably cheaper and easier to monitor even in developing countries.

Conclusively, it is suggested that further studies aimed in nonmelanoma skin cancer are needed to present better evidence about the predictive value of certain demographic, clinical, and histologic factors in identifying high-risk populations. The authors of this chapter have conducted a study of this type. Studies have now been published. Should the Editor wish to add them to chapter references.^{97,98}

What We Know

- A number of clinico-epidemiologic factors are associated with higher risk for nonmelanoma skin cancer development.
- Patients with prolonged Ultra Violet (UV) radiation exposure are at higher risk of developing nonmelanoma skin cancer. The association between risk and UV exposure appears to be less dose-responsive in BCC than in SCC.
- Biomarkers for NMSC can be classified as:
 - Biomarkers related to defective host response to ultraviolet radiation
 - Biomarkers related to Genomic instability
- A subset of patients with NMSC exhibits a higher risk of developing a second primary NMSC. Another subset of patients with NMSC exhibits a higher risk of experiencing a recurrence. These patients may be screened via certain risk factors and followed up in a structured fashion.
- BCC is believed to originate from stem cells of the hair follicle. SCC is believed to originate from stem cells of the basal cell layer in the epidermis.
- BCC does not metastasize.
- The incidence of NMSC is anticipated to rise as well as the socioeconomic burden of the disease.
- Research on biomarkers for NMSC is justified in order to develop preventive and follow-up strategies and to better understand the pathophysiologic process of the disease so as to facilitate more efficient treatment modalities.
- Conventional clinical and demographic risk factors need also to be studied more thoroughly since they can be most cost-effective for the prevention of the disease.
- Further research on vitamin D receptor polymorphisms could allow for separation of the group of patients for whom vitamin D supplementation shall have a protective effect against NMSC development. On the contrary, higher risk for SCC was reported in women with a specific VDR Bsm1 polymorphism and high vitamin D intake. Pharmacogenomics screening in the general population is already of value to avoid unfavorable effects of Vitamin D supplementation.
- Six distinct loci associated with susceptibility to basal cell carcinoma have been named to date.

Risk Factors for Alopecia

Nadia Aldoori, M.B.Ch.B., M.R.C.P., and Andrew Messenger, M.B.B.S., M.D., F.R.C.P.

INTRODUCTION

The alopecias are a diverse group of disorders characterised by loss of hair. Their causes are similarly diverse involving varying degrees of genetic and environmental influences. In this article, we discuss the risks associated with the development and prognosis of some of the more common types of alopecia including pattern hair loss, alopecia areata, cicatricial alopecia, and chemotherapy alopecia.

PATTERN HAIR LOSS

Pattern hair loss, or common balding, is a familiar human trait that occurs in both men and women (Figure 55-1). The patterns of hair loss in the two sexes generally differ although there is overlap and racial variation. For example, a ‘female’ pattern characterised by a diffuse reduction in hair density with retention of the frontal hair line is occasionally seen in men and a ‘male’ pattern, with

FIGURE 55-1 Female pattern hair loss.

fronto-temporal recession and vertex balding, occasionally occurs in women. In general terms, the etiology of male balding is quite well defined. Less is known of the causes of pattern hair loss in women. The term ‘androgenetic alopecia’ has been used to describe pattern hair loss. The role of androgens and genetic factors is well established in male balding but the etiology in women is less clear-cut, hence the recent preference for using the term ‘female pattern hair loss’ (FPHL).

Risk Factors for Pattern Hair Loss in Men

Male balding is determined by three factors – age, androgens, and a genetic predisposition.

Age

In view of its inevitability, it is difficult to regard aging as a risk factor in male balding. Nevertheless, the frequency and severity of balding increase in the population as a function of age and the risk that an individual will develop balding clearly increases with advancing years. Almost all Caucasian men develop some recession of the frontal hair line at the temples during their teens. Deep frontal recession and/or vertex balding may also start shortly after puberty, although in most men the onset is later. Hair loss progresses to end stage balding (i.e., Norwood-Hamilton stage VI-VII, in 50-60% of men by the age of 70). A small proportion of men (15-20%) do not show balding, apart from post-pubertal temporal recession, even in old age. Some authorities have suggested that scalp hair loss in elderly men may develop independently of androgens (senescent alopecia) but this remains to be verified.¹

Androgens

It has been known since ancient times that eunuchs do not go bald. Hippocrates stated that ‘eunuchs are not subject to gout nor do they become bald’ (Aphorisms VI, 28). The role of testosterone was first recognized by James Hamilton, an American anatomist.² He observed that men castrated

before puberty retained a pre-pubertal hair line and did not go bald. Of twelve such men who were subsequently treated with testosterone, four developed typical male hair loss. Castration later in life halted the progression of hair loss but did not result in regrowth of hair.

Testosterone is the major circulating androgen in men. However, it is the more potent androgen, dihydrotestosterone (DHT), the 5 α -reduced metabolite of testosterone that is responsible for driving hair loss. The conversion of testosterone to DHT is catalyzed by the enzyme 5 α -reductase. There are two isoforms of 5 α -reductase which are encoded by different genes. Males with a mutation in the gene for the Type 2 isoform (pseudovaginal perineoscrotal hypopspadias) have low circulating levels of DHT, ambiguous external genitalia and do not go bald.³ Accordingly, treatment of male balding with finasteride, an inhibitor of type 2 5 α -reductase, prevents progression of balding in most men and stimulates some recovery of hair growth in about two thirds.⁴ This latter finding also illustrates that, contrary to Hamilton's conclusions from his observations in eunuchs, male balding is partially reversible.

Androgens act on tissues via binding to a specific intracellular protein, the androgen receptor, a member of the steroid-thyroid nuclear receptor superfamily. Mutations in the androgen receptor gene are responsible for the androgen insensitivity syndrome. XY individuals with the complete form of the syndrome (Complete Androgen Insensitivity Syndrome), in which there is failure of functional androgen receptor expression, have intra-abdominal testes but female external genitalia and body form, and female psychosexual development. After puberty, circulating testosterone is in the normal or elevated male range but pubic and axillary hair fail to develop, and there is no beard growth and no balding.⁵

A role for androgens in the etiology of male balding is incontrovertible. Nevertheless, other factors are clearly involved as not all men develop balding despite similar androgen levels to those that do. The above discussion emphasizes that there are multiple points in the pathway leading to androgen action in the target tissue that may modulate the response but to date we have little evidence of what these factors might be. There have been several studies reporting higher levels of androgens in balding men compared to men without hair loss. These include elevated DHT: testosterone ratios,^{6,7} raised levels of free testosterone,^{8,9} and dehydroepiandrosterone in plasma.¹⁰ However, all are quite subtle and total testosterone levels and other features of 'masculinity'¹¹ do not differ between balding and nonbalding groups.

Genetics

Twin studies demonstrate that the predisposition to male balding in young men is predominantly caused by genetic factors.^{12,13} Published concordance rates for monozygotic twins are around 80–90%, with consistently lower rates

in dizygotic twins. The most obvious risk factor is paternal hair status and several studies have shown there is a high frequency of balding in the fathers of bald men. For example, Ellis and colleagues reported that 32 of 54 bald men (59.3%) had fathers with a greater degree of baldness, whereas only one of 65 sons of 50 non-bald controls had type III baldness or greater.¹⁴ In a study involving 572 men aged 16–91, there was a significant increase in the risk of balding in young men with a balding father over those with a non-bald father (odds ratio (OR) 5.5, 95% CI 1.26–23.99), which fell with increasing subject age to approach unity in elderly men.¹⁵ The opposite trend was seen in non-bald men where the risk of nonbalding in men with a non-bald father increased with age (OR 3.2, 95% CI 1.82–5.58 in subjects aged 70 and over).

There are also racial differences in the prevalence of male balding, presumably genetically determined, although there are no parallel studies in different racial groups. Compared to Caucasians balding is less common in oriental men. Takashima and colleagues reported the male balding starts approximately one decade later in Japanese men than in Caucasians and the prevalence is about 1.4 times lower in each decade group.¹⁶ In Korean and Chinese men the frequency is 20–40% lower than in Caucasian men in the 40–70 age group, although the difference becomes less pronounced with advancing age.^{17,18}

Androgenetic alopecia is probably a polygenic trait.¹⁹ Three independent candidate gene studies have found significant associations, positive^{20,21} and negative,²² with variant regions of the androgen receptor (AR) gene. Genome wide scans have also identified susceptibility loci at 3q26²³ and 20p11.22.^{24,25} Richards and colleagues calculated that men carrying risk alleles at AR and 20p11.22 had a seven-fold increased risk of androgenetic alopecia.²⁵

Risk Factors for Pattern Hair Loss in Women

Age

As in men, the population frequency and severity of FPHL increase with age. Two studies in Caucasian women in the United Kingdom and United States reported prevalence rates of 3–6% in women aged under 30, increasing to 29–42% in women aged 70 and over.^{26,27} The frequency is lower in oriental women.^{17,18} Cross sectional data show that, from around the age of 30, hair density in the female population declines gradually with advancing years. Mean hair diameter also falls over a similar age range.²⁶ These data show no evidence that the decline in hair density and hair diameter accelerates following the menopause.

Androgens

Several studies have reported that women with hair loss are more likely to have elevated androgen levels or show an increased frequency of other features of androgen excess

than women without hair loss. Futterweit and colleagues studied 109 women with hair loss and reported that 38.5% showed clinical or biochemical evidence of androgen excess.²⁸ In a series of 187 women with hair loss, Vexiau et al. reported abnormal hormonal profiles, mostly of minor degree, in 67% of women with hair loss alone and in 84% of women who were also hirsute.²⁹ In a series of 89 women presenting to a trichology clinic with hair loss 67% showed ultrasound evidence of polycystic ovaries compared to 27% in a control group of 73 women, and 21% were significantly hirsute compared to 4% of controls.³⁰ However, other investigators have failed to find evidence of raised androgen levels in women with FPHL,³¹ and in all studies there is a variable proportion of women with hair loss who do not show clinical or biochemical signs of androgen excess.

There is limited information on the frequency of hair loss in women with hyperandrogenism. Reports of hair loss in women with androgen secreting tumors^{32,33} predated Hamilton's seminal observations on testosterone and male balding. In a small personal study, seven of 21 women referred with hirsutism (33%) also had pattern hair loss compared to 11 of 143 (8%) age-matched nonhirsute controls. However, in a large series of 1000 women with hyperandrogenism, only 4% had hair loss, whereas 75% showed hirsutism.³⁴

Genetics

Less is known of the inheritance of pattern hair loss in women than in men but published genetic models have generally assumed that male balding and female pattern hair loss are the same entity. Osborn proposed that balding in men and in women is attributed to a single gene with two alleles, *B* (balding) and *b* (non-balding).³⁵ She suggested that balding occurs in homozygous (*BB*) and heterozygous (*Bb*) men but only in homozygous (*BB*) women. However, in a critique of the published data, Kuster and Happle argued that the predisposition to balding is a polygenic trait in which clinical expression represents a threshold effect.¹⁹ They suggested that the threshold is higher in women because of their lower androgen levels, and women, therefore, need a stronger genetic component than men in order for hair loss to occur. In the only other published study of family histories in balding women other than that of Osborn, Smith, and Wells, found that first degree male relatives showed an increased frequency of balding compared with the male relatives of non-balding women.³⁶ In a case control study Yip and colleagues found a weak statistically insignificant association between a variant region of the aromatase gene and female pattern hair loss.³⁴

Environmental factors

In a twin study, using the Danish Twin Registry, Gunn and colleagues found a strong genetic contribution to frontal

hairline recession and hair graying in women.³⁷ However, unexpectedly the data suggested that hair thinning was not genetically determined. The study participants were elderly and none showed hair loss greater than Ludwig I. The findings may, therefore not be applicable to early onset FPHL. However, they raise the possibility that environmental factors, as yet unknown, contribute to hair loss in older women.

ALOPECIA AREATA

Alopecia areata is a chronic inflammatory disease that affects the hair follicle and sometimes the nails. It is generally thought to be a T cell-mediated autoimmune disease, although the poor response to immunosuppressive therapies casts some doubt on this idea. The onset may be at any age and male and female are probably equally affected.

Epidemiologic information on alopecia areata is limited because only one formal population study of the disorder has been published.³⁸ This examined the occurrence of alopecia areata in Olmsted County, Minnesota, USA from 1975-1989, where the incidence rate was 0.1-0.2% with an estimated lifetime risk of 1.7%.

Genetic Factors

Alopecia areata is more common in family members of affected individuals than in the population at large, although the reported frequency of a positive family history varies widely between published series from around 4% to 28%.³⁹ The risk of developing alopecia areata is probably increased by the presence of a family history. Van der Steen and colleagues calculated the risk of alopecia areata in the children of a proband at around ten-fold greater than that in the general population.⁴⁰ Colombe et al. found that a family history was more common in individuals developing alopecia areata before the age of 30 (37% compared to 7.1% in cases with onset after 30).⁴¹ In a series of 513 patients, Goh et al. found that those with more than one affected relative were more likely to have severe forms of alopecia areata.⁴²

The predisposition to alopecia areata is polygenic. Case control studies have identified a number of genes associated with alopecia areata (Table 55-1). The majority are involved in regulating immune and inflammatory responses and associate with disease severity. The most consistent relationship is with Class II MHC genes where both positive and negative associations have been reported. Alopecia areata is particularly common in Down syndrome, 8% in the series reported by du Vivier,⁴³ suggesting involvement of genes on chromosome 21. In the rare autosomal dominant disorder autoimmune polyglandular syndrome Type 1 (APS-1), over 30% of sufferers develop alopecia areata as well as other autoimmune disorders. APS-1 is caused by a mutation in the Autoimmune Regulator (AIRE) gene, which lies within the Down critical region on

chromosome 21. Variant regions within the AIRE gene associate with disease severity in sporadic cases of alopecia areata.⁴⁴

The association of alopecia areata with the MHC region has been confirmed in a genome-wide association study.⁴⁵ This study also identified associations with several other genes involved in predisposing to autoimmune disease, including those controlling activation and proliferation of regulatory T cells (T_{reg} cells), cytotoxic T lymphocyte-associated antigen 4 (*CTLA4*), interleukin genes, and with regions containing genes expressed in the hair follicle (*PRDX5* and *STX17*). There was a region of strong association within the *ULBP* gene cluster on chromosome 6q25.1, encoding activating ligands of the natural killer receptor NKG2D, which has not previously been implicated in autoimmune disease.

The genetic predisposition to alopecia areata is likely to involve complex haplotypes. For example, alopecia areata in APS-1 is associated with carriage of HLA-DRB1*04 and HLA-DQB1*0302.⁴⁶

Prognosis

Most information available on risk factors in alopecia areata relates to prognosis rather than to development of the disease.

Disease severity is the most reliable indicator of prognosis. From their population study, Savaki and colleagues estimated that around 8% of affected individuals developed chronic disease.³⁸ Ikeda reported that approximately 80% of patients with patchy hair loss regrew their hair within 12 months, although the provenance of her cases was not described.⁴⁷ Most published data on the prognosis of alopecia areata, however, comes from secondary and tertiary referral centers, and is therefore biased towards the more severe end of the disease spectrum. Tosti and colleagues reported that only half of those presenting to their department with patchy hair loss were disease-free 15–20 years later and that 25% had progressed to alopecia totalis (AT) or universalis (AU). In patients presenting with AT/AU 33 out of 38 still had severe disease and only one was disease-free.⁴⁸ Previously, Walker and Rothman reported that a third of 230 patients followed for 5 years failed to recover from the original attack and all patients followed for 20 years had at least one recurrence.⁴⁹ Similar results were reported by Gip and colleagues in a 10-year follow-up study.⁵⁰

Several large case series have emphasized the unfavorable prognosis when onset of alopecia areata occurs during childhood.^{42,49,51–53}

Published rates of nail involvement vary widely, perhaps reflecting the nature of the investigators' practice but is probably around 20–30% in patients seen in specialist centres.^{54–56} Onychodystrophy is more common in alopecia totalis and universalis than in patchy alopecia.^{48,56,57}

A number of studies have reported an association between alopecia areata and atopic disease,^{47,51,52} although this has not been found by all investigators.^{55,58} In a large controlled study Barahmani et al. found that a history of any atopic disorder was associated with an overall increased risk of alopecia areata, especially the more severe forms (AT and AU), with the risk increasing particularly with atopic dermatitis.⁵⁹ Having more than one atopic disease did not increase the risk. Betz and colleagues reported that atopic subjects with alopecia areata who carried loss-of-function mutations in the filaggrin gene had a highly significant increased risk of severe alopecia compared to atopics without filaggrin mutations.⁶⁰

Other prognostic indicators include an ophiasis pattern of hair loss,⁵³ loss of body hair, and failure to respond to contact immunotherapy.

CICATRICIAL ALOPECIA

This category includes a diversity of diseases with different etiologies but with the common outcome of follicular deletion. Cicatricial alopecias are divided into primary and secondary forms. In the latter group, hair follicles are destroyed as a result of a general insult to the skin such as thermal injury, trauma, or inflammatory skin disease, and will not be considered further. In the primary cicatricial alopecias, such as lichen plano-pilaris and discoid lupus erythematosus, the hair follicle is the primary target of the disease process. There is recent evidence implicating reduced hair follicle expression of the transcription factor peroxisome proliferator-activated receptor (PPAR) gamma in the pathogenesis of lichen plano-pilaris.⁶¹

Primary Cicatricial Alopecias

The risks predisposing to primary cicatricial alopecias are largely unknown apart from the concentration of specific types to certain population groups.

FIGURE 55-2 Central centrifugal cicatricial alopecia

Central centrifugal cicatricial alopecia (CCCA) is almost exclusively a disease affecting women of African ethnicity (Figure 55-2). Its cause has long been a source of controversy, reflected by the changing nomenclature through ‘hot comb alopecia’⁶² and ‘follicular degeneration syndrome’⁶³ to its present less cause-specific designation. However, the concept that CCCA is caused by hair care practices remains the most likely explanation.⁶⁴ In a controlled study Gathers and colleagues found a strong association between CCA and a history of hair weaves or braiding but not with the use of chemical relaxers.⁶⁵

Frontal fibrosing alopecia (Figure 55-3) was first described by Kossard in 1994.⁶⁶ It affects the scalp margins,

FIGURE 55-3 Frontal fibrosing alopecia

predominantly the frontal hairline, and the eyebrows and is generally regarded as a variant of lichen plano-pilaris.⁵⁷ It is largely, though not exclusively, a disease of postmenopausal women. The cause is unknown but it appears to be becoming increasingly common since its first description suggesting involvement of an environmental factor, yet unidentified.

CHEMOTHERAPY ALOPECIA

Alopecia is a common complication of antimitotic chemotherapy (Table 55-2). Hair shedding typically occurs within 1 to 3 weeks and is complete within 1 to 2 months after initiation of chemotherapy. In most cases hair loss is temporary and recovers fully within a period of months following cessation of the causative insult. A wide variety of anticancer drugs will cause hair loss with frequencies differing for the four major classes – more than 80% for antimicrotubule agents, e.g. paclitaxel, 60–100% for topoisomerase inhibitors, e.g. doxorubicin, more than 60% for alkylating agents, e.g. cyclophosphamide, and 10–20% for antimetabolites (e.g. 5-fluorouracil). The risk of chemotherapy alopecia is also related to the particular therapeutic protocol and is greater if treatment combines two or more antimitotic agents. (reviewed in⁶⁸).

TABLE 55-2—Cytotoxic Agents and Hair Loss

Cytotoxic agents that commonly cause hair loss

Adriamycin	Docetaxel
Daunorubicin	Paclitaxel
Etoposide	Ifosfamide
Irinotecan	Vindesine
Cyclophosphamide	Vinorelbine
Epirubicin	Topotecan

Cytotoxic agents that sometimes cause hair loss

Amsacrine	Vincristine
Cytarabine	Vinblastine
Bleomycin	Lomustine
Busulphan	Thiotepa
5-fluorouracil	Gemcitabine

Cytotoxic agents that rarely cause hair loss

Methotrexate	Procarbazine
Carmustine	6-mercaptopurine
Mitoxantrone	Streptozotocin
Mitomycin C	Fludarabine
Carboplatin	Raltitrexate
Cisplatin	Capecitabine

(From Trueb RM. Chemotherapy-induced alopecia. *Semin Cutan Med Surg*. 2009;28:11–4.)

Permanent Alopecia

Although chemotherapy alopecia is usually reversible, this is not always the case. In particular, permanent alopecia is well-described following high-dose chemotherapy conditioning prebone marrow transplantation. The alopecia most commonly affects scalp hair, but permanent alopecia of eyelashes, eyebrows, axillary, and pubic hair has been reported.⁶⁹

Regimens incorporating busulphan, a drug that is widely used in patients undergoing allogeneic or autologous bone marrow transplantation, seem most likely to cause permanent alopecia.^{69–72} The extent of the alopecia appears to be dose related, but there is no clear threshold over which all patients treated with busulphan will develop permanent alopecia.⁷¹

Although busulphan is considered the main culprit of permanent alopecia, it can be seen across the spectrum

of diseases, transplant types, and with nonbusulphan containing regimes.⁷² Other chemotherapy agents have been implicated in causing permanent alopecia. De Jonge et al. reported incomplete scalp hair regrowth and permanent hair loss in patients who received high-dose chemotherapy with combination therapy of cyclophosphamide, carboplatin, and thiotepa (CTC).⁷³ The permanent hair loss was associated with having had more than one course of treatment. Vowels and colleagues⁷⁴ reported chronic graft versus host disease (GVHD) is a risk factor for alopecia, but this association was not reproduced in a later study.⁷¹ Cranial irradiation in association with busulphan was also found to increase the rate of alopecia.⁷⁴

There has been one report of permanent hair loss in women receiving treatment with taxanes for breast cancer.⁷⁵

What We Know

- The risk of developing male pattern hair loss is determined largely by a genetic predisposition. The relative contribution of paternal and maternal genes has not been established but balding in the father is a strong predictor of balding in male offspring. Variants in increasing number of genes are associated with male balding, in keeping with the concept of a polygenic predisposition.
- Less is known about risks predisposing to female pattern hair loss. There is limited evidence implicating genetic factors but a recent study suggests there is also an environmental influence on hair thinning in elderly women. Female pattern hair loss is associated with hyperandrogenism in some women, although less common than hirsutism, and many women with pattern hair loss do not show clinical or biochemical evidence of androgen excess.
- A family history of the disease is a weak predictor of the risk for developing alopecia areata. The strongest risk factor of an adverse prognosis is disease severity at presentation. Onset in childhood, nail involvement, and ophiasis are also associated with a less favorable prognosis. A large number of genetic associations have been reported with alopecia areata, especially immune response genes. Most are associated with more severe forms of the disease.
- Central centrifugal cicatricial alopecia is largely confined to women of African ethnicity. There is some evidence that it is related to hair care practices.
- Frontal fibrosing alopecia mainly affects postmenopausal women. Its cause is not yet known.
- Many antimitotic drugs cause temporary hair loss. Permanent alopecia may follow conditioning treatment for bone marrow transplantation, particularly when busulphan is used.

Risk Factors for Occupational Contact Dermatitis

Boris D. Lushniak, M.D., M.P.H.

OCCUPATIONAL CONTACT DERMATITIS

The skin serves as a protective barrier and provides a physiologic first-line of defense against various environmental influences. In this role as a protective barrier, the skin can be directly injured, or damaged by environmental exposures such as irritants or serve as a conduit and site for immunologic reactions to cutaneous allergens. Common sources of environmental exposures to the skin can be found within the work environment. Within this environment, there are a myriad of potential exposures including physical insults, biologic organisms, and chemical exposures. Within the occupational environment, skin injury, damage, and immunologic reactions manifest on the skin surface, and can result in skin diseases, which include irritant contact dermatitis, allergic contact dermatitis, as well as contact urticaria.

Contact dermatitis is the most common occupational skin disease and epidemiologic data show that contact dermatitis comprises 90 to 95 percent of all occupational skin diseases.¹ Occupational contact dermatitis is an inflammatory skin condition caused by skin contact with an exogenous agent or agents found in the workplace. Contact dermatitis can be divided into two general categories based upon the exposure, etiology, and pathophysiology of the resulting skin disease. These are irritant contact dermatitis (ICD) and allergic contact dermatitis (ACD).

Irritant contact dermatitis (ICD) is a nonimmunologic reaction to chemical irritants resulting in a cutaneous inflammation from a direct cytotoxic effect of a chemical agent. ACD is a reaction to allergens and is a type IV, delayed or cell-mediated, immune reaction. Over 57,000 chemicals can cause skin irritation, and about 3,700 chemicals have been identified as skin allergens.² Most everyone exposed to a skin irritant will develop an ICD. Allergens usually are low-molecular-weight chemicals that act as haptens, and usually only a small percentage of people will develop ACD after contact with these haptens.

Both ICD and ACD can have similar clinical manifestations and both can be evident as an acute, subacute, or chronic condition (Figures 56-1 thru 56-3). The skin initially becomes erythematous and symptoms can include

FIGURE 56-1 Acute contact dermatitis from exposure to the strong irritant, ethylene oxide.

stinging, burning, and pruritus. The skin can later develop papules or vesicles and bullae. With time, a crusting or scaling of the skin surface can develop. If there is no further exposure to the etiologic agent, the dermatitis usually resolves in 1 to 3 weeks. However, with chronic or repeated exposure, deep fissures, extensive scaling, and hyperpigmentation can occur.

The parts of the body most commonly affected include the exposed areas of the skin, such as hands and forearms,

FIGURE 56-2 Subacute dermatitis from the rubber accelerator, mercaptobenzothiazole, from the rubber in a work boot.

FIGURE 56-3 Chronic dermatitis from exposure to kerosene, a solvent that was used for cleaning the skin.

which have the greatest contact with irritants or allergens. Over 80 percent of occupational contact dermatitis involves the hands.^{2,3}

RISK FACTORS

A risk factor, as it applies to diseases such as occupational contact dermatitis, is defined as a variable associated with an increased risk of developing that specific disease. It is important to note that in many circumstances, risk factors are correlational and should not necessarily be considered as direct etiologic causes of the disease in question. Ideally, risk factors are determined by evaluating and comparing the risk of disease in those exposed to or possessing that potential risk factor to those not exposed or those without those attributes.

Understanding risk factors for a disease is important in the potential prevention of that disease state. Some risk factors often associated with diseases are endogenous factors and may be beyond the control of the individual. These include age, gender, race, and heredity/genetics. In these circumstances, an understanding of risk factors can lead to an increased awareness of one's risk of a disease. In some cases risk factors, including those considered to be exogenous, can be modified, treated, or controlled and aid in preventative measures. Examples of these types of risk factors associated with diseases include specific exposures, such as workplace chemicals and smoking tobacco, high blood pressure, physical activity, and obesity.

Inherent as a primary exogenous risk factor for occupational contact dermatitis is skin contact with an irritant or a sensitizer in an occupational setting. If an irritant or allergen does not contact the skin, then there will be no skin disease. It becomes more complex in that the relatively simple risk factor of direct exposure to these substances is related to many other factors including the occupation, the specific work duties, the work environment, the work practices, and experience level of the worker, and the protective measures used. Add to these the further complexity of

the susceptibility of an individual with "sensitive" skin or one susceptible to developing allergic reactions. Many of these risk factors have been poorly studied and are not well described.

Data on occupational contact dermatitis risk factors are limited and all sources have their limitations. Information on risk factors for occupational contact dermatitis comes from a variety of sources including occupational disease and injury surveys, workers' compensation records, specific workplace investigations, clinical investigations (e.g., patch test studies), and clinical case studies. It can be difficult to obtain full information on risk factors associated with occupational contact dermatitis for a variety of reasons, many of which are inherent in the disease process. These include: (1) lack of a clear and consistent case definition for the disease; (2) difficulty of definitive diagnosis as to etiology and work-relatedness; and (3) in many cases the disease goes untreated or is not evaluated by a health care professional.

In particular, the work-relatedness of contact dermatitis may be difficult to prove. The accuracy of the diagnosis is related to the skill level, experience, and knowledge of the health professional who makes the diagnosis and confirms the relationship with environmental or workplace exposures. Guidelines are available for assessing the work-relatedness of dermatitis, but even with guidelines, the diagnosis may be difficult.⁴ The diagnosis is based on the medical and occupational histories and physical findings. The importance of the patient's history of exposures and disease onset is clear. Standardized questionnaires for surveying work-related skin diseases are available and can be helpful in the workplace.⁵ In ICD, there are no additional confirmatory tests. In many instances, ACD can be confirmed by skin patch tests using specific standardized allergens or, in some circumstances, by provocation tests with nonirritating dilutions of industrial contactants. ICD may be overestimated (and allergic contact dermatitis underestimated) because of time, expense, and availability of skin patch testing; physician experience; and the limited availability of allergens in the United States (US).

Occupation as a Risk Factor

Specific national occupational disease and illness data are available from the U.S. Bureau of Labor Statistics (BLS), which conducts annual surveys of approximately 176,000 employers selected to represent all private industries in the United States.⁶ All occupational skin diseases or disorders, including contact dermatitis, are tabulated in this survey. BLS data show that occupational skin diseases consistently accounted for 30 to 45% of all cases of occupational illnesses from the 1970s through the mid-1980s, and in recent years accounted for nearly 18 percent of all occupational illness.⁶

U.S. Bureau of Labor Statistics data for occupational skin diseases for 2002 to 2007 are shown in Table 56-1.

TABLE 56-1—Numbers and Rate of Occupational Skin Diseases Per Year, United States, BLS Survey Data 2002–2007⁶

Year	Number of cases (000's)	Incidence rate per 100,000
2002	44.9	51
2003	43.4	49
2004	38.9	44
2005	40.1	44
2006	41.4	45
2007	35.3	37

However, because of BLS survey limitations it is thought that these data underestimate the actual number of occupational skin diseases. In 2007, BLS estimated 35,300 cases of occupational skin diseases or disorders in the U.S. workforce for an annual incidence rate of 37 cases per 100,000 workers.⁶ Total numbers and incidence rates of occupational dermatologic conditions, by major industry division, based on the BLS survey for 2007 are shown in Table 56-2. The greatest number of cases of occupational skin diseases is seen in manufacturing, but the highest incidence rate is seen in the industrial sector of agriculture, forestry, fishing, and hunting.

In 1988, the National Health Interview Survey (NHIS) included an Occupational Health Supplement, which included questions on dermatitis. Although dated and scheduled to be updated in 2010, the 1988 Occupational Health Supplement offers the most complete data available in the United States for specific information on

self-reported dermatitis. The survey consisted of personal interviews of people in randomly selected households. For 30,074 people participating in the NHIS, the annual period prevalence was 11.2 percent for all dermatitis, 2.8 percent for contact dermatitis, and 1.7 percent for occupational contact dermatitis. Projecting these results to the U.S. working population resulted in an estimate of 13.7 million people with dermatitis, 3.1 million people with contact dermatitis, and 1.9 million people with occupational contact dermatitis.⁷

In the NHIS, the occupational groups with the highest prevalence of self-reported occupational contact dermatitis included physicians, dentists, nurses, pharmacists, and dieticians (5.6%); public transport attendants, cosmetologists, and other personal service occupations (4.9%); health care therapists, technologists, technicians, and assistants (3.5%); and mechanics and repairers of vehicles, engines, heavy equipment, and machinery (3.5%).⁷

An analysis of Oregon workers' compensation claims data for 1990 through 1997 estimated the average claim rate of occupational dermatitis to be 5.7 per 100,000 workers. In this 8-year period, 727 workers' compensation claims were filed for occupational dermatitis, of which 611 were determined to be compensable.⁸ Of all accepted workers' compensation claims for occupational contact dermatitis in Oregon, the occupations with highest claim rates were farming, fishing, and forestry workers (18.2%); machine operators and assemblers (16.5%); service-related workers (15.3%); laborers (13.7%); precision production crafts workers (8.0%); and protective services workers (5.7%), followed by technicians and related support workers, transportation and material movers, and professional specialty, administrative support, executive, administrative, and sales employees.⁸ Self-employed individuals, such as hairdressers and cosmetologists, are not represented in these claims.

TABLE 56-2—Numbers and Incidence of Occupational Skin Diseases by Industry Sector, 2007 BLS Survey Data⁶

Industry Sector	Number of cases	Incidence rate per 100,000
Agriculture/forestry/fishing/hunting	1200	123
Manufacturing	8800	62
Education and Health Services	7700	57
Leisure and Hospitality	4100	46
Construction	2600	36
Professional and Business Services	3600	26
Other services	800	26
Trade/transport/utilities	5500	24
Information	400	17
Mining	<100	13
Financial Activities	600	8
TOTAL	35,300	37

Exposure as a Risk Factor

The irritating potential of a substance is dependent on a variety of factors including physical and chemical properties, concentration and dose as well as exposure duration and occlusion. The etiology of ICD is often multifactorial, but the most common skin irritant is wet work, defined as exposure of skin to liquid for more than 2 hours per day, use of occlusive gloves for more than 2 hours per day, or frequent handwashing.⁹ Other common causes of ICD include soaps and detergents, solvents, food products, cleaning agents, plastics and resins, petroleum products and lubricants, metals, and machine oils and coolants.⁹ Frictional ICD can be caused by low humidity, heat, paper, tools, metals, fabrics, plastics, fibrous glass and other particulate dusts, and cardboard, among other causes.¹⁰

The induction and elicitation of sensitization and the resulting clinical picture of ACD is dependent on a complex process of exposure to a low-molecular-weight chemical, penetration of that chemical through the skin,

TABLE 56-3—North American Contact Dermatitis Group Patch-Test Results, 2003 to 2004¹³**Prevalence of 20 most common positive reactions (n varies from 5106 to 5145)**

<i>Test Substance</i>	<i>Common sources</i>	<i>% Positive</i>
Nickel sulfate 2.5% pet	Metals, jewelry	18.7
Neomycin sulfate 20% pet	Creams, lotions	10.6
Myroxylon pereirae (balsam of Peru) 25% pet	Fragrance chemicals	10.6
Fragrance mix 8% pet	Toiletries, scented products	9.1
Quaternium-15 0.5% pet	Cosmetics, sunscreens	8.9
Sodium gold thiosulfate 0.5% pet	Jewelry, dental products	8.7
Formaldehyde 1% aq	Fabrics, skincare products	8.7
Cobalt chloride 1% pet	Metals, jewelry	8.4
Bacitracin 20% pet	Ointments, creams	7.9
Methyldibromo glutaronitrile phenoxyethanol 2.5% pet	Biocides, skincare products	6.1
p-Phenylenediamine 1% pet	Hair dyes, leather	4.7
Thiuram mix 1% pet	Rubber, pesticides	4.6
Potassium dichromate 0.25% pet	Cement, leather	4.3
Carba mix 3% pet	Rubber, pesticides	4.0
Diazolidinylurea 1% pet	Skin care products	3.5
Propylene glycol 30% aq	Cosmetics, topical meds	3.3
Imidazolidinylurea 2% pet	Skin care products	2.9
Colophony 20% pet	Glues, adhesives	2.8
Tixocortol-21-pivalate 1% pet	Corticosteroids	2.7
Diazolidinylurea 1% aq	Skin care products	2.5
Ethylenediamine dihydrochloride 1% pet	Dyes, rubber, fungicides	2.4

protein reactions, and a cascade resulting in a cell-mediated immune response. The major factors related to this process and inherently related to the exposure parameters include potency of the allergen, dose per unit area of skin exposed, duration and frequency of that exposure, vehicle, and occlusion of the chemical.¹¹ Contact allergens show both threshold and dose-response characteristics and potential sensitizing risks of substances have been graded using the murine local lymph node assay.¹²

Common causes of ACD include plants, such as poison ivy, poison oak, and poison sumac, metals, biocides, epoxy resins, rubber additives, and fragrances. The most common skin patch test allergens found to be positive in patients along with potential sources of exposure are shown in Table 56-3.¹³ In patients with occupational contact dermatitis who were skin-patch tested, the most common relevant allergens included thiuram mix, carba mix, bacitracin, methyldibromo glutaronitrile/phenoxyethanol, formaldehyde, glutaraldehyde, methylmethacrylate, nickel, cobalt, and chromium.^{14,15}

Work Practices as Risk Factors

Protective gloves and clothing can reduce or eliminate skin exposure to hazardous substances if used correctly. However, if used improperly or selected poorly there is a

danger of increasing permeation and penetration of irritants and allergens through the occlusion induced by contaminated gloves or clothing. In addition, glove or clothing components may directly irritate the skin or contain allergens, such as latex or rubber additives, so the correct use of personal protective equipment is at least as important as their selection.¹⁶ Similarly, the excessive pursuit of personal hygiene in the workplace may actually lead to misuse of soaps and detergents and resulting ICD. Proper handwashing methods and adequate moisturizing is valuable in preventing contact dermatitis.³ The effectiveness of barrier creams is controversial because there are limited data on the protective nature of these topical products during actual working conditions involving high-risk exposures. Educating the workforce about skin care, exposures, and personal protective equipment use is an especially important measure in the prevention of occupational contact dermatitis.

Age, Race, and Gender as Risk Factors

It is difficult to view age as an independent risk factor for occupational ICD and ACD. For example, age plays a role in job seniority and the potential transitioning of job duties and therefore exposure, skin hardening, the learning curve of job-related best practices to protect the skin, and the healthy worker effect. When looking at skin irritation

responsiveness, there are reports that older individuals have a reduced reactivity to irritants.¹⁷ Information on occupational ACD is less clear, although there have been immunologic changes described with age.

Racial differences in the skin and the reaction of the skin have been described, although it has been difficult to draw definitive conclusions as to their applicability in the clinical setting. African American skin types have been found to have an increased number of layers of the stratum corneum, are more resistant to the effects of tape stripping, have higher lipid contents and elasticity compared to other skin types.¹⁸ However, there still are conflicting findings as to susceptibility of skin irritation and sensitization. There is some evidence that Asian skin may be more reactive and Black skin less reactive than Caucasian skin.¹⁹

In many studies, occupational ICD is seen more often in females. Epidemiologic assessments, which may be biased by chemical exposure patterns and specific gender-related occupations, give a perception that females are more reactive to irritants than males, however this is not necessarily supported by direct comparative testing.¹⁷ Similarly, females may be more predisposed to develop ACD, but again this is likely related to exposure patterns and not to intrinsic skin characteristics.²⁰

Genetics and Atopy as Risk Factors

Variations in genes play a role in skin barrier function and inflammatory mediators. Genetic susceptibility markers have been found for both ICD and ACD affecting the production of proinflammatory cytokines interleukin (IL)-1 α , IL-1 β , IL-8 and tumor necrosis factor (TNF- α), and anti-inflammatory IL-10.²¹ In addition, mutations in the filaggrin gene, which result in impaired skin barrier functions have been identified as risk factors for atopic dermatitis and possibly for ICD and ACD. Polymorphisms in genes encoding for metabolic enzymes, such as

N-Acetyltransferases, play a role in ACD.²¹ Studies in twins show that monozygotic twin pairs have a higher risk of hand eczema when compared to dizygotic twins.²¹

Atopic diathesis is known to increase the susceptibility of skin to irritants but not to allergens.²¹ As a result, workers with atopic skin disease are more likely to develop occupational skin diseases, especially in occupations involving wet work and irritant chemicals.²² Also, maceration and other skin diseases which disrupt the skin barrier can enhance penetration of both allergens and irritants.

What We Know

- Occupational contact dermatitis remains a relatively common disease with a noteworthy public health impact. These factors, along with the potential chronicity of the disorder, its effect on an individual's vocational and avocational activities, and its preventability make occupational contact dermatitis a disease of public health importance. Understanding risk factors and where applicable modifying those risk factors are key components to preventing occupational ICD and ACD. Risk factors for occupational ICD and ACD include specific occupations, exposures to specific irritants and allergens, improper work practices, genetic predispositions, and atopic diathesis. Less defined risk factors include age, race, and gender.

Viral Infections and Skin Cancer

L. Katie Morrison, M.D., and Stephen Tyring, M.D., Ph.D.

I. MERKEL CELL CARCINOMA

Background

Merkel cell cancer (MCC) is considered to be a rare and aggressive neuroendocrine tumor. Approximately 30% of all MCC patients die from metastatic disease within 2 years of diagnosis. Merkel cells are normally found in the basal layer of the epidermis and near hair follicles and have features of both mechanoreceptor and neuroendocrine cells.

Risk factors for the development of MCC include sun exposure and age. In addition, there is an increased risk for developing MCC among patients who are immunocompromised. Consistent with reports that the incidence of MCC is increasing, there were an average of three cases per year from 1979 through 1999 and then 10 per year from 2000 through 2004.

Remarkably, a new human polyomavirus, which has been termed Merkel cell polyomavirus (MCPyV), was first published in 2008 to be integrated into the genome of MCC¹. Mounting evidence supports MCPyV to be involved in one pathway of MCC oncogenesis. Integrated MVC DNA has been identified in MCC tumors at both primary and metastatic tumor sites indicating integration prior to metastasis.

Multiple factors point to the role of MCPyV in MCC. MCC occurs more frequently than expected among immunosuppressed patients, indicating an infectious component, or at least a final common pathway influenced by immune dysfunction. The virus has been found to be mutated in cases of MCC where it is integrated; it loses its ability to replicate and cause cell lysis, but still maintains other gene functions which effect cell cycle progression.

EPIDEMIOLOGY

MCC occurs mostly in Caucasians between 60 and 80 years of age. It occurs about twice as often in males as in females. Researchers believe that exposure to sunlight or ultraviolet light may increase a person's risk of this disease.

Historically MCC has been viewed as having low 5-year survival rates ranging from 29% to 64%. Currently, a 4-tiered system is widely used that separates the patients with localized cutaneous disease based on the largest clinically assessed diameter of the primary tumor (<2 cm or > 2 cm). Lymph node-negative disease with a tumor <2 cm is classified as stage I, lymph node-negative disease with a tumor >2 cm is classified as stage II, lymph node-positive disease is classified as stage III, and the presence of distant metastatic disease is categorized as stage IV. Although low-stage disease predicts a relatively good prognosis, it is not an optimal indicator, because approximately 20% of patients with clinical stage I MCC will die of disease within 5 years of diagnosis².

TREATMENT

MCC is known to be both radio- and chemosensitive. Patients are generally treated with surgery as a first-line therapy, supplemented with adjuvant radiotherapy and chemotherapy if required. The use of adjuvant therapies in MCC is under debate.

Stage-specific treatment regimens have been outlined involving various combinations of surgery, radiation and chemotherapy for International Union Against Cancer (UICC) stage I to III disease while the emphasis of treatment in patients with UICC stage IV disease is on palliative care with or without radio- or chemotherapy. There is a need for more structured clinical research to better illuminate the most effective treatments for this disease³. In part due to the rarity of the disease, prospective randomized clinical trials are lacking.

SEARCH METHODOLOGY

The Cochrane Library for systematic reviews (2009) and Pubmed/Medline (1976–September 2009) were searched for prognostic outcomes for MCC. The following questions were formulated, and additional cross-references were performed under each sub-category.

What is the prognosis of MCC associated with the merkel cell associated polyomavirus (MCPyV) versus without it?

MCPyV is believed to have a role in the development of a substantial portion of MCC tumors. Approximately 80% of MCC evaluated for MCPyV, have shown evidence of this virus integrated in a monoclonal pattern, indicating viral DNA integration into the host precursor cell prior to oncogenesis¹. MCPyV has not been demonstrated in at least 20% of MCC tumors suggesting a distinct etiopathogenesis. Like other tumor viruses, some people who demonstrate prior infection, even with genomic evidence of MCPyV clonal integration, do not develop MCC. Currently it is not clear what other factors are necessary for MCC oncogenesis. Intriguingly, the MCPyV obtained from tumors has specific mutations that render the virus uninfected and even replication incompetent⁴. The significance of this relates to the mutated viruses' ability to transform the cell without causing cell destruction, which is a common component in viral associated cancers.

One retrospective study has been published looking at the prognosis of MCC with and without associated MCPyV. Data was evaluated from 1979 to 2004 in Finland. The national cancer registry in Finland is known for its quality, making this data nearly representative of all MCC cases diagnosed within this 26 year period⁵. This yielded 114 cases of MCC that were analyzable for the presence of viral DNA by polymerase chain reaction (PCR) amplification for viral detection as well as viral quantification. MCPyV DNA was detected in 91 (79.8%) of the 114 MCCs tested. The quantity of viral DNA was found to vary between a few copies per 10, 000 cells to more than 4000 copies per cell. The majority of MCCs had a substantial amount of viral DNA, and only 9 of those 91 MCC with associated MCPyV DNA, had less than one copy of viral DNA per 10 cells. In addition to the detection of viral DNA, this study evaluated the prognosis of the MCCs associated with and without DNA. Those MCC that were found to have MCPyV DNA had a better prognosis than those without the associated viral DNA (5-year survival 45% vs 13% respectively; P < .001, two-sided log-rank test).

Additionally in this study it was noted that the extremities were most frequently affected by the MCC with associated MCPyV DNA. This has been found in other studies and has been postulated to be associated with UV exposure by some, while others have hypothesized a link between UV exposure and viral oncogenetic activation in virally associated cancers. Also of note in this and other studies was that the MCC associated with MCPyV DNA and those MCC without MCPyV DNA, were indistinguishable from one another on histology.

In another quantitative PCR for MCPyV, as well as immunohistochemical staining of tumor cell proteins, retinoblastoma gene product (pRb) and terminal deoxyribonucleotidyl transferase (TdT) were evaluated. MCPyV

was detected in 19 of 23 (74%) primary MCC tumors, but 8 of these had less than 1 viral copy per 300 cells. Interestingly those tumors with higher viral abundance were associated with longer survival (p < or = 0.08) (and less p53 expression). Their data suggested that MCC might arise through several oncogenic pathways, including ones independent of MCPyV. This also lends some support to improved prognosis of MCC with the association of MCPyV⁶.

Limitations

This study did not address whether there were mutations present, as previously seen in specific MCPyV sequences in relation to prognosis. It was also not evaluated if the viral DNA was integrated into the host chromosome, because PCR cannot distinguish episomal from integrated viral DNA. In addition there was no analysis by stage of tumor at diagnosis, or any correction for other clinical factors such as treatment which may have affected outcomes.

Conclusion

Studies have shown that MCPyV DNA is widespread and the genomic presence and associated mutations are being studied to further uncover the significance of its presence in a majority of MCC. Future retrospective and prospective treatment studies may improve understanding of this topic of prognosis of MCC and viral DNA, and take into account stage at diagnosis as well as treatment modalities.

What is the prognosis of MCC as stratified by demographic and clinical features?

According to a retrospective evaluation and smaller studies, there are several demographic and disease factors which portend a poor prognosis with MCC. These include male sex, age greater than 70 years at diagnosis, size >1 cm, the number of positive lymph nodes, metastatic dissemination, presentation with recurrent disease, and the presence of residual disease during radiation treatment⁷. While most studies have found most of the demographic and clinical features to affect prognosis some studies, such as one by Guler et al. reported that parameters such as sex, site of tumor, sentinel node biopsy, excision margins, skin and non-cutaneous malignancies were not found to be significant for survival outcomes⁷.

In a large meta-analysis, stage of disease has been shown to be an independent predictor of survival (P < 0.03) and disease-specific survival.³

This finding was seen in multiple other studies evaluating prognosis in patients with MCC. One study even reported that prognosis based upon stage was independent of treatment modality. Lewanda et al. found in their study that even amongst different treatment groups, the Kaplan-Meier survival curves leveled off at 30 months with 82%

survival for the stage I/II group and at 19 months with 60% survival for the stage III group⁸.

The importance of stage on prognosis has been evaluated in several different ways including overall survival outcomes and tumor-specific survival. Guler et al. reported that the stage of the disease and age at initial presentation were statistically significant with regard to overall ($P < 0.0001$; $P = 0.0327$) and tumor-specific survival ($P < 0.0001$; $P = 0.0156$). Use of the Cox regression model revealed initial stage of the disease as the only significant factor in their multivariate analysis⁷. While the majority of studies have reported stage at diagnosis to be a predominant factor in prognosis, however, another studies did not support this⁹.

A meta-analysis also determined that the stage of disease at diagnosis affected prognosis with MCC. Stage I and stage II disease have good prognostic outcome measures, while those with stage III and IV had significantly worse survival outcomes³. The demographic and other clinical features aside from staging which have demonstrated prognostic importance for MCC are male sex, increasing age, tumor size, metastasis, and evidence of initial treatment failures³.

What is the prognosis (5 year survival) of MCC based upon treatment modalities?

MCC has a high rate of recurrence after treatment. In part due to the uncommon nature of MCC, there is a lack of prospective controlled trials to guide management of this disease. Surgery is generally considered a first-line therapy, with adjuvant radiotherapy and chemotherapy being used in various clinical settings with variable outcomes, making the use of these therapies subject to debate. Meta-analyses of existing retrospective data suggests that adjuvant radiotherapy has a benefit on overall 5 year disease-free survival, and a reduction in local and regional recurrence rates. Results on the survival benefit and recurrence rate data with the use of chemotherapy is much more variable, and while chemotherapy appears to not improve prognosis, a clear evidence-based recommendation is difficult to take away from the existing data. Stage-specific treatment regimens have been outlined by the International Union Against Cancer (UICC) for stage I to III disease with the use of combinations of surgery, radiotherapy, and chemotherapy. The emphasis on UICC stage IV disease is on palliative care. While these recommendations are a useful tool, the evidence-based data on outcomes is variable and limited to primarily retrospective cases and cohorts, implicating a need for more structured clinical research to guide treatment.

Surgical Treatment

Surgery is usually the first treatment that a patient undergoes for MCC. Multiple retrospective reviews have been completed regarding surgical treatment of MCC. One retrospective review of 95 consecutive patients treated with

wide local surgical excision demonstrated a highly variable prognosis for surgically managed early stage MCC. The primary recommendation from this analysis was that a multidisciplinary tumor-board consultation approach be utilized for optimization of individual MCC patient management. In this study clinically negative regional nodes were either followed up ($n=42$) or staged with sentinel lymph node biopsy ($n=21$). Those clinically positive nodes underwent lymph node dissection ($n=32$). A total of 45 (47%) patients relapsed. The 5-year crude cumulative incidence (CCI) of recurrence and disease-specific survival (DSS) were 52% and 67%, respectively.¹⁰

Another retrospective study looked at surgery alone for treatment by wide local excision. Wide local excision resulted in a trend of decreased local recurrence when 2 cm margins were obtained. Those tumors with at least 2 cm margins had 0% local recurrence versus < 2 cm margins had 29% local recurrence. However, overall survival was not significant between the groups, since nearly a third of all patients undergoing wide local excision still died of distant metastasis¹¹.

Another retrospective review of patients undergoing resection of primary MCC was performed. Analysis was on 213 patients that had undergone resection of the primary tumor and evaluation of the draining lymph node basin. Those patients with MCC $<$ or $=$ 1.0 cm had a low likelihood of having had regional lymph node metastasis. They concluded that surgical treatment is appropriate and that regional nodal evaluation may always be necessary in these tumors, but that their data supports sentinel lymph node evaluation for MCC more than 1 cm in diameter. Of these 213 patients, 54 patients (25%) had tumors $<$ or $=$ 1.0 cm in diameter, and only 2 of these 54 patients (4%) had regional lymph node metastasis, compared with 51 patients (24%) with tumors more than 1.0 cm ($P < .0001$) with regional lymph node metastasis. Of note both of the patients with less than 1 cm MCC had clinically evident nodal disease at presentation, and this was the reason they underwent lymph node biopsies¹².

One limitation of this study was that not all patients with MCC disease identified during their time period were included in their analysis, but rather only those patients whom had undergone surgery and regional lymph node basin evaluation. There may have been MCC cases in their time period that were below 1 cm and ended up with metastatic recurrence, but based on a different treatment modality were not included in their analysis.

Noteworthy is that in addition to primary surgical therapy, sentinel lymph node biopsy was found to have a significant outcome on survival and nearly every prognostic indicator evaluated in several meta-analyses on the subject^{3,13-15}.

Adjuvant radiotherapy

In general the retrospective data is in support of radiotherapy in conjunction with surgical removal. Possibly in

part because of the retrospective review nature, the wide differences in patient presentations, and different analyses of the data used, the results are variable.

Several articles have reported the effectiveness of surgery with adjuvant radiotherapy. A recent meta-analysis evaluated the data on adjuvant local radiotherapy compared with surgery alone for stage I and II patients only. In their subgroup analysis a significant overall (HR, 0.63; $P = .02$) and cause-specific (HR, 0.62; $P = .04$) survival advantage was demonstrated after treatment with combined surgery and radiotherapy⁷.

Another retrospective analysis of 57 patients with MCC was performed in regards to outcome measures. All of these tumors (except for one which was stage III) were initially staged as I or II. This analysis reported that radiotherapy applied after primary tumor excision extended the time to disease progression significantly ($P = 0.0376$) but did not prolong overall or tumor-specific survival⁷.

A retrospective review of 36 patients with MCC of the head and neck ranging from stage I to III at diagnosis was performed to evaluate the impact of radiotherapy on prognostic outcomes. This review demonstrated that radiation therapy to the primary tumor site resulted in a local control rate of more than 90% in patients with head and neck MCC. A trend toward improved regional control of the clinically negative neck with the addition of radiation therapy was also seen but was not found to be statistically significant⁸.

A retrospective review of 60 patients with MCC of the lower limb was performed to evaluate prognostic indicators in this group. They included patients that were treated with surgery, radiation, or chemotherapy all for curative intention. The 5-year overall survival, disease-specific survival, and relapse free survival (RFS) were 53%, 61%, and 20%, respectively. On univariate analysis the addition of any radiotherapy improved RFS ($p < 0.001$). When stratified by location of radiotherapy, both radiotherapy to the inguinal nodes ($p = 0.01$) or primary site and inguinal nodes ($p = 0.003$) were significant in regards to survival. On multivariate analysis the addition of radiotherapy (hazard ratio = 0.51, $p = 0.03$) had a significant improvement in survival over surgery alone⁹.

Two other retrospective analyses also favored the use of adjuvant radiotherapy. One found that post-excisional adjuvant radiation treatment increased the proportion of patients without recurrence as compared to surgery alone (75% vs 53%; $P = 0.02$)¹⁶. In the other study, this data was reported as less local recurrence for surgery with adjuvant post radiotherapy, i.e. 6% local recurrence, (vs 19% surgery alone)¹⁷. Similar trends were seen for regional metastatic recurrence (50% with surgery, 36% with combination treatment). The rate of distant metastasis was 25% in both retrospective treatment groups¹⁷.

Other retrospective review studies found that radiotherapy significantly increased the median relapse free survival months compared with surgery alone. This was

up to 30 months difference between the treatment groups in the study with the longest follow-up data¹⁸, but in the other two studies the relapse free survival rates were at least a factor of 2 different between groups, favoring the radiotherapy treatment group in both publications^{19,20}.

In one retrospective study with 86 patients, nodal relapse rates were significantly different amongst the two treatment groups, but local disease recurrence was not. This study specifically reported that surgery in comparison to surgery with adjuvant radiotherapy to the nodal basin had a greater nodal relapse rate (26% vs 13%)²⁰.

In a couple of other retrospective studies of surgery versus surgery with radiotherapy, no significant improvement in local recurrence rates was seen between these two groups. These studies were with 102 and 251 patients. Local recurrence rates were seen as 8-11% for radiotherapy versus 10-11% for surgery alone $P = 0.84^{21}$, $P = 0.76^{22}$.

In addition in one of these studies, while adjuvant chemotherapy did not show a survival advantage or improvement in local disease recurrence, it is noteworthy that only 15 patients had received adjuvant radiotherapy, and only 2 of these experienced local recurrence. Because of the low incident numbers in these groups, this data has limited power²².

One retrospective analysis specifically looked at Mohs surgery combined with radiation therapy. Forty-five patients were included in this analysis, which indicated that radiation therapy initiated after Mohs surgery did not have a significant affect on survival or recurrence rates when compared to Mohs surgery alone. The Kaplan-Meier disease-specific overall survival estimates by treatment groups demonstrated 5-year survival rates of 79% for Mohs surgery alone and 80% for Mohs surgery and radiation treatment²³.

While there is some variation on the outcome and prognostic data between surgery and the addition of radiotherapy, overall the data, including that from the meta-analysis, supports the use of adjuvant chemotherapy. Further studies of a randomized prospective nature may help better elucidate in which patients radiotherapy has the best benefit.

Chemotherapy

Chemotherapy has been used in certain scenarios primarily in advanced stages of MCC. An overall conclusion regarding the prognosis with chemotherapy use in the literature appears to be the most variable of all three of these treatment modalities. The data is variable in relation to chemotherapy use for MCC both in the adjuvant setting and in treatment of metastatic disease. This may in part be due to the great variability of clinical disease conditions it is used, which specific regimens are used, and that these retrospective cases were often cases of advanced disease where prognosis is already poor.

Various retrospective analyses of the utility and affect on survival of chemotherapy exist. One such study by

Poulsen et al. failed to find a clear benefit of chemotherapy over surgery alone. It was noted in the analysis that because of the wide confidence intervals, a clear conclusion could not be derived from their analysis²⁴.

Many studies indicate that salvage chemotherapy to the metastatic site does not have any significant effect on survival^{8,21,25}. There is variation in the way the data is analyzed and reported in terms of outcome and prognosis amongst these studies. For instance in one study patients with unresectable metastases were marginally responsive to chemotherapy with 12.5 % having a complete response, another 12.5% having a transient response, and 75% with no detectable response²¹.

A couple of other studies reported a negative impact on survival with the use of chemotherapy. However in one of these studies the baseline factors were adjusted for in the analysis, such as adjusting for advanced disease and alteration of expected outcomes in advanced cases²⁶. With this adjustment factor, the survival rates between chemotherapy and non-chemotherapy treatment groups were not seen to be significantly different¹¹.

Data from a meta-analysis on 107 subjects published in 1999 demonstrated no difference in response rates of first line chemotherapy between those patients with locally advanced disease versus distant metastatic MCC (69% vs 57%)²⁶. However, progression after first-line chemotherapy was associated with significantly worse survival for patients with metastasis. Rates of response to second-line (n = 33) and third-line (n = 10) chemotherapy were 45% and 20%, respectively. Their overall conclusion from this meta-analysis was that while MCC is chemosensitive, it is rarely chemocurable in patients with metastasis or locally advanced tumors²⁶.

Surgery and adjuvant radiation therapy appear to have the best supporting survival data at this time for treatment of MCC. Chemotherapy does not appear to improve survival, however, the data being compared in this area is the most variable in regards to protocols and treatments used, making evidence-based conclusions the most difficult. In addition to randomized controlled trials to better evaluate prognosis amongst treatment groups, consortia are still needed to clarify the risks and benefits of sentinel lymph node biopsy, adjuvant radiation therapy, and salvage therapies, based upon a standardized histological diagnosis and staging of MCC. Further studies are also necessary and underway regarding the etiologies of MCC and the role MCPyV plays in oncogenesis and prognosis.

See What We Know-MCC

II. KAPOSI'S SARCOMA

Background

Kaposi's Sarcoma (KS) is a tumor with an etiologic association with human herpes virus 8 (HHV8), also known as Kaposi's sarcoma-associated herpesvirus (KSHV). Background and treatment of this tumor are described in the prior chapter regarding treatment of KS. There are several types of KS, however the type we will be discussing in this chapter is the type associated with immune suppression. Prognostic factors for immune deficient and AIDS-related KS have been evaluated and used to formulate staging of the disease. The prognosis is related to the type of KS, the extent of cutaneous and visceral involvement, as well as the patient's immune status and the viral load burden. Typically KS is an indolent disease progressing

What We Know: MCC

- Merkel cell carcinoma (MCC) is a rare, aggressive skin cancer of neuroendocrine origin, most commonly seen in immunosuppressed patients and patients over 50 years of age.
- A more recently discovered Merkel Cell Polyomavirus (MCPyV) has been demonstrated in approximately 80% of MCC to date. Limited data thus far suggested that MCPyV may have a role in oncogenesis with this tumor. While it is not required for the development of all MCC, in MCC cases with associated MCPyV, limited data suggests improved survival outcomes.
- The rarity of MCC means that there is a lack of prospective controlled trials with this disease. Patients are generally treated with surgery as a first-line therapy.
- There traditionally has been some variability in which patients undergo sentinel lymph node biopsy.

The use of this procedure has been documented in multiple retrospective studies and meta-analyses to impart survival benefit.

- The use of adjuvant therapies in MCC remains controversial. Data from retrospective analyses in addition to meta-analyses suggests that the addition of radiotherapy in patients with MCC may impart significant improvement in local and regional recurrence rates as well as disease-free survival. The use of chemotherapy treatment with curative intention is less supported by the current literature.
- Stage of disease has been shown to have a significant correlation with disease free survival rates. More structured clinical research will improve the evidence-based data on the most effective treatments for this disease.

over years, with the gradual development of new sites of involvement. However KS in immunosuppressed patients may be a fulminant disease.

The tumor burden (T), the immune status (I), and the severity of the systemic illness (S) are all prognostic determinants proposed by the ATCG, which were formulated based upon prior outcome measures. This system is used in patient staging and to determine management and was proposed based upon prospective data. In the post HAART era an updated version of the ATCG system has been proposed due to data indicating that other determinants are involved in patient outcome and prognosis.

Prognosis

The most recent National Cancer Institute's SEER program data, shows an overall 5-year relative survival of about 60% for KS. When looking at patients staged by the ACTG staging system, those at low risk T and I factors combined, have a 5-year survival of 90%. For those at high risk in these categories, the 5-year survival was around 50%. It dropped to 30% if the KS was in the lungs.

Outcome measures

In addition to survival rates, other data is used to evaluate response to treatment, which affects outcome and prognostic measures. The clinical trials discussed below use the AIDS Clinical Trials Group (ACTG) Oncology Committee criteria for evaluating KS and its response to treatment. Much of the clinical response criteria has been standardized. A complete response is defined as the absence of residual KS for at least 4 weeks, a partial response as $\geq 50\%$ reduction in size or at least 50% flattening of the lesions, stable disease as not fulfilling the criteria for partial or progressive disease, and progressive disease as $\geq 25\%$ increase in size²⁷.

SEARCH METHODOLOGY

The Cochrane Library for systematic reviews (2009) and Pubmed/Medline (1976–September 2009) were searched for prognostic outcomes for randomized controlled trials with prognostic outcomes for AIDS-related KS.

What is the prognosis of AIDS associated KS based upon CD4 levels?

As briefly mentioned above, KS is staged in part based upon CD4 levels at time of KS diagnosis. I0 is considered good risk, and is defined as a CD4 cell count of 200 cells/mm³. Some of the more recent studies since the advent of HAART have used counts of either 150 or 100. I1 is

considered a poor risk, and corresponds to a CD4 cell count lower than 200 cells/mm³.

While recent studies have supported the ACTG staging determinants to be important prognostic markers which are still used in staging currently, some adjustments to the staging system have been proposed based upon prognostic data, predominantly associated with the wide use of HAART in HIV patients.

Most studies have indicated that while treatment of KS has improved, the patient's CD4+ levels remain to have a significant association with prognosis of KS. This finding has been demonstrated in several different ways by several different measurements of prognosis, but the vast majority demonstrates that prognosis is related to CD4 levels.

A study published in 1997 prospectively validated the previously established ACTG staging classification for AIDS-associated KS. Data from 8 ACTG therapeutic trials for AIDS-associated KS on 294 patients were staged prospectively according to tumor extent (T), severity of immunosuppression (I), and other HIV associated illness (S), and were observed for survival²⁸.

Survival was significantly shorter for patients in the poor-risk category for each of the TIS variables. Multivariate analysis indicated that the severity of immunosuppression gave the most predictive information. Cox models using a CD4 count of 150/ μ L rather than the previously adopted 200/ μ L to prognosticate disease based upon I0 and I1, yielded a clearer difference in prognosis in their analysis. They suggested an update of the prior staging system I category to reflect these CD4 levels. Their conclusions were that a lower CD4 count than the one originally proposed provides better discrimination between prognostic groups, and hypothesized that the advent of HAART may have affected this outcome measure²⁸.

Another retrospective study compared the clinical course of 91 patients with AIDS-related KS with CD4 counts >300 cells/mL and undetectable HIV viral loads (VLs) to patients with AIDS-KS with lesser CD4 counts and detectable HIV VLs. Twenty (22%) of the 91 patients had newly diagnosed, persistent or progressive KS despite CD4 counts >300 cells/mL and undetectable HIV VLs. Although tumor stage and response to KS therapy were similar, there was a significantly greater risk of death among the patients with CD4 counts <300 cells/mL and detectable HIV VLs ($P = .048$). The patients with the higher CD4 counts required systemic therapy to control their KS but were significantly less likely to die and demonstrated a trend toward better 15-year survival than patients having KS with lesser CD4 counts and detectable HIV VLs²⁹.

Another retrospective analysis looked at survival of KS when diagnosed as an AIDS defining illness (ADI). Median survival for the 130 patients in this analysis with KS as an ADI, was 20 months versus 9 months for KS subsequent to another ADI ($n = 75$, $P < 0.001$). Poorer survival following KS diagnosis was associated with a lower CD4 count

at diagnosis of KS ($P = 0.002$), as well as extensive cutaneous or visceral involvement at diagnosis ($P = 0.009$ and $P < 0.001$ respectively)³⁰.

Limitations in the two prior studies include that their analysis was related to overall survival and not specific survival of KS. Therefore the patients with lower CD4 levels were likely to be more immunocompromised and sicker overall, with a higher potential to succumb to illnesses other than KS. In such an instance, the CD4 level prognosticates, but not directly with KS outcomes.

A retrospective study of 5873 individuals with HIV-1 infection found 326 (6%) of these patients had a history of KS. In 262 (80%) of these KS patients, KS was their first ADI. Univariate and multivariate Cox regression analyses were performed to identify predictors of survival in this group. A prognostic index model was developed from this analysis. Increasing CD4 counts were found to have a significant positive effect upon survival, and used as a major point in their proposed prognostic index in AIDS patients diagnosed with KS³¹.

A large retrospective trial looked at prognosis in terms of relapse rate and mortality. Ninety-eight patients that had been treated with pegylated liposomal doxorubicin (PLD) were evaluated to assess tumor relapse rate, mortality, and cause of death in these subjects. A relapse study was performed for 61 patients who had complete or partial response to PLD and who attended a control visit after treatment completion. After a median follow-up of 50 months (interquartile range, 17.2-76 months), 8 patients (13%) had experienced relapse, 5 of which experienced relapse within the first year after stopping PLD. The only factor found to be independently related to risk of relapse was having a CD4 cell count < 200 cells/ μ L at baseline (HR, 6.2; 95% CI, 1.2-30). CD4 cell counts that were lower at the end of follow-up were also associated with relapse but to a lesser degree (HR for every increase in CD4 cell count of 100 cells/ μ L, 0.7; 95% CI, 0.6-1.01)³².

In 2003, the Italian Cooperative Group on AIDS and Tumors published a retrospective review of 211 patients with AIDS related KS. This is the one retrospective study that did not find prognostic information correlating with CD4 counts in AIDS patients diagnosed with KS. Their conclusions were that CD4 levels no longer provide prognostic information in their study in the era of HAART.

Other prognostic information and survival data in regards to ACTG classification was obtained from their data analysis; their 3-year survival rate was 83% for I0 patients and 71% for I1 patients ($P = .06$). For T0 patients this was found to be 83% and 69% for T1 patients ($P = .007$), and 83% for S0 patients and 63% for S1 patients ($P = .003$). In the multivariate analysis, only the combination of poor tumor stage (T1) and poor systemic disease (S1) risk identified patients with unfavorable prognosis. The 3-year survival rate of patients with T1S1 was 53%, which was significantly lower compared with the 3-year survival rates of patients with T0S0, T1S0, and T0S1, which were 88%,

80%, and 81%, respectively ($P = .0001$). Therefore while this study did identify good risk categories (T0S0, T1S0, T0S1) and a poor risk category (T1S1), it did not find prognostic information with CD4 counts or I at diagnosis of KS²⁷.

Overall the data supports CD4 levels to be correlated with various outcome measures and prognosis. CD4 levels studied include those at time of diagnosis, at follow-up and at relapse, all of which to some degree were found to predominantly correlate to outcome. While many of the specific treatment trials are not discussed in this chapter, the data presented here and in the literature is predominantly limited to retrospective studies. Additional prospective randomized controlled trials are necessary to further evaluate the CD4 levels and their correlation with prognosis.

What is the prognosis of KS treated with HAART?

One randomized controlled trial, but no systemic reviews of antiretroviral therapy as a systemic treatment for AIDS KS were found. A small prospective cohort and several retrospective studies were also identified.

For AIDS-KS the initiation of HAART improves overall survival. It is associated with an 80% reduction in death, prolongs the time to treatment failure, and prolongs survival of patients with pulmonary KS who also receive chemotherapy. It is still not entirely clear if, when, and what chemotherapy regimens should be used in addition to HAART, and for how long in advanced KS stages should HAART be continued. New prognostic indexes are being proposed based upon HAART therapy as the primary treatment in AIDS KS patients, with the addition of chemotherapy in more advanced disease stages. The development of a prognostic index model may help aid in the development of future prospective randomized controlled studies, which may help to further answer these questions regarding chemotherapy initiation.

One randomized controlled trial was found in the literature on this subject. It included moderate to severe KS patients who were failing HAART therapy or were HAART naïve. The patients were randomized to treatment with HAART therapy or HAART therapy with pegylated liposomal doxorubicin (PLD). The response rates in the HAART group were 20%, versus 76% in the HAART plus PLD group. While HAART clearly has a role in the treatment of AIDS and KS, these results indicate that in moderate and advanced KS, the addition of PLD is superior to HAART alone.

There are many systemic treatment modalities for KS, especially in advanced disease, but none of these other therapies have been compared in a randomized trial to HAART alone.

Using multivariable analysis, undetectable HHV-8 ($p = 0.009$) and relative variation of CD4 ($p = 0.005$) were

independently selected as having a predictive value for clinical response. KSHV=8 quantitative viral charge is an independent predictive factor of the efficacy of HAART on AIDS-KS. Their results support immune reconstitution as a mechanism of response of KS to HAART³³.

A prospective study on 254 consecutive patients was performed to evaluate the clinical outcomes of patients diagnosed with KS since the introduction of HAART. The median follow-up was 4 years and a maximum of 12 years. At KS diagnosis, only 19% of patients were on HAART. Seventy-nine (31%) patients had ACTG stage T1 disease at KS diagnosis, and 122 (48%) had CD4 cell count < 150 cells/ μ L. The overall 5-year survival was 89% (95% CI 84-93). One hundred and sixty-three patients were treated with HAART alone for T0 stage KS. One patient died of KS and 37 (22%) required chemotherapy, resulting in an overall survival at 5 years of 91% (95% CI 87-95) and a systemic treatment-free survival at 5 years of 74% (95% CI 67-82)³⁴. This study showed a good success rate of HAART in KS patients over a prolonged period of follow-up for KS with low staged disease.

This was the first randomized study to assess HAART on HIV-related KS survival. The other retrospective studies mentioned have demonstrated degrees of positive outcomes with HAART, but these were not randomized controlled trials, and many pertained to patients with low grade KS. The retrospective and limited prospective data indicate that HAART improves outcomes and survival in treatment of KS and has a definite role in the treatment of AIDS and KS. What is still not entirely clear is the role of HAART in improving outcomes in advanced disease and what role it has in the spectrum of treating KS. While many treatment studies have continued HAART AIDS therapy when treating advanced KS with other chemotherapeutics, it is unclear how much the HAART therapy affected KS survival in those advanced cases. The one study that compared HAART and chemotherapy versus chemotherapy alone did show increased survival benefit. Additional prospective studies are needed to better stratify this data since there are multiple limitations with this approach in critically evaluating long-term survival comparisons. Evidence-based data on specific chemotherapeutic regimens are discussed under the chapter regarding treatment of KS and are not covered in this chapter.

A prospective study evaluated the efficacy of HAART for KS in 22 HAART naïve patients who were treated at a single Italian HIV/AIDS referral center³⁵. Clinical, virological and immunologic responses to HAART were assessed. Peripheral blood mononuclear cell (PBMC)-associated HHV-8 viral load was also evaluated by PCR in 13 patients with clinically sustained complete response (CR). In a median follow-up of 40 months (range 17-78), the KS overall clinical response rate was 91%; 18 complete and 2 partial responses were achieved. For the complete sustained responders, a decrease in PBMC HHV-8 load was observed at CR, and a significant further reduction

was found at the end of follow-up. In this study, HAART naïve AIDS patients diagnosed with KS showed high clinical response rate of KS to HAART. These findings support HAART as a treatment modifier of KS in AIDS patients³⁵.

Multiple other studies have evaluated HAART in the treatment of KS. None of these were randomized controlled trials, but they do show evidence to support the important role of HAART in the treatment of KS.

A retrospective analysis was performed on 162 patients treated with HAART for stage T0 KS. Of the 162, 1 died of KS and 37 (22%) required additional chemotherapy for disease control, giving a systemic treatment-free survival at 5 years of 74% (95% CI 67-82) and the overall survival at 5 years is 91% (95% CI 87-95). While not a randomized controlled trial, these findings support HAART as an effective approach for treatment stage T0 Kaposi's sarcoma³⁴.

A retrospective analysis was performed using data from 387 HIV-infected men in the Multicenter AIDS Cohort Study who had been diagnosed with either KS non-Hodgkins lymphoma in the 1990s. Potential prognostic factors, including prior HAART treatment, were evaluated. Forty-three of 287 KS patients (15%) had been treated with HAART. HAART treatment was associated with improved survival (log-rank p = 0.0001). In multivariate analyses, HAART was associated with an 81% reduced risk of death among KS patients [relative hazard (RH) 0.19, 95% confidence limits (CL) (0.08, 0.45)], compared to those not exposed to HAART. Their conclusion was that HAART appears to be effective in improving survival in KS patients even in those who were HAART naïve prior to diagnosis³⁶.

A retrospective study performed on a cohort of 78 patients whom had received systemic or local treatment for AIDS-related Kaposi's sarcoma who subsequently commenced HAART, looked at the time to treatment failure for KS before and after starting HAART. Time to treatment failure was calculated from the end of last therapy to the start of the next new treatment for KS. Thirty-eight percent of patients were stage T0I0 at presentation. The median time to treatment failure before starting HAART was 0.5 years. The median follow-up after starting HAART was 12 months (range, 0.5-52 months) and anti-Kaposi's sarcoma treatment had been required for 24 (31%) patients. The median time to treatment failure for KS from the start of HAART was 1.7 years, which was a longer time to treatment failure for the same cohort of patients before they started HAART (log rank chi² = 16.5, P < 0.0001). Their conclusions were that HAART is associated with prolonged time to treatment failure in KS³⁷.

A retrospective cohort study on epidemiologic, clinical, and outcome data for 160 patients who were naïve to HAART at the time of KS diagnosis was compared with the corresponding data for 51 patients already receiving HAART at the time of KS diagnosis. The frequency of cutaneous involvement was similar in both groups, but cutaneous disease was more indolent among KS-HAART patients, with 1 anatomic site of involvement in 9 patients (21%)

and less than 10 lesions in 26 patients (60%), compared with 16 patients (12%; $P = 0.06$) and 47 patients (34%; $P = 0.01$), respectively, in the KS-naive group. The 3-year survival rates of KS-HAART patients (64%) and HAART-naive patients (78%) were not significantly different. They concluded that KS exhibits a less aggressive presentation in patients already receiving HAART compared with patients who are naive to HAART at KS diagnosis but outcome measures do not appear to be influenced by the initiation of HAART before development of KS²⁷.

A retrospective analysis of 48 AIDS patients with extensive KS who received chemotherapy from 1995 to 1999 was performed to evaluate differences in prognosis in those also receiving a protease inhibitor (PI)-based antiretroviral (ARV) therapy. All patients received at least one cycle of chemotherapy, including vincristine/bleomycin or an anthracycline-containing regimen. There was a significant difference in the median survival (MS) between the 28 patients (58%) treated with PI-based antiretroviral therapy (31 months [range, 1.8-48]) and the group not receiving PI (7 months [range, 1-28], $p = .0001$). In addition, 81% of patients in the PI group were alive at 18 months from initiation of chemotherapy versus 12% in the non-PI group. Death due to KS occurred in 6 of 28 (21%) patients (total 9 deaths) in the PI group and 14 of 20 (70%) patients (total 18 deaths) in the non-PI group ($p = .001$). Their results indicate that patients with advanced KS who received PI-based ARV therapy in addition to their chemotherapy treatment had improved survival, including KS survival, when compared to the group not treated with a PI²⁵.

A study evaluating survival with HAART in pulmonary KS retrospectively looked at 37 consecutive patients with pulmonary KS treated with chemotherapy. There were 16 patients not treated with HAART and 21 patients treated with HAART in their review. Kaplan-Meier analysis indicated that patients on HAART had substantially better survival ($P < .0001$). Cox multivariate analyses showed that HAART therapy was associated with a reduced risk of death (HR = 0.09; 95% CI, 0.03 to 0.69). They concluded that in patients with AIDS-associated PKS undergoing chemotherapy, administration of HAART was associated with increased survival³⁸.

Limitations with this study are that these groups were stratified by dates into the pre-HAART era and the post-HAART era. Those in the post-HAART era were likely to

have an independently improved survival since treatment and understanding of AIDS increased over time significantly in the 1990s, as did treatment for AIDS related KS.

Conclusions

KS is more frequent in immunosuppressed patients. Immune status and CD4 counts have been known to correlate with prognosis. The prognosis of KS has improved in AIDS patients in correlation with the advent of HAART. While HAART has a role in KS treatment, exactly what that role is and when to start, when to initiate other treatments independent of HAART, and when to stop HAART has been a subject of debate. The data indicates that HAART improves prognosis of KS with or without other treatments, and evidence supports continuation if possible while on other treatments as indicated.

See What We Know-KS

III. SQUAMOUS CELL CARCINOMA AND HUMAN PAPILLOMA VIRUS

Background

Human papilloma virus (HPV) has been demonstrated to be one etiologic agent associated with the development of squamous cell carcinomas, (SCC), especially of the anogenital and oropharyngeal mucocutaneous locations. HPV has been found to be present at high copy numbers, frequently integrated, and often transcriptionally active in these SCCs. There is a significantly higher incidence of HPV associated SCCs in immunosuppressed patients.

Perhaps the most well known, and possibly most studied of the SCC within this category, is the association of HPV and cervical cancer. In this section we will focus on SCC in external, non-cervical, mucocutaneous locations including those in non-cervical anogenital lesions, oropharyngeal, and other head and neck cancers. While HPV SCCs are certainly known to occur in other cutaneous sites, the vast majority of prognostic data on SCC induced in association with HPV currently exists in regard to cervical, anogenital, and head and neck cancers.

Based predominantly upon studies with HPV and cervical cancers, “high risk” HPV types have been defined. These include HPV types 16 and 18, which are the types most associated with 70% of cervical carcinomas. Over

What We Know: KS

- KS is a multi-focal vascular neoplasm that may regress in response to improvement in host immune function
- Prognosis, including disease free survival specific for KS, has been demonstrated to relate to CD4 count in AIDS-related KS.
- In randomized controlled trials HAART with the combination of chemotherapy in more extensive or advanced KS cases has been shown to improve survival compared to pegylated liposomal doxycy whole. Several other trials have shown improved survival, including KS disease free survival, with HAART.

expression of p16 is considered a surrogate marker for HPV infection, and has been looked at in some studies to evaluate for HPV status.

SEARCH METHODOLOGY

The Cochrane Library for systematic reviews (2009) and Pubmed/Medline (1976–September 2009) were searched for prognostic outcomes for HNSCC mesh terms HPV.

Additional searches were performed under the sub-category questions in regard to prognosis.

What are the prognostic outcomes of SCC of the oropharynx with HPV versus without HPV?

HPV infection has been associated with improved outcome in HNSCC, although not all the studies have shown consistent results. Based on the epidemiological evidence to date, hypotheses exist that HPV-positive and negative HNSCC represent different lineages formed through diverse, though overlapping, mechanisms of multi-stage tumor genesis. This is a not an uncommon relationship seen in viral oncogenesis.

A meta-analysis was performed evaluating OS and DFS in HNSCC. They found that patients with HPV-positive HNSCC had an improved outcomes compared to HPV-negative HNSCC. Specifically this was seen as a lower risk of dying (HR: 0.85, 95% CI: 0.7-1.0), and a lower risk of recurrence (HR: 0.62, 95%CI: 0.5-0.8) than HPV-negative HNSCC patients. Site-specific analyses show that patients with HPV-positive oropharyngeal tumors had a 28% reduced risk of death (HR: 0.72, 95%CI: 0.5-1.0) versus patients with HPV-negative oropharyngeal tumors. For DFS similar findings were obtained (HR: 0.51, 95% CI: 0.4-0.7). However for non-oropharyngeal tumors, this improvement in both survival measures was not seen, leading them to conclude that HPV-positive HNSCC tumors may have a distinct etiology from those tumors in non-oropharyngeal sites in this meta-analysis³⁹.

A large international randomized controlled phase III trial was performed on patients with previously untreated Stage III or IV head and neck squamous cell cancer who were randomized to receive >60 Gy definitive radiotherapy concurrently with either cisplatin or cisplatin plus tirapazamine. The prognostic importance of HPV in patients with oropharyngeal SCC (OPSCC) was evaluated in the analysis. Assays were obtained for HPV types 16/18 in 195 patients, for p16 in 186, and for both in 173 patients. Twenty-eight percent (54/195) were HPV positive, and this group was associated with better 2-year OS (94 vs. 77%, $p = 0.007$) and better failure-free survival (FFS) (86 v 75%, $p = 0.035$) compared to HPV negative tumors. After adjustment for clinical factors, including stage, the HPV positive group had better OS than the HPV negative group (HR

0.29, $p = 0.018$). Another finding in their analysis was that tumors with p16 expression fared better overall independently of tumor HPV status. This marker has been looked at in several studies and is discussed further under subsequent studies⁴⁰.

A prospective study evaluated outcome in HPV-16 negative HNSCC versus HPV-16 positive HNSCC when treated with surgical plus chemotherapy treatments and found that HPV-16 positive tumors had better outcomes in comparison to the HPV-16 negative group. Patients with resectable, untreated stage III or IV HNSCC of the oral cavity, oropharynx, hypopharynx or larynx, and stage II cancer of the base of tongue, hypopharynx and larynx were included. HPV-16 was detected by PCR in 14 of 24 cases. There was a trend toward better progression-free (HR=0.15, 95% CI=0.002-12.54; $p=0.06$) and OS (HR=0.14, 95% CI=0.001-14.12; $p=0.10$) for HPV-16 positive patients. There were however no significant differences in response rates (86% vs. 90%) in HPV-positive and HPV-negative patients, respectively.

HPV-16 has been demonstrated to be associated with a higher risk of cancer than other HPV strains in cervical and some anogenital infections. Despite its association with cancer, in this selected subgroup analysis, it fared a better prognosis than those tumors without HPV-16⁴¹.

Several other retrospective analyses have been performed evaluating HPV presence in various HNSCCs. Predominantly, these analyses have shown that HPV positive tumors are associated with a better outcome. Kong et al. demonstrated that a group showing strong HPV signal presence on molecular analysis fared significantly better than the group not demonstrating this HPV presence. Time to progression (TTP, $p = 0.008$) and overall survival (OS, $p = 0.004$) for all patients and for the oropharyngeal subset was seen in the HPV positive tumor group in their analysis⁴².

Despite studies that predominantly support HPV HNSCC as having improved prognostic outcomes, one retrospective study on 101 patients did not find differences in OS or DFS between HPV negative and positive SCC of the upper aerodigestive tract (UDAT). They found HPV DNA by PCR in 17 of 101 specimens. The HPV detection rate was similar for T1-T2 tumors (17.4%) and T3-T4 tumors (15.6%). While they did report that tumors without lymph node metastasis were more likely to be HPV positive (21.4%) than tumors that had metastatic lymph node involvement (6.5%), no overall differences in survival were found. These findings may have been in part due to the low detection rate of HPV or having tumors in the UDAT, with some outside the anatomical areas of other studies on HNSCC⁴³.

Many studies have shown that patients with HPV and p16 positive oropharyngeal squamous cell carcinoma (OPSCC) have a significantly better prognosis, which is hypothesized by some to be caused by increased radiosensitivity of these

tumors. A study by Fischer et al, analyzed p16 expression and prognosis of OPSCC treated by either radiotherapy (RT) or primary surgery of 365 HNSCC, which included 85 OPSCC. Patients with p16 positive OPSCC exhibited a significantly better overall survival than those with p16 negative tumors ($p = 0.007$). In a multivariate analysis, survival benefit of patients with p16 positive OPSCC was independent of clinicopathological parameters such as stage classification and treatment modality. Also of note, the improved prognosis of p16 positive OPSCC was found after both RT and surgery, indicating that the increased radiosensitivity of the p16/HPV positive tumors is unlikely to be the mechanism of improved prognosis⁴⁴.

A few other studies looked specifically at HPV-16 in relation to prognosis in HNSCC. One of these was a retrospective study, 111 cases of OPSCC were evaluated for OS and DFS in relation to molecular HPV presence. Specifically HPV16 E6 mRNA was positive in 73 (66%) of 111 samples. On multivariate analysis adjusted for age, stage, and treatment, positive E6 mRNA was the only independent predictor for superior OS; for DFS, p16 expression or HPV-16 status determined by either method was significant. They concluded that HPV-16 positivity is associated with improved OS and DFS⁴⁵.

Another retrospective analysis looked at 71 cases of HNSCCs for evidence of HPV-16/18. They found no clear relationship between expression of HPV-16 and prognosis⁴⁶.

The overall evidence supports that HPV-positive HNSCC has a significantly better survival advantage compared with patients who were HPV tumor negative. This data will undoubtedly spur future treatment trials, which will yield further data regarding HPV status in HNSCC and prognosis, and move our understanding forward of viral oncogenesis.

What is the prognosis of anogenital SCC associated with the presence of HPV DNA?

A lot of information exists regarding HPV types and prognosis in regards to the development of cervical cancer. Less evidence exists in regards to cutaneous anogenital cancers

and prognosis with HPV. In this review we have focused on non-cervical anogenital lesions for several reasons including that dermatologists are not routinely involved in the management and outcomes of cervical cancers.

Van de Nieuwenhof et al. looked at molecular and histological expression in 130 vulvar cancers. They found that vulvar cancers without HPV integrated DNA had a worse prognosis⁴⁷.

Another retrospective analysis evaluated 55 vulvar cancers for the presence of HPV DNA for type 6, type 16, and type 18. When adjustment factors were controlled for including lesion size, age, tumor grade, and nodal metastasis using the Cox proportional hazards model, only HPV status remained an independent positive prognostic factor in their analysis⁴⁸.

Guo et al. retrospectively evaluated the relationship between clinicopathological features and HPV types in 100 cases of female lower genital tract carcinoma. Their findings concluded that the prognosis in vulvar carcinoma was more related to the histologic type rather than HPV⁴⁹.

Indennimo et al. looked at 18 anal cancers for the presence of HPV DNA. Twelve of these were SCCs. In these tumors HPV types 31-33 and 16 were found. They also included 6 cloacogenic tumors of the anorectal junction in their analysis. There was no significant difference in the prognosis between HPV-positive patients and HPV-negative patients. These results may have been partly due to the inclusion of the cloacogenic tumors in their analysis which may have a different mechanism and prognosis than the anal SCCs⁵⁰.

Conclusion

In SCC of the oropharyngeal and non-cervical anogenital locations, presence of HPV supports an improved prognosis. In the case of head and neck cancers, meta-analyses and large prospective trial data support this finding. In the case of anogenital SCC, there is limited, retrospective data regarding the prognostic value of finding HPV DNA. Future studies may substantiate improved prognosis of HPV associated tumors in these anatomical locations and are necessary to improve our understanding of the etiopathogenesis specific to these SCCs and to improve management.

See What We Know-SCC with HPV infection

What We Know: SCC with HPV infection

- HPV is frequently associated with SCC of the anogenital and head and neck cancers.
- Those cancers of the head and neck have predominantly been found to have HPV type 16 on molecular analysis.
- The prognosis of SCC of the head and neck has good prospective randomized controlled and meta-analysis data demonstrating that those SCC of the head and

- neck with HPV, regardless of treatment modalities, have an improved prognosis as compared to those SCC without HPV presence.
- More limited data suggests that anogenital cancers, excluding cervical cancer, may also have improved prognosis of SCC with HPV found in the tumors. Future randomized controlled trials will help to better clarify this.

IV. CONCLUSION

Our understanding of viruses in relation to mucocutaneous tumors has greatly expanded over the last twenty years. Prognosis related to these cancers is dependent on the type of virus and cancer, as well as many other clinical factors. As our understanding of the role of the viruses in mucocutaneous oncogenesis continues to expand, so likely will our understanding of treatment and prognosis of these entities. In the case of malignancies in which data supports improved outcomes in the virus positive tumors, enormous opportunities exist for improving treatments very specific to these subsets of tumors.

Pharmaco- epidemiology

Principles of Pharmacoepidemiology

58

Seema Kini, M.D., M.S., and Suephy C. Chen, M.D., M.S.

Pharmacoepidemiology is the study of the use and the effects of drugs in large numbers of people. The term pharmacoepidemiology reflects its roots in pharmacology, the study of the effect of drugs, and epidemiology, the study of the distribution and determinants of disease in populations. In short, pharmacoepidemiology is the application of epidemiologic methodology to pharmacologic issues. Although pharmacoepidemiology arose out of a need to study adverse drug reactions (ADRs), the field has grown to encompass many other issues such as pharmacoeconomic analyses, quality of life (QoL) outcomes, and pharmacovigilance.¹

The basic idea of pharmacoepidemiology is to measure the use and effects of drugs in a population and to determine the frequency and distribution of drug use outcomes in that population. Pharmacoepidemiologists employ a variety of research methods in order to study drugs. A *cross-sectional* study provides a 'snapshot' of health and illness in the population. That is, a cross-sectional study determines the prevalence of disease at one point in time. A *case-control* study, on the other hand, is a retrospective analysis which compares subjects with the condition of interest (cases) to those without the disease (controls) with respect to a possible exposure. Alternatively in a *cohort* study, a population of disease-free individuals are followed over time and studied for the development of disease with respect to the exposure in question. A cohort study is the best way to determine incidence of disease in a population. Finally, the gold standard of research methods is the *randomized clinical trial* (RCT). A RCT is an experimental approach in which subjects are randomly assigned to a treatment group (typically an experimental therapy) and the outcomes are compared to that of a control group (placebo or standard therapy).²

PHARMAECONOMICS: ECONOMIC ANALYSES IN PHARMACOEPIDEMIOLOGY

As healthcare expenditures continue to grow in the face of increasingly limited funds, pharmacoeconomic studies are becoming particularly relevant to dermatologists. There are four fundamental types of pharmacoeconomic studies: cost analysis, cost-effectiveness analysis, cost-utility analysis,

and cost-benefit analysis. This chapter outlines the four types of studies (Table 58-1) and provides a framework for applying these studies as they relate to dermatology.

Cost Analysis

Cost analysis is the most basic form of pharmacoeconomic study. This type of analysis measures the cost associated with the treatment of a certain disease, irrespective of the outcome of the therapy. Researchers can derive costs from either microcosting or macrocosting. Microcosting involves enumerating each component of a therapeutic strategy and then determining the cost of each component.³ Cook et al. utilized microcosting methods to determine the true cost of treating a series of skin cancers with Mohs micrographic surgery and compared the costs to that of traditional methods of surgical excision. The authors systematically itemized the cost of treatment using Mohs micrographic surgery including diagnosis, surgery, reconstruction (if applicable), follow-up, and the cost to treat disease recurrence. The cost of Mohs surgery was then compared to the cost of diagnosis, excision, pathology, reconstruction, and disease recurrence using three traditional methods of surgical excision.⁴

Macrocosting determines the overall cost to care for a particular disease usually with a population-based approach. Emerson et al. utilized a macrocosting approach to evaluate the economic burden of atopic dermatitis in children aged 1-5 years in Nottingham, UK in 1995-1996. The estimation of disease costs included not only costs to the National Health Service for consultation and prescribing, but also the cost to families associated with changes to the home environment (e.g., mattress covers to reduce exposure to the house-dust mite), transportation to appointments, and loss of income for days taken off work as a direct result of the child's eczema.⁵

While cost analysis is useful as a source of enumerating costs and as the basis for other pharmacoeconomic studies, cost analyses do not account for outcomes and potential side effects. As such, the value of the therapeutic intervention cannot be easily measured. Even if a medication is costly, if it routinely improves lives it may have very high value.³

TABLE 58-1—Four Types of Pharmacoconomic Studies (Adapted from Ellis et al.¹ and Chen et al.²)

Type	Definition	Reported Results	Advantages/Disadvantages
Cost analysis	A determination of costs associated with an intervention with no consideration of outcomes	Sum of cost of medications, physician visits, and hospitalizations over a defined period of time	Does not account for side-effects, outcomes, or measure the value of a therapy
Cost-effectiveness analysis	A comparison of the cost per standardized unit of effectiveness for two or more interventions that provide varying outcomes	Cost-effectiveness ratio (Cost/Unit of clinical outcome)	Accounts for side-effects, outcomes, and value of a therapy Outcomes are not standardized across disease processes Results are not weighted according to importance
Cost-utility analysis	A comparison of the cost per quality-adjusted life year for two or more interventions	Cost-utility ratio (Cost/QALY)	Accounts for outcomes and value of a therapy Results are standardized and weighted according to importance Need to invoke some external criterion of value to interpret results
Cost-benefit analysis	A comparison of the costs and benefits of two or more interventions where outcomes are measured in dollars	Cost-benefit ratio (cost/benefit measured in dollars)	Accounts for outcomes and value of a therapy Do not need external criterion of value to interpret results Ethically difficult to assign a monetary amount to health

Cost-Effectiveness Analysis

With the increasing presence of managed care, dermatologists will have to demonstrate that they can provide cost-effective care. Cost-effectiveness analysis (CEA) is one form of pharmacoeconomic analysis that can be helpful when decision-makers are confronted with a scenario in which an intervention is thought to be more effective but also more expensive than the currently available therapy.⁶ That is, CEA considers both the effectiveness of a health care intervention as well as the resources required to deliver the intervention.⁷ Unlike cost analysis where there is no attention devoted to the relative effectiveness of various therapies, in CEA, costs are related to a single common effect that may differ in magnitude between the alternative programs.⁸

In an incremental CEA, an old healthcare intervention is compared to a new intervention by a measure that compares the two: the difference in costs and outcomes between the old and new interventions. The alternative method may be some other treatment as long as there is a common effect. For example, psoriasis could be compared to seborrheic dermatitis if the common effect of interest is ‘years of clear skin,’ and these are independent programs (the cost and health effects in one patient group are not affected by the treatment alternative in any other patient group.)

A CEA in which the therapy in question is not compared to anything is termed an average CEA. This approach does

not provide useful information to the policymaker or clinician unless the currently available alternative therapy is to do nothing.⁷ However, if the standard of care is to “do nothing” and there are no associated costs and outcomes, then the average CEA is the same as the incremental CEA.

In quantifying the balance between costs and effectiveness, the cost-effectiveness ratio (CE ratio) is used to relate the extra costs required to achieve one extra unit of clinical outcome. The CE ratio is presented with costs in the numerator and health outcomes in the denominator. The CE ratio is a measure of value; the smaller the ratio, the fewer the resources required for a given unit of health outcome. The determination of costs in CEA is the same as discussed in cost analysis. The units of clinical outcome can be measured in direct clinical terms such as ‘years clear of psoriasis’ or ‘life years extended’.⁷

Once the CE ratio is determined for a particular intervention, how does one decide whether it should be adopted? In CEA, a cost-effectiveness threshold assists with this dilemma. The CE threshold is traditionally held at \$50,000 per quality adjusted life year (QALY). Interventions which cost less than this threshold, compared to standard therapy, would be considered cost-effective whereas interventions that cost much more than this threshold would not be considered cost-effective. This threshold is historically derived from the cost per QALY of providing dialysis, one of the first interventions thought to extend life years as well as improve QoL. At the time, the CE of dialysis was

\$35,000/QALY; adjusted for inflation, the threshold has risen to \$50,000/QALY.

Keogh-Brown *et al.* published a CEA comparing the cost-effectiveness of different treatments for cutaneous warts in the UK. The most common treatments for cutaneous warts, salicylic acid and cryotherapy, were compared to ‘spontaneous resolution’ (i.e., do nothing) and incremental cost-effectiveness ratios for each treatment were constructed.⁹

Though CEAs are useful measures of pharmacoeconomic analysis, they do have two main drawbacks. First, while CEA is useful for comparing a variety of therapies for a specific disease or within a field, the outcome measure is not standardized making comparison among different disciplines difficult. For instance, the outcome measure in a CEA studying a new therapy for psoriasis may be the ‘number of years of clear skin’. While this could be a common measure of effect when comparing psoriasis and seborrheic dermatitis, in most cases policy makers need to consider a multitude of therapies for a variety of different diseases in fields other than dermatology. It would be difficult to compare incremental CE ratios for new therapies in diabetes and onychomycosis if the outcomes measures were ‘mean HbA1c’ and ‘smooth nails,’ respectively.⁶

Second, CEA does not assign a weight to outcomes based on preferences of patients or society. At a time when health care funds are limited and policymakers are trying to stretch already constrained budgets, decision-makers are in need of a way to determine the relative importance of various outcomes in order to allocate limited resources.³

Cost-Utility Analysis

Cost-utility analyses (CUA) addresses the limitations of CEAs. While the determination of cost is the same as in CEA, the measure of outcome in CUA incorporates QALYs as the outcome measure such that results are expressed in terms of the cost per QALY gained by using one therapy versus another. In this way, CUA across different diseases can be measured.

The measure used to adjust life year in QALYs is derived from utilities. A ‘utility’ is a term used to reflect the preferences individuals or society may have for any particular set of health outcomes. As a preference-based metric, a utility is a numeric value that reflects ‘levels of subjective satisfaction, distress, or desirability that people associate with a particular health state’.¹⁰ These values are expressed on a continuous 0 to 1 scale with a utility= 0 being death and a utility=1 representing perfect health. Therefore, utilities closer to a value of ‘0’ indicate greater QoL burden compared to those values closer to ‘1’.

Thus, QALYS reflect both the additional quantity of life that a therapy extends and the quality of that additional amount of life. Mathematically, a QALY is calculated by multiplying life expectancy with a utility for that health state so that the length of life appropriately reflects the

decrease in QoL. By taking into account QoL through utilities, outcomes are not only standardized, but they are also weighted. CUA is particularly important in dermatology where many diseases and their therapies do not affect the length of life, but rather, QoL.

Pitt et al. published a CUA comparing pimecrolimus as a treatment for mild and moderate atopic eczema with conventional treatments such as topical corticosteroids and emollients. The authors utilized a condition specific QoL survey to estimate the utility of mild to moderate eczema in children. Costs were approximated by enumerating drug costs, quantity of treatment used, total area of body surface affected by eczema, and number of general practitioner and consultant visits. From this analysis, the authors concluded that there are likely to be few situations in which use of pimecrolimus for the treatment of atopic eczema could be justified on economic grounds.¹¹

Cost-Benefit Analysis

Unlike CEA and CUA, cost-benefit analysis (CBA) allows for comparison of health outcomes by assigning them a monetary value. Results are reported as differences between the costs and health benefits of a therapeutic program. The health benefits are represented in monetary terms, often by asking subjects how much they would be willing to pay for the therapy, although some CBAs are more indirect in their methodology. The ideal therapy is that which has the lowest cost per dollar of benefit. For instance, a study by Wootton *et al.* utilized CBA to compare real time teledermatology to conventional outpatient dermatologic care within the UK. The chosen measure of effectiveness was fewer number of additional primary and secondary care visits.¹²

The advantage of CBA is that by assigning a strictly monetary value to health outcomes there is a standard measure of comparing net benefits across diseases. In CBA, the decision to adopt a new therapy while foregoing an alternative therapy is strictly a monetary one. This is unlike CEA and CUA in which the investigator must utilize some measure of value, such as the CE threshold. In CBA, comparison of outcomes across diseases, whether it be disability days avoided or life-years gained, makes no difference.⁸

The task of assigning a generic measure of value to a health outcome is not easy. As such, one of the main criticisms of CBA lies in the moral and ethical nature of assigning a monetary value to human lives and QoL. However, proponents of this technique argue that translating health effects into monetary benefit is inherent in other pharmaco-economic studies, such as CEA/CUA where investigators must select a threshold below which a therapy is worth the cost. Another disadvantage of CBA lies in the ‘willingness to pay’ estimate of health benefits which is based on a patient’s conceptualization of how much they would be willing to pay for a therapy. In dermatology, however,

therapeutic options are often neither overly costly nor complex and thus it is reasonable to expect subjects to envision how much they would be willing to pay for a dermatologic therapy.³

In any pharmacoeconomic analysis, it is important to be clear about the perspective of the analysis as the perspective determines how costs and benefits are allocated. The three main perspectives in any pharmacoeconomic analysis are the individual patient, the third party payer, and society. If the perspective is that of the individual patient, then costs relate to co-pays and out-of-pocket expenses for a physician visit, medications, and time off from work needed to see the doctor. Conversely, third-party payers would be concerned about the cost of the medication and the physician visit, but not the co-pay or the time off from work. An analysis performed from the societal perspective would factor in costs that affect society as a whole: the cost of the medication and physician visit, loss of productivity from time off from work, and any impact on family members. The reader is encouraged to consult other references for a detailed explanation of standards in pharmacoeconomic analyses.¹³

QUALITY OF LIFE MEASUREMENTS AND THEIR APPLICATION TO PHARMACOEPIDEMIOLOGY

Health-related QoL, a patient's assessment of his or her QoL within the specific context of health, is an important component of pharmacoepidemiology. Drugs are not only studied for their ability to reduce mortality or prevent disease reoccurrence, but for their ability to improve a patient's subjective well-being as it relates to their health. This is particularly important within dermatology, where few cutaneous diseases are fatal, but nearly all diseases have the potential to significantly affect QoL.

There are a number of instruments available to assess QoL impact of disease. These instruments can be classified into two broad categories of health-related QoL instruments: health status surveys and preference-based measures. Health status surveys capture the impact of disease on various dimensions of QoL (e.g., physical, function, psychological, social aspects). These surveys can be generic measures that can be applied across a variety of medical conditions such as the Short Form 36 (SF-36) Health Survey. Dermatology-specific measures, such as the Dermatology Life Quality Index (DLQI) or the Skindex allow comparison of QoL among cutaneous diseases. Disease-specific measures such as the Psoriasis Disability Index (PDI) and RosaQoL measure QoL impact caused by psoriasis and rosacea, respectively. While generic health instruments allow for comparison of QoL among different diseases, they may not be sensitive enough to detect important aspects of QoL within a certain disease, nor are they usually as responsive to changes in health state as disease-specific measures. Conversely, disease-specific

instruments are not generic enough to compare QoL among different diseases.¹⁴

A Swedish study by Bingefors et al. sought to evaluate the impact of skin disease on QoL measured with the Short-Form-36 (SF-36), a multidimensional generic QoL instrument. As part of this study, the authors attempted to study differences in QoL by use of prescription and nonprescription dermatologic drugs. The authors found that a large segment of the population (20.5%) reported dermatologic problems and that skin disorders caused a significant decrease in QoL. Subjects using prescription topical dermatologic drugs generally scored lower (worse QoL) than other groups with cutaneous problems, reflecting the differences in severity and diagnoses among those reporting cutaneous problems.¹⁵

The preference-based QoL approach was discussed in the context of CUA above as utilities. Preference-based measures assess patients the desirability of life in a certain health state by having patients theoretically give up something of value (e.g., money, time, risk of death) in order not to have the disease in question. In this manner, the true burden of disease can be estimated.

The measurement of health-related QoL continues to gain significant attention in both clinical and research practice. Numerous studies indicate a substantial discordance between patient reporting and physician documentation of symptoms, as well as the degree to which physicians appreciate which symptoms patients find most burdensome.^{16,17} This discordance may affect quality of care, patient safety, and outcomes. Correctly estimating health-related QoL is not only important in clinical practice, but is garnering attention as an acceptable endpoint in randomized clinical trials as emphasis on patients' experiences and preferences has grown.¹⁸ The United States Food and Drug Administration (FDA) has noted that the measurement of QoL is more important than most other traditional measures used to assess efficacy (e.g., objective tumor response) in trials comparing treatments with similar or no impact on survival.¹⁹ Although more trialists are incorporating measurement of health-related QoL in their studies, the prevalence of reporting on QoL remains low.

A study by Sanders et al. examined the frequency and quality of reporting on QoL in randomized clinical trials from 1980-1997. The authors found that less than 5% of all randomized clinical trials reported on QoL. This proportion was below 10% even for cancer trials.¹⁸ One reason why relatively few randomized clinical trials measure QoL may be because of methodologic difficulties in determining what type of health-status measure to utilize and which measures have the most appropriate psychometric properties. While a disease-specific measure may be more responsive, certainly a more generic measure of QoL is critical in determining a global assessment of QoL. As initiatives are taken to develop standards for assessing and reporting QoL in clinical trials, it is hopeful that more trials will

incorporate endpoints based on a patient's determination of their own health status.

PHARMACOVIGILANCE

Pharmacovigilance, as defined by the World Health Organization (WHO), is the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug related problems.²⁰

The steps involved in pharmacovigilance begin with systematic data collection and management to determine possible drug safety hazards. Pharmaceutical companies are required by law to collect and submit all data relevant to the safety of their products both before and after licensing. Drug safety signals (a possible causal relationship between an adverse event and a drug) are also detected through spontaneous reports of suspected ADRs, primarily by healthcare professionals.²⁰ The number of ADR cases reported, however, may not be a good indicator of a signal as channeling of high-risk patients to newer therapies also leads to increased reporting with a newer agent. Nevertheless, when a signal of a suspected ADR arises from spontaneous reports, a case series should be constructed based on any previously reported cases. Although an analysis of the balance between benefit and risk is conducted throughout the life of a medicine, as data become available with each year on the market, regulatory bodies and companies may adjust their conclusions of benefit and risk. As such, regulatory action may be taken to increase benefit by improving use, reducing risk by improving communication about the drug, or restricting use altogether. Finally, an audit (evaluation) is conducted to determine the impact of the regulatory action.¹

The main outlets for pharmacovigilance in the United States include pharmaceutical manufacturers, academic/non-profit organizations, and the FDA. MedWatch is the FDA's voluntary reporting system for ADRs. Through MedWatch, healthcare professionals, patients, and consumers alike may report a serious adverse event, product quality problem, product use error, or therapeutic inequivalence and failure that is suspected to be associated with an FDA-regulated product (i.e., drug, biologic, medical device, dietary supplement, or cosmetic). The MedWatch system was created to maintain safety surveillance of these products. If a problem is detected, the FDA may modify use or design of the product, change its safety profile, or order product recalls and withdrawals. In addition, MedWatch disseminates important safety information in the form of medical safety alerts to both the medical community and the general public.²¹

One of the principal examples of pharmacovigilance within dermatology is the prescription of isotretinoin, a vitamin A derivative approved in 1982 for the treatment of cystic acne. Isotretinoin (trade name, Accutane) is a known teratogen when used during pregnancy because of the risk of spontaneous abortions and congenital malformations.

Since 1983, when isotretinoin was first documented as teratogenic in humans, the Dermatologic and Ophthalmic Drugs Advisory Committee of the FDA has issued restrictions on the prescription and dispensing of Accutane so that it may still be used as a treatment for cystic acne while minimizing the potential for fetal malformations.²² In response to the advent of generic isotretinoin compounds in 2002, the FDA launched iPLEDGE, a computer-based risk management program designed to further the public health goal of eliminating fetal exposure to isotretinoin. As of March 2006, physicians, patients, and pharmacists are required by the FDA to register and comply with the iPLEDGE program in order to use isotretinoin compounds.²³

SUMMARY

Pharmacoepidemiology is a diverse field, whose depth is beyond the scope of this chapter. Rather, this section serves to provide a framework for appreciating the basic principles of pharmacoepidemiology particularly as they relate to dermatology. Ensuring that patient care is delivered with an emphasis on minimizing costs and maximizing QoL impact with therapies that are deemed safe will continue to be a challenge for dermatologists and policy makers alike.

What We Know

- Pharmacoepidemiology is the study of the use and effects of drugs in large numbers of people.
- Pharmacoepidemiologists utilize cross-sectional, case-control, and cohort studies and randomized clinical trials in order to study drug outcomes in populations.
- Cost analysis, cost-effectiveness analysis, cost-utility analysis, and cost-benefit analysis are the four fundamental types of pharmaco-economic studies.
- Health-related quality of life is an important component of pharmacoepidemiology and can be assessed using health status surveys or preference-based measures.
- Pharmacovigilance occurs throughout the lifetime of a drug to identify potential adverse effects or any drug-related problems.

Azathioprine

59

Jennie T. Clarke, M.D., and Jeffrey P. Callen, M.D.

INTRODUCTION

Azathioprine (AZA) is an antimetabolite drug that was developed in the late 1950s¹. It rapidly became a mainstay in post-transplantation immunosuppressive regimens². Currently, AZA is approved by the U.S. Food and Drug Administration for the treatment of rheumatoid arthritis and the prevention of renal transplant rejection; however, because of its favorable side effect profile relative to other immunosuppressive agents, AZA became widely used by dermatologists, rheumatologists, neurologists, and gastroenterologists for other “off-label” indications.

MECHANISMS OF ACTION

The exact mechanisms through which AZA exerts its immunosuppressive properties are not completely known. The active metabolites of AZA are 6-thioguanine nucleotides that act as purine analogues. They are incorporated into DNA, RNA, and some coenzymes preventing protein synthesis. Cell cycle arrest and apoptosis are triggered after incorporation of the purine analogues by a process involving the mismatch repair pathway³. Cytotoxicity is specific for the S-phase of the cell cycle⁴. Azathioprine also inhibits *de novo* purine biosynthesis through the actions of one of its metabolites, 6-methyl-thioinosine 5'-monophosphate (Figure 59-1). Consequently, rapidly dividing cells and cells lacking the purine salvage pathway (that therefore are dependent upon *de novo* purine) synthesis are those most affected by AZA. The function and proliferation of T-cells, B-cells, and antigen-presenting cells is reduced. Antibody production is reduced in B-cells, and there is decreased production of interleukin-2⁵. In the skin there is a reduction in Langerhans cells and other antigen-presenting cells⁶. Tiede et al. found that the AZA mediates T-cell apoptosis via the binding of its 6-thioguanine metabolite 6-Thio-GTP to Rac1 with consequent inhibition of CD-28-dependent Rac1 activation⁷. Blockade of Rac1 activation prevents the expression Rac1 target genes including mitogen-activated protein kinase, NF-κB, and bcl-xL, and leads to T-cell apoptosis via a mitochondrial pathway. Gene expression profiling studies in activated lymphocytes have demonstrated that AZA inhibits the expression of genes with prominent immunologic and inflammatory functions including TRAIL, 4-integrin, and TNFRSF7⁸.

PHARMACOKINETICS

Absorption

The oral bioavailability of AZA ranges from 27-83%, and the biologic half-life of the active metabolites is several hours^{4,9}. Steady state levels of the active metabolites of AZA are reached after 2-4 weeks of use⁴, and clinically, efficacy is usually apparent 8-12 weeks after treatment is started. The drug may be administered once daily or may be divided into two or three daily dosages. It may be given with food without interfering with levels of the active metabolites^{10,11}.

Metabolism and Excretion

AZA is a prodrug that must be converted into its active form (see Figure 59-1). The initial conversion of AZA to 6-mercaptopurine (6-MP) occurs via nonenzymatic attack by sulfhydryl-containing compounds such as glutathione or cysteine primarily in erythrocytes. Ninety percent of AZA is converted to 6-MP. 6-MP is then converted into active or inactive molecules by one of three competing enzyme pathways:¹ Hypoxanthine-guanine phosphoribosyltransferase (HPRT) converts 6-MP into 6-thioguanine metabolites that act as purine analogs, which are responsible for the immunosuppressive and cytotoxic properties of the drug.² Xanthine oxidase (XO) degrades 6-MP into inactive thiouric acid and is the enzyme responsible for the majority of the elimination of the drug.³ Thiopurine methyltransferase (TPMT) degrades 6-MP into inactive metabolites, and this is the main elimination pathway in hematopoietic cells. Inactivity, inhibition, or reduction in the amount of the two degradative enzymes, leads to an increase in the conversion of 6-MP by HPRT into active thioguanine nucleotides with a consequent increased risk of myelosuppression. Patients with high glutathione transferase activity are predisposed to adverse reactions to AZA therapy because of excessively high concentrations of free 6-MP and by depleting cellular glutathione¹².

Thiopurine Methyltransferase Genetic Polymorphism

Wide interindividual differences in the accumulation of thioguanine nucleotides occur after AZA administration. In the 1980s this was determined to be related to inherited

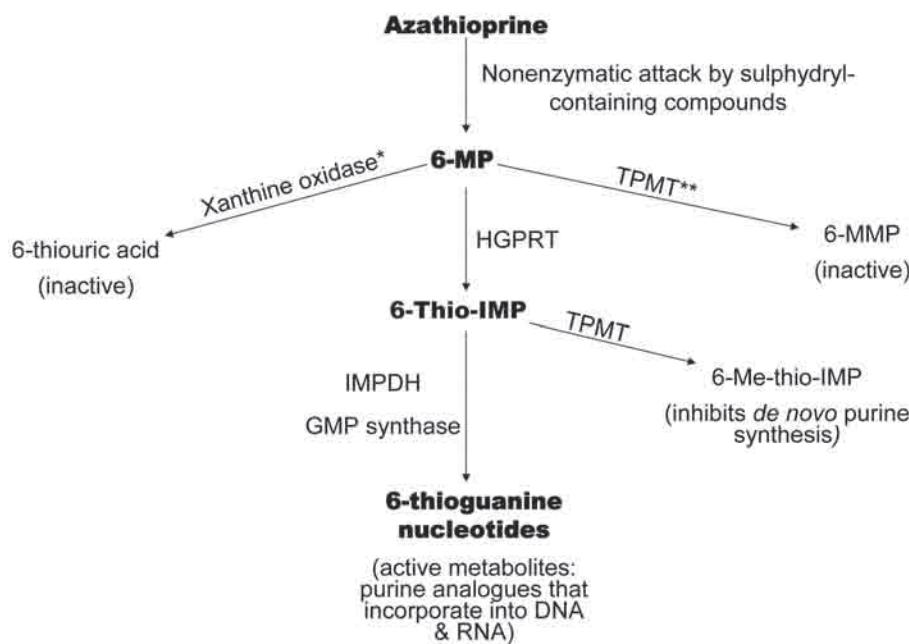

FIGURE 59-1 Metabolism of azathioprine. TPMT thiopurine methyltransferase, 6-MMP 6-methylmercaptopurine, HGPRT hypoxanthine-guanine phosphoribosyltransferase, 6-Thio-IMP 6-thiourine 5'-monophosphate, 6-Me-thio-IMP 6-methyl-thiourine 5'-monophosphate, IMPDH inosine monophosphate dehydrogenase, GMP synthase guanosine monophosphate synthase. *Main elimination pathway of azathioprine; inhibited by allopurinol. ** Main degradation pathway of azathioprine in hematopoietic cells.

differences in the activity of the TPMT enzyme¹³. The TPMT enzyme is encoded by a 27-kb gene on chromosome 6p22.3¹⁴, and 18 variant alleles have thus far been identified^{15,16}. Inheritance of alleles leading to normal TPMT activity is most common. Eighty to 95% of the intermediate and low activity TPMT phenotypes are caused by mutations in three alleles: *TPMT**2, *TPMT**3A—the most common variant alleles responsible for low TPMT activity in Caucasians^{17,18}, and *TPMT**3C, the most common variant allele identified in African, African American, and Southeast Asian populations^{18,19}. Although different alleles predominate among ethnic groups, some alleles have been reported in only one or a few individuals, suggesting that unique mutations may also be responsible for TPMT enzyme activity in some patients²⁰. In addition to the numerous TMPT variant alleles, variable-number tandem repeats in the promoter region of the TPMT gene that might be associated with differences in TPMT enzyme activity have also been identified⁴. Therefore, although genetic testing for common TPMT polymorphisms is widely available, genetic testing alone may miss a small number of patients with novel or rare mutations that affect TPMT.

Clinical Significance of the Azathioprine Metabolic Pathway

A high degree of concordance between TPMT genotype and phenotype (level of enzyme activity) has been demonstrated in Caucasians; patients whom are homozygous wild type have normal TPMT activity; those whom are heterozygous for mutant alleles often have intermediate enzyme activity, and those that are homozygous for mutant alleles have low or undetectable enzyme activity. This same high degree of genotype phenotype concordance has not been

observed in all other ethnic groups, and overall genotype-phenotype concordance rates of 57-99% in different populations have been reported^{19,21-25}. Because the concordance rates between genetic testing of TPMT mutations and phenotypic expression of TPMT activity are not high in all populations, baseline phenotypic testing is the more clinically useful tool for predicting patients at greatest risk of bone marrow suppression (those with low or undetectable TPMT activity). The TPMT enzyme activity level in erythrocytes correlates with that of all other cells, and therefore, the erythrocyte TMPT enzyme assay is a convenient means of assessing a patient's phenotype prior to initiating AZA therapy. This test should be performed in all patients prior to initiating AZA therapy to reduce the risk of drug-induced myelosuppression. It should be noted that exogenous factors such as recent blood transfusion might interfere with the interpretation of the TPMT activity assay.

There is a trimodal distribution of activity of the TPMT enzyme with approximately 90% of individuals having high activity, 10% having intermediate activity and 0.3% having low or no activity^{14,26}. Those found to have low or undetectable TPMT activity should not be treated with AZA because of the risk of fatal myelosuppression; those with intermediate TPMT activity level should initially receive dosages that are 30-50% of standard dosage. The majority of cases in which there is genotype-phenotype disparity are among those patients determined to have intermediate enzyme activity. When patients fail to respond to AZA at dosages prescribed based upon pretreatment TPMT activity, knowledge of their TPMT genotype may enable the physician to safely increase the dose (i.e., in a patient with intermediate baseline TPMT enzyme activity who is determined to actually have the wild type genotype), or seek an alternative therapeutic agent.

Recently, it has been shown that treatment with AZA may induce increased expression of the TPMT activity in some patients²⁷. Treatment with 5-aminosalicylic acid and uremia may also induce TPMT expression or increase its activity²⁸. Patients with immunobullous disease treated with AZA who experienced large inductions in TPMT were found to have disease that was resistant to AZA therapy²⁷. These patients had low levels of 6-thioguanine nucleotides, and elevated levels of 6-methylmercaptopurine (6-MMP), a metabolite that has been associated with hepatic damage in some patients when present in high levels^{29,30}.

Monitoring of 6-thioguanine levels and 6-MMP levels has been used to facilitate the safe use of AZA in several diseases. In patients receiving AZA for inflammatory bowel disease (IBD), the therapeutic effect has been found to have a better correlation with 6-thioguanine levels than with the absolute AZA dose^{28,31}. Specifically, 6-thioguanine concentrations greater than 235 pmol/8 X 10⁸ RBC are required for optimal efficacy in inflammatory bowel disease; however concentrations exceeding 400 pmol/8 X 10⁸ RBC have been associated with a high risk of myelosuppression^{31,32}. Similar studies have demonstrated that the optimum 6-thioguanine concentrations associated with therapeutic effect differ among diseases (Table 59-1). AZA metabolite monitoring has been studied in autoimmune hepatitis³³, leukemia³⁴, and solid organ transplantation³⁵, with different optimal therapeutic ranges of 6-thioguanine for each disease state found. In patients with systemic lupus erythematosus (SLE), 6-thioguanine levels of 159 pmol/8 X 10⁸ RBC were typical of patients benefiting from AZA therapy³⁶; however an earlier study failed to find a correlation between 6-thioguanine levels and outcomes of AZA therapy in patients with inflammatory diseases⁵. el-Azhary et al. evaluated 6-thioguanine concentrations in patients with immunobullous diseases and found mean optimum levels of 179.4 pmol/8 X 10⁸ RBC for pemphigus vulgaris and pemphigus foliaceus and 205.6 pmol/8 X 10⁸ RBC for patients with bullous pemphigoid²⁷. Patients with limited disease required lower concentrations than did those with generalized disease. These authors recommend assessing

the 6-thioguanine and 6-MMP concentrations in patients who fail to respond to AZA therapy. Low 6-thioguanine concentrations could indicate noncompliance or inadequate dosing (if 6-MMP concentrations are also low), or true refractoriness to AZA therapy (if 6-MMP levels are high, possibly mediated by induction of increased TPMT activity). It should be noted that the analytic method utilized can affect the results of 6-TGN monitoring assays with concentrations of 6-TGN varying up to 2.6-fold depending on the HPLC method used³⁷. While it may be helpful in determining the best course of action for a nonresponding patient, until adequately powered prospective studies confirm optimum metabolite concentrations for specific clinical indications, the measurement of AZA metabolites is not considered standard in the care of any dermatologic diseases. An approach to dosing AZA incorporating an understanding of its metabolism, and the effects of the TPMT genetic polymorphism is presented in Figure 59-1.

EFFICACY IN HUMAN STUDIES

Dermatologists have used AZA to treat a broad range of inflammatory dermatoses. It has been considered as a corticosteroid-sparing agent or alternative in almost any condition for which long-term immunosuppression might be warranted. The use of AZA for any dermatologic disease is off-label. Because dermatologists have used AZA since the 1970s, and its usefulness, especially in treating immunobullous and chronic eczematous diseases, was acknowledged before the advent of evidence-based medicine, the evidence to support its dermatologic uses is lacking in comparison to that of newer agents. Those dermatologic diseases for which AZA is most often used are discussed below.

Immunobullous Diseases

Corticosteroids remain the cornerstone for management of immunobullous diseases; however, steroid-sparing agents including AZA are widely used to aid in achieving disease control, to permit tapering of corticosteroids,

TABLE 59-1—Reported Disease-Specific Optimum 6-Thioguanine Concentrations

Disease	Optimum 6-TGN level (pmol/8X10 ⁸ RBCs)	Level of Evidence	Grade of Recommendation
Inflammatory bowel disease	235-400	II-3	C
Systemic lupus erythematosus	159	III	D
Pemphigus foliaceus & pemphigus vulgaris	179	III	D
Bullous pemphigoid	206	III	D
Renal transplantation	100-200	III	D

Adequately powered prospective studies confirming optimum metabolite concentrations for specific clinical indications are lacking; therefore, the measurement of AZA metabolites is not considered standard in the care of any dermatologic diseases. 6-TGN 6-thioguanine

and to maintain disease remission. In a 2007 review of interventions for the treatment of pemphigus vulgaris and pemphigus foliaceus from the Cochrane Database of Systematic Reviews, Martin, et al. determined that there is inconclusive evidence on the effects of AZA in treating pemphigus vulgaris. There is also inconclusive evidence regarding pemphigus foliaceus and remission, death, relapse, or withdrawal because of adverse events, and that no studies have yet adequately addressed the effect of AZA on time to disease control, severity score, antibody titer, or quality of life³⁸. Despite an overall lack of adequately powered, prospective, controlled trials, AZA is commonly used as a first-line steroid-sparing agent in immunobullous diseases³⁹⁻⁴⁵. AZA has been demonstrated to have a steroid-sparing effect⁴⁶, and a steroid-sparing effect superior to that of cyclophosphamide^{46,47} and mycophenolate mofetil⁴⁶. One study of 40 patients with pemphigus vulgaris found AZA to be less effective than mycophenolate mofetil in achieving disease control⁴⁷.

Cutaneous Lupus Erythematosus

The majority of patients with cutaneous lupus erythematosus (CLE), respond to standard therapies including photoprotection, topical, or intralesional corticosteroids, and antimalarial drugs. For patients with disease that is recalcitrant to these measures, second-line therapy with immunosuppressive or immunomodulating agents is required; however, there are no large, prospective, randomized controlled trials of any of these drugs in the treatment of CLE. Case reports and series have described the successful treatment of CLE with AZA. These reports have described the successful use of AZA for lesions of subacute CLE⁴⁸ and chronic CLE⁴⁸⁻⁵¹.

Dermatomyositis

There are many case series that report a steroid-sparing effect for azathioprine for muscle disease associated with dermatomyositis, but there is a relative paucity of reports about its usefulness for skin disease. Two papers appeared in the early 1980s based upon the same set of patients, first demonstrating a lack of steroid-sparing effect in a double-blind, placebo-controlled trial⁵² then in the open-label extension, demonstrating a corticosteroid-sparing effect⁵³. The probable reason for the initial study's lack of effect was that it was a 12-week study and the time to onset of effect is often just beginning at the time that this study was ended. It has been our experience that azathioprine has little effect on dermatomyositis skin lesions, but it continues to be used as a potential option as a third-line therapy.

Dermatitis

The use of AZA therapy for severe, refractory atopic dermatitis has been well described^{54,55}. In addition to case reports,

case series and retrospective studies, two randomized, double-blind, controlled trials of AZA therapy for atopic dermatitis have demonstrated significant improvement in atopic dermatitis severity, pruritus, and quality of life^{56,57}. Both of these trials included only adult patients; however, reports of AZA use in pediatric patients with severe recalcitrant atopic dermatitis suggest that it is a beneficial steroid-sparing agent in children⁵⁸⁻⁶⁰.

Chronic actinic dermatitis is treated with photoprotection, emollients, and topical corticosteroids. As in atopic dermatitis, brief intermittent courses of systemic corticosteroids may be needed for disease flares. For patients who require chronic systemic therapy, AZA is the first-line steroid-sparing drug⁶¹⁻⁶⁴. This recommendation is based on the results of two prospective controlled trials^{63,64}.

AZA has also been used to treat severe refractory pompholyx⁶⁵⁻⁶⁷ and severe chronic contact dermatitis⁶⁸⁻⁷⁴.

Neutrophilic Dermatoses – Pyoderma Gangrenosum and Behçet Disease

Neutrophilic dermatoses including pyoderma gangrenosum and Behçet disease⁷⁵⁻⁷⁷ have been treated with AZA. In pyoderma gangrenosum, corticosteroids (topical, intralesional, and/or oral) are typically utilized as first-line therapy. For those patients who fail to respond quickly to systemic corticosteroids, AZA may be of benefit; however, there have been no prospective, randomized-controlled trials to confirm its merits or lack thereof in the treatment of this disease. Results of case reports indicate that while some patients may improve with AZA⁷⁸⁻⁷⁹, others fail to respond^{80,81}. AZA should be considered only in patients with pyoderma gangrenosum who are refractory to or who will require prolonged courses of systemic corticosteroids. Although, it is a therapeutic option, we have most often used other agents, particularly the tumor necrosis factor alpha antagonists in the management of pyoderma gangrenosum, prior to considering AZA.

In addition to treating neutrophilic dermatoses, AZA has also been implicated as a potential causative agent in some patients with acute febrile neutrophilic dermatosis (Sweet syndrome)⁸²⁻⁸⁴.

Cutaneous Vasculitis

AZA has been used successfully in the treatment of many types of cutaneous and systemic vasculitis, including rheumatoid vasculitis⁸⁵, idiopathic leukocytoclastic vasculitis⁴⁹, polyarteritis nodosa⁸⁶, and Wegener's granulomatosis⁸⁷. Recent studies have shown that AZA is a safer and equally effective agent in maintaining remissions of ANCA-positive vasculitides in comparison to cyclophosphamide⁸⁷. In the treatment of purely cutaneous vasculitis, AZA should be reserved for treating severe disease.

Other Dermatoses

Reports of successful AZA use have been described for a number of other dermatoses including psoriasis^{88–90}, lichen planus^{91–96}, chronic erythema multiforme^{97,98}, chronic graft versus host disease^{99–100}, and polymorphous light eruption¹⁰². Alternatives that are safer, or for which there is better evidence, should be utilized before considering AZA in the treatment of these conditions.

SAFETY PROFILE

As an antimetabolite immunosuppressive agent, AZA use is associated with adverse effects including, myelosuppression/cytopenias, carcinogenesis, infection, and teratogenicity. Adverse gastrointestinal effects, hepatic effects, and idiosyncratic hypersensitivity reactions may also occur.

Myelosuppression/Cytopenias

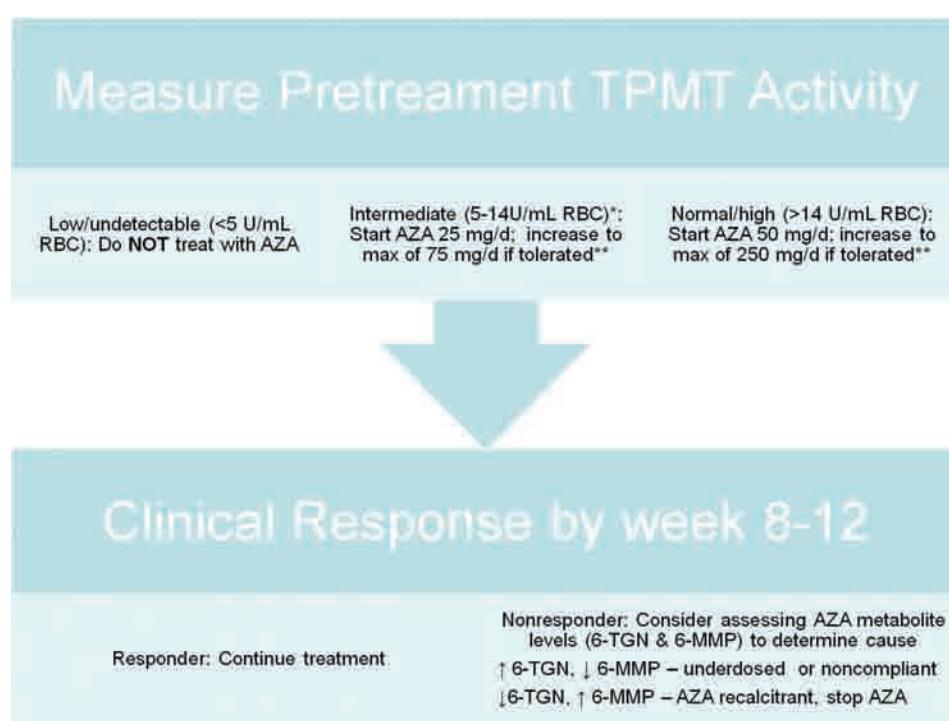

Myelosuppression and even more rarely, pancytopenia, may occur within weeks of initiating AZA or after years of use. It is therefore necessary to monitor complete blood counts at regular intervals throughout the duration of AZA therapy. Patients with low or absent TPMT activity (~0.3% of patients) will accumulate excessive levels of 6-thioguanine purine analogs that interfere with nucleic acid synthesis, especially in cells with high mitotic activity such as hematopoietic cells. These patients, therefore, are predictably at risk of acute myelosuppression after initiation AZA therapy and should not be treated with AZA (Figure 59-2). Abnormalities in other enzymes in the complex AZA metabolic pathway may be responsible for the cytopenias

that rarely occur in patients with intermediate or normal TPMT activity; consequently, complete blood count monitoring is still required for patients throughout the course of therapy regardless of TPMT status. Mutations in the inosine triphosphate pyrophosphatase gene have been found to be associated with increased cytotoxicity of AZA and with adverse events including thrombocytopenia, rashes, flu-like symptoms, and pancreatitis^{4,103–106}.

Carcinogenesis

Immunosuppressive agents have been associated with increased risk for carcinogenesis, and this risk is influenced by factors such as age, ethnicity, duration, and dosage of immunosuppression, and underlying disease state. There have been no significant studies evaluating the risk of carcinogenesis in patients taking AZA for dermatologic disease. An increased risk of malignancies, especially lymphoproliferative malignancies and cutaneous squamous cell carcinomas, has been reported in association with AZA use in select populations. Those whom appear to be at greater risk of developing malignancies in association with AZA therapy are organ transplant recipients and patients with rheumatoid arthritis.¹⁰⁷ Rates of malignancies have been evaluated in patients taking AZA for inflammatory bowel disease¹⁰⁸ SLE¹⁰⁹, and multiple sclerosis¹¹⁰, and an increased risk of carcinogenesis has not been demonstrated. However, there does appear to be an increased risk of hepatosplenic T-cell lymphoma, a rare peripheral T-cell lymphoma, in young patients who are treated concomitantly with AZA or prednisone and infliximab¹¹¹. This suggests that the risk of carcinogenesis may be linked to iatrogenic immunosuppression from any agent in certain

FIGURE 59-2 Dosing strategy for azathioprine. Doses are based on a 70 kg patient. *TPMT* thiopurine methyltransferase, *AZA* azathioprine, *6-TGN* 6-thioguanine, *6-MMP* 6-methylmercaptopurine. *An assessment of TPMT genotype by PCR should be considered for patients at the upper range of intermediate TPMT activity since some will be homozygous for the wild type (normal activity level) genotype and may be underdosed if treated based on TPMT activity assay alone. **The initial dose can be increased within 1–2 weeks and rapidly increased thereafter although gastrointestinal symptoms or abnormalities in laboratory monitoring studies may prevent dose escalation.

predisposed populations rather than to AZA specifically. Nonetheless, AZA has been found to be carcinogenic and mutagenic in animal and *in vitro* studies utilizing supratherapeutic doses of AZA¹¹², and conflicting studies in human subjects continue to raise concern for the risk of malignancy associated with this drug. Patients should receive counseling regarding the potential risk for systemic malignancy prior to beginning AZA therapy.

Patients with a history of marked sun exposure and long-term AZA therapy may be at greater risk of aggressive cutaneous squamous cell carcinomas¹¹³. AZA use in organ transplant recipients has been associated with a higher incidence of cutaneous squamous cell carcinomas than have other immunosuppressive drugs^{114,115}. *In vitro* studies have demonstrated that cells treated with the active metabolite of AZA (6-thioguanine), and UVA generate reactive oxygen species that could be responsible for the development of nonmelanoma skin cancers¹¹⁶. Although an increased risk of cutaneous squamous cell carcinomas has not been reported among patients with other underlying disease states, it seems prudent that the dermatologist closely follow patients receiving AZA for the development of cutaneous malignancies.

Infection

Patients taking AZA are at increased risk of infection. This risk is greater in patients taking higher dosages and in those taking additional immunosuppressive drugs. Patients who are immunosuppressed should not be given live attenuated vaccines because of the potential risk of atypical responses. Diminished cell-mediated immune responses to influenza vaccines have been demonstrated in organ transplant recipients receiving AZA¹¹⁷ (as well as in those on alternative immunosuppressive regimens), although humoral responses were similar to those of healthy controls¹¹⁸. In patients with SLE receiving AZA therapy, cell-mediated¹¹⁹ and humoral responses¹²⁰ to influenza vaccination were also reduced; although it should be noted that reduced humoral responses to vaccines is common in SLE regardless of treatment. Inactivated viral vaccines are safe in patients receiving AZA and should be administered when routinely indicated.

Gastrointestinal

The most common adverse effects of AZA are gastrointestinal, particularly nausea, vomiting, and diarrhea, and symptoms are worst in the first 1-2 weeks of therapy¹⁰⁷. These symptoms can often be relieved by dividing or reducing the dose and by administering it with food. Drug-induced pancreatitis has been reported with AZA; although the mechanism is not known, an association between mutations in the inosine triphosphate pyrophosphatase gene and AZA-induced pancreatitis was found in one study¹⁰⁴.

Hepatic

Hepatic dysfunction is a risk of AZA therapy. Hepatotoxicity has been associated with high concentrations of 6-methylmercaptopurine (6-MMPR)^{29,30}, the inactive metabolite generated by degradation of 6-MP by TPMT (see Figure 59-1). The measurement of 6-MMPR, however, lacks sensitivity and specificity to detect AZA-induced hepatotoxicity, and serial measurement of aminotransferases throughout the course of AZA therapy remains the most effective means of detecting liver damage. Hepatic dysfunction typically improves with AZA discontinuation, dose reduction, or dose division.

Hypersensitivity

Hypersensitivity reactions are idiosyncratic systemic drug reactions characterized by fever, flu-like symptoms, rashes, and leukocytosis (often with marked eosinophilia), and involvement of multiple organ systems including, but not limited to, the gastrointestinal tract, liver, kidneys, lungs, and cardiovascular systems. These reactions usually arise within the first 1-4 weeks of therapy and can be life threatening. Hypersensitivity reactions have occurred with AZA therapy^{121,122}.

Pregnancy and Lactation

AZA is classified by the U.S. Food and Drug Administration as pregnancy category D. AZA and 6-MP cross the placenta. The placenta strongly impedes their diffusion to the fetus; placental concentrations of AZA are 64-93% of that of maternal blood levels, and fetal blood concentrations of AZA and 6-MP are 1-5% and 1-2% of maternal blood levels of respectively¹²³. A number of studies have suggested that fetal risk may be more closely related to the mother's underlying disease rather than to effects of the drug itself^{124,125}. The most common pregnancy related risks include spontaneous abortion, growth restriction/low birth weight, and prematurity¹²³⁻¹²⁵. A slight increase in the risk of congenital malformations has been reported (0-11%), though there appears to be no consistent pattern of defects¹²³. Although there have been case reports of neonates with immunologic or hematologic dysfunction following *in utero* AZA exposure¹²⁶, overall, there does not appear to be a higher than expected rate of immunologic dysfunction amongst newborns with antenatal AZA exposure^{123,127}.

The safety of AZA in lactating women for whom the drug is deemed necessary has been suggested by studies demonstrating very low or undetectable, levels of 6-MP in breast milk^{128,130}, and undetectable levels of 6-thioguanine nucleotides in breast milk¹³¹. One study has suggested that infants ingest <0.008 mg/kg/24 hour of mercaptopurine from breast milk¹³². Although exposure to active metabolites of AZA to nursing infants appears to be minimal, long-term and large-scale studies demonstrating safety are lacking.

Drug Interactions

There are several important AZA-drug interactions including those with allopurinol, warfarin, angiotensin-converting enzyme inhibitors, sulfasalazine, and trimethoprim-sulfamethoxazole. Allopurinol inhibits xanthine oxidase, by blocking one of the inactivation pathways of AZA metabolism and causing elevated concentrations of the active metabolites. Patients taking both drugs are at increased risk for myelosuppression, and if a patient requires both, the AZA dose should be reduced by two thirds¹³³. The anticoagulant effects of warfarin are reduced by AZA, and patients frequently require 3-4 times the amount of warfarin to achieve appropriate anticoagulation^{134,135}. Sulfasalazine, trimethoprim-sulfamethoxazole, and angiotensin-converting enzyme inhibitors^{107,136} may increase the risk of myelosuppression when taken with AZA.

Monitoring

Monitoring recommendations based on a number of studies and expert recommendations^{27,107,137,138} are summarized in Figure 59-3.

CONCLUSION

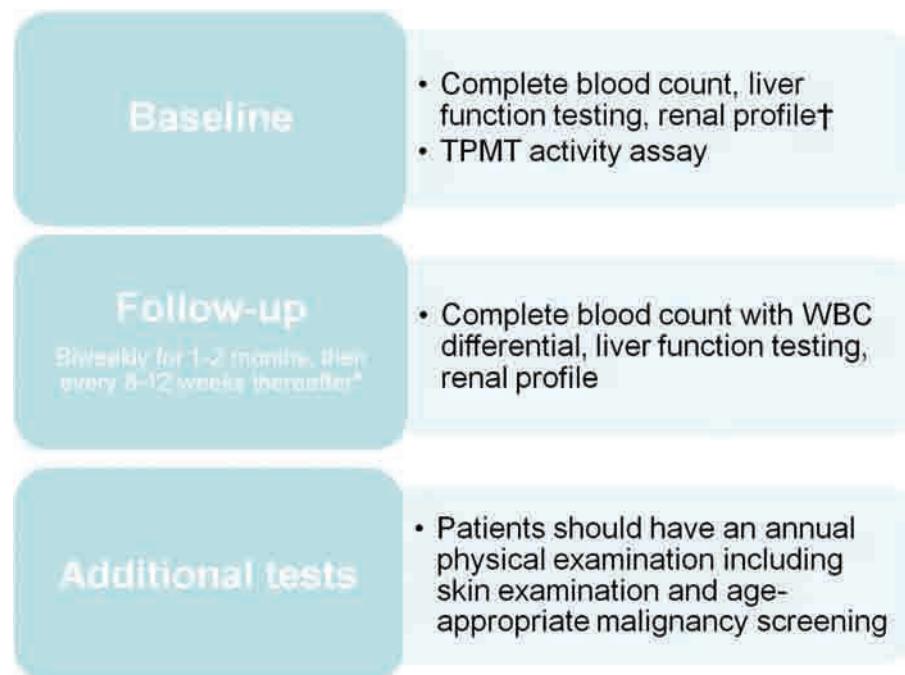

For more than 40 years, AZA has been used by dermatologists to treat severe inflammatory and immunobullous disease, and it remains commonly used despite the development of newer immunosuppressive drugs. The observation of the wide interindividual differences in accumulation of the drug and subsequent myelosuppression

What We Know

- Azathioprine is a prodrug of 6-mercaptopurine that is metabolized by 3 competing pathways. The active metabolite, 6-thioguanine, is a purine analog that is incorporated into DNA and RNA. T-cells, B-cells, and natural killer cells are preferentially affected.
- There is a trimodal distribution in the activity of the TPMT enzyme that is caused by a genetic polymorphism in the TPMT gene. Most patients (~90%) have high levels of TPMT activity; few (~10%) have intermediate activity, and even fewer (~0.3%) have low to undetectable activity. Patients with low TPMT activity accumulate higher levels of active metabolites and are at risk for life-threatening myelosuppression. All patients should undergo baseline evaluation of TPMT status prior to starting azathioprine, and the dose should be altered accordingly.
- Azathioprine is used (off-label) for a wide range of severe dermatoses, especially immunobullous diseases, refractory atopic and chronic actinic dermatitis, vasculitis, and autoimmune connective tissue diseases.
- Adverse effects of azathioprine include: myelosuppression, infections, carcinogenesis, hypersensitivity syndrome, hepatotoxicity, and gastrointestinal problems.
- Drug interactions include: ACE inhibitors, allopurinol, folate antagonists, and warfarin.

led to the discovery of the TPMT genetic polymorphism. The routine use of pretreatment testing of a patient's TPMT status to prevent toxicity made AZA a pioneering agent in the practice of pharmacogenomics. Refinements in our

FIGURE 59-3 Azathioprine monitoring guidelines. *TPMT* thiopurine methyltransferase. [†]If GFR <10 mL/min reduce dose by 50%; If GFR 10–50mL/min reduce dose by 25%. *When a dose increase is made, the monitoring should again be performed at biweekly intervals for 1-2 months and then resumed at every 8-12 weeks thereafter.

understanding of the complex metabolism of AZA and the genetic basis for varying responses to it, continue to shape clinical practice and pave the way for optimizing its safety and efficacy.

Imiquimod

60

David Vidal, M.D., Ph.D.

INTRODUCTION

Imiquimod (IM) is a synthetic toll-like receptor 7 agonist that induces the expression of many proinflammatory cytokines. IM increases the host's innate and acquired immune responses against cutaneous infections and skin cancer. IM 5% cream is a home-based patient-applied treatment approved by the U.S. Food and Drug Administration (FDA) for external anogenital warts (AGW), superficial basal cell carcinoma (sBCC), and actinic keratosis (AK). Moreover, randomized-controlled trials (RCT) support the efficacy of IM for AGW and AK in immunocompromised patients, cutaneous leishmaniasis, nodular BCC, Bowen's disease, anogenital intraepithelial neoplasia and prevention of recurrence of shaved keloids.

MECHANISM OF ACTION

Our knowledge about the mode of action of IM has greatly increased in the past few years, and the mechanism of action is complex and appears to comprise several complementary components.¹ IM is a nucleoside analog without nucleoside-like activity that activates the immune response stimulating the toll-like receptor (TLR) 7. TLR7 is indispensable for host defense against viral infection by recognizing pathogen-associated molecular patterns (e.g. virus-derived single-stranded RNA) and IM is a potent TLR 7 agonist.² TLR7 is localized to the intracellular endosomal membranes of several immune cells. IM binds to TLR7 of macrophages/monocytes, dermal dendritic cells and plasmacytoid dendritic cells (PDC). IM induces a massive recruitment and activation of circulating PDC from the blood into the treated skin, and PDC are the main producers of cytokines after IM topical application.³ The TLR7 signaling pathway translocates nuclear factor-kappa B into the nucleus and activates the transcription of many immunomodulatory genes. The vast majority of the stimulated genes portray immunologic functions predominantly involving the activation of cellular innate and adaptive immune-effector mechanisms.

Interferon alpha (IFN- α) is the main cytokine induced by IM, but many other cytokines and chemokines are induced: IFN- β , tumor necrosis factor-alpha (TNF- α), interleukin (IL) 1 α , IL-1 β , IL-1 receptor antagonist, IL-6, IL-8, IL-10, IL-12, granulocyte-macrophage colony

stimulating factor (CSF), granulocyte CSF, macrophage/monocyte chemotactic protein 1 (CCL2) and macrophage inflammatory proteins 1 α (CCL3) and 1 β (CCL4).⁴ The cytokine induction by IM is dose-dependent, as early as 1 to 4h after stimulation with IM in human peripheral blood mononuclear cells, and the maximum peak production 8 hours occurs after topical application.⁵ Most of these cytokines and chemokines display proinflammatory activity and promote T helper cell type 1 adaptative immune responses. Moreover, IM also inhibits the production of IL-4 and IL-5, thus suppressing the development of a T helper cell type 2 adaptative immune responses.⁶

IM enhances the functional maturation of Langerhans cells (LC), bone marrow-derived epidermal dendritic cells that represent the major antigen-presenting cells in the skin. Activated LC takes up, processes local antigens within the skin, and migrates to the draining regional lymph nodes.⁷ Within the nodes, LC present processed antigens to naive CD4 T lymphocytes using MHC class II molecules. As a result, T lymphocytes develop clonal expansion and differentiate to memory and activated T cells that return to the skin, where they express T helper cell type 1 cytokines (INF- α , INF- γ and TNF- α).

IM rapidly increases the dermal inflammatory infiltrate, with a significant number of CD4+ T helper cells mixed with activated dendritic cells, CD8+ T cells, CD68+ macrophages, CD20+ B lymphocytes and PDC (CD 123+).⁸ Most CD8+ T cells express cytotoxic granules, T-cell restricted intracellular antigen 1, granzyme B and perforin. Furthermore, IM is a potent activator of B-lymphocytes, augments immunoglobulin production, up-regulates opioid growth factor receptor protein and suppresses the adenosine receptor signaling.^{9,10}

Apoptosis, also known as programmed cell death or cellular suicide, is a basic physiologic cellular process by which nonviable cells are eliminated. Apoptosis is a strictly regulated process, and many genes and proteins participate in its control. The main pro-apoptotic pathways are the membrane-bound death receptors (Fas, TRAIL and TNF receptors), P53, Bax and the activated cytotoxic cells, through the release of granules of granzyme B. The main anti-apoptotic protein is the Bcl-2, which interferes with Bax in the mitochondria. In vitro, IM induces apoptosis in melanoma, squamous cell carcinoma, human epithelial (HeLa S3) and human keratinocyte cell lines (HaCaT).

Moreover, IM activates several caspases and the Bcl-2-dependent cytosolic translocation of cytochrome c independently of the death receptors.¹¹ In vivo, IM increases apoptosis in melanoma and BCC, downregulates Bcl-2 expression in BCC,¹² and induces expression of Fas in BCC.

Finally, IM has demonstrated antiangiogenic activity. This effect appears to be mediated by IL-18, probably through promoting the production of INF- γ , the most important inhibitor of tumor cell-induced angiogenesis.¹³

PHARMACOKINETICS

IM is the lead compound of the synthetic imidazoquinolone family of drugs. The chemical formulation of IM is 1-(2-methylpropyl)-1*H*-imidazo[4,5-*c*]quinolin-4-amine (C14H16N4), and has a molecular weight of 240.3 Daltons (Figure 60-1). IM is a crystalline, odorless solid that varies from white to off-white in color. It is a stable compound, hardly soluble in aqueous systems and most organic solvents. IM sublimes at a melting point of 297°C to 299°C. The constant ionization for IM is about 7.5.

IM 5% cream is marketed in 12 sachet boxes (AldaraTM), manufactured by 3M Health Care Limited and distributed by Graceway Pharmaceuticals Inc (USA), MEDA AB (Europe) and iNova Pharmaceuticals (South Africa, Asia-Pacific region). The cream is packaged in single-use sachets containing 250 mg of cream and 12.5 mg of IM. Each gram of the cream contains 50 mg of IM in an off-white oil-in-water vanishing cream base consisting of isotearic acid, cetyl alcohol, stearyl alcohol, white petrolatum, polysorbate 60, sorbitan monostearate, glycerin, xanthan gum, purified water, benzyl alcohol, methylparaben, and propylparaben.¹⁴

IM 5% cream is a patient-applied therapy for external use only (Table 60-1). Before applying the cream, the

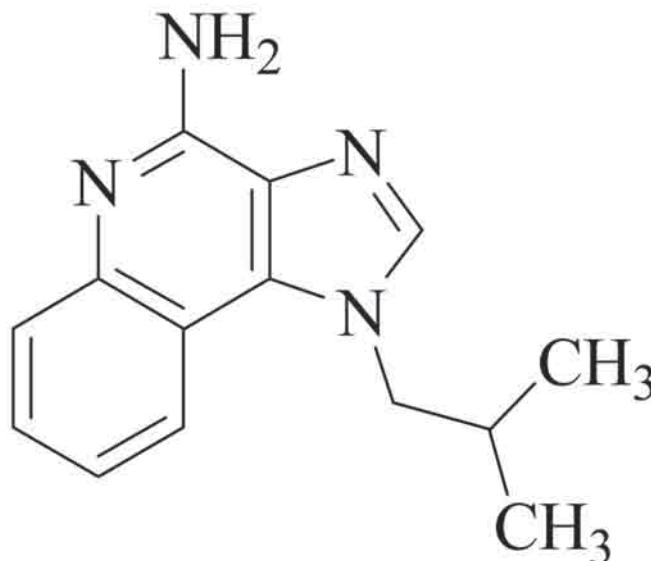

FIGURE 60-1 Imiquimod 1-(2-methylpropyl)-1*H*-imidazo[4,5-*c*]quinolin-4-amine, C14H16N4, 240.3 Da.

patient should clean the treatment area and dry it thoroughly. Enough cream should be applied to cover the treatment area, including one centimeter of surrounding skin. The contents of a sachet may be applied to a skin area of up to 386 square cm.¹⁵ The cream should be rubbed into the treatment area until absorbed (i.e., the cream is no longer visible), and the treatment area should not be bandaged or otherwise covered or wrapped to be occlusive. IM is applied before normal sleeping hours and left on the skin for 8 hours. After the treatment period, the cream should be removed by cleaning the treated area with mild soap and water. Minimal systemic absorption of IM through intact skin occurs during treatment with topical IM. Systemic drug levels were very low after single and multiple doses of IM in children aged 2-12 years.¹⁶

ANIMAL MODELS

The safety of IM has been studied extensively in mice. No treatment-related tumors were noted in an oral rat carcinogenicity study. IM revealed a statistically significant increase in the incidence of liver adenomas and carcinomas in a dermal mouse carcinogenicity study. The vehicle cream of AldaraTM decreased the median time to onset of skin tumor formation in a dermal photoco-carcinogenicity study with hairless mice, and no additional effect on tumor development beyond the vehicle effect was noted with the addition of the active ingredient. IM revealed no evidence of mutagenic or clastogenic potential based on the results of three in vivo genotoxicity tests (rat and hamster bone marrow cytogenetics assay and a mouse dominant lethal test). Daily oral administration of IM to rats, throughout mating, gestation, parturition and lactation, demonstrated no effects on growth, fertility or reproduction.¹⁴

The mechanism of action of IM has also been studied in mice. The murine dermal mast cells activated by IM were essential to initiate an early inflammatory reaction. Activated mast cells expressed TNF- α and IL-1 β and were able to promote the migration of LC in mice.¹⁷ Using a mouse hemangioendothelioma model, IM was found to be a strong inhibitor of tumor cell-induced angiogenesis.¹⁸ IM-treated tumors showed decreased tumor cell proliferation, increased tumor apoptosis, and increased expression of tissue inhibitor of matrix metalloproteinase-1 with decreased activity of matrix metalloproteinase-9.

EFFICACY IN HUMAN STUDIES

External Genital Warts

Anogenital warts (AGW, condyloma acuminata) are common highly contagious benign epithelial lesions occurring on the genitals, perianal area, and inguinal folds. AGW are one of the most common sexually transmitted diseases and are caused by human papillomavirus (HPV), with HPV 6 and 11 causing 90% of cases. Multiple therapeutic

TABLE 60-1—Clinical Applications of Imiquimod 5% Cream

Prevention of recurrence of shaved keloids (56)

options are available for AGW. IM is one of five therapies equally recommended by the CDC for AGW. Standard therapies are invasive, ablative, caustic, painful and treat only the visibly appearing AGW, thus, recurrences are frequent. IM is approved by the FDA for the treatment of external AGW in individuals aged 12 years and over.¹⁹ IM is applied 3 times per week until total clearance or a maximum of 16 weeks. The once-daily regimen does not improve treatment efficacy but results in greater incidence and severity of local skin reactions.²⁰ IM is more effective for women and uncircumcised men than circumcised men. A meta-analysis of IM and 0.5% podophyllotoxin in the treatment of AGW revealed that the clinical cure rates of IM and podophyllotoxin were 50% and 56%, respectively, but podophyllotoxin had more serious adverse effects.²¹ IM is also associated with lower treatment-associated morbidity and lower recurrence rates when compared to conventional ablative methods.²²

The effect of IM on innate and cell-mediated immunity highlighted the possibility of using IM for viral skin infections in immunocompromised patients, and a RCT demonstrated IM efficacy for AGW in HIV-infected patients.²³

Other Viral Diseases

Although the use of IM for managing other skin infections has not yet been approved, there is a growing body of evidence supporting the efficacy of IM in the treatment of other HPV-related diseases such as common warts, subungual and periungual warts, plantar warts, flat warts, lip papillomatosis and epidermodysplasia verruciformis, even in immunocompromised patients.

Molluscum contagiosum (MC) is a skin infection caused by a poxvirus that causes small, firm, umbilicated papules. No consensus has been established concerning

the management of this condition. In-office therapies are very efficacious but they must be performed with adequate anesthesia and are time-consuming procedures. A small RCT demonstrated that IM was well tolerated and with high clearance rates in children with MC.²⁴ However, two RCT involving 702 children aged 2–12 years failed to demonstrate efficacy of IM for MC.¹⁴ Case reports suggest IM efficacy for MC in HIV-infected patients.

Although there are case reports of herpes simplex virus infections successfully treated with IM, it is not recommended in patients with recurrent disease. A pilot study with subjects with recurrent herpes labialis was terminated early because of severe local adverse events that occurred in recipients of IM.²⁵ Moreover, a RCT failed to show an effect on the short-term natural history of herpes genitalis recurrences.²⁶

Human orf or ectyma contagiosum is a self-limiting zoonosis caused by a parapox virus. Case reports suggest that IM is a safe and effective treatment for human orf infection.

Cutaneous Leishmaniasis

Cutaneous leishmaniasis is a serious public health problem in the developing world. Current treatments for this disease are limited by their toxicity, high cost, discomfort and drug resistance. New world cutaneous leishmaniasis has been treated with IM with some success. The combination therapy with topical IM and intravenous meglumine antimonate was well tolerated, accelerated healing of lesions, and improved scar quality in Peru.²⁷ However, a RCT showed no beneficial effect of combining IM and a standard course of treatment with parenteral pentavalent antimony in Iran.²⁸

Superficial Basal Cell Carcinoma

Basal cell carcinoma is the most prevalent malignant skin tumor in whites, and its incidence continues to rise. BCC is a slow-growing, locally invasive malignant epidermal skin tumor, and the most common growth patterns are superficial (sBCC) and nodular (nBCC). A variety of surgical and nonsurgical interventions are available to treat sBCC.²⁹ However, the immune system plays a crucial role in the development and pathogenesis of skin cancer, and IM increases the host's immune response against BCC cells. IM offers a minimally invasive therapy, better cosmetic results, and self-application by the patient improves convenience and appeal. Thus, IM is a reasonable treatment option for patients who are not good candidates for surgery, refuse surgery and/or require less aggressive interventions, and can be useful to prevent or defer surgery.

Imiquimod is approved by the FDA for the treatment of biopsy-confirmed, primary nonfacial sBCC in immunocompetent adults, when surgical methods are less appropriate (Figure 64-2). Dose-response studies indicated that the

FIGURE 60-2 Superficial basal cell carcinoma (sBCC) on the trunk prior to treatment.

FIGURE 60-3 Marked erosion and crusting at the end of the treatment with topical imiquimod.

FIGURE 60-4 Clinical resolution of the sBCC after 5 years of follow-up.

highest response rates were associated with more frequent or prolonged dosing, together with a significant inflammatory reaction (Figure 60-3).^{30,31} The optimal application schedule is 5 times per week for a full 6 weeks, and occlusion of the treatment site does not appear to be beneficial.³² Most sBCC achieve complete remission or decrease in size with IM, and short-term studies showed a histopathologic

clearance rate of 82% for IM in the treatment of sBCC.³³ A 5-year follow-up study to evaluate the recurrence rate of sBCC treated with IM revealed 81% sustained clinical clearance rate in those patients who achieved initial clearance (Figure 60-4).³⁴ Finally, open-labeled studies and case reports suggest that IM is an effective alternative for the treatment of sBCC in patients with basal cell nevus syndrome, xeroderma pigmentosum, and immunosuppressed patients.³⁵

Nodular Basal Cell Carcinoma

Nodular BCC (nBCC) is the most common type of BCC. It is a round, shiny, translucent nodule with overlying small blood vessels and a pearly-appearing rolled border. Surgery is the gold-standard treatment, but IM has also been evaluated for nBCC. Short-term studies with patients receiving a once-daily IM dose showed a histopathologic clearance rate of 71% and 76% after 6 and 12 weeks of treatment respectively.³⁶ The clearance rate depended on both the dosing regimen and the size of the tumor, and increasing severity of local inflammatory reactions was associated with higher clearance rates. IM thrice weekly for 8 and 12 weeks in the treatment of nBCC achieved 64% complete histopathologic clearance, with higher efficacy for tumors that were less than 1 cm in diameter.³⁷ In this study, 17% of patients with clinical clearance had pathologic evidence of residual disease. Thus, some authors recommend a test-of-cure biopsy of the nBCC clinically cleared with IM. In addition, anecdotal case reports suggest the efficacy of IM for nBCC in patients with basal cell nevus syndrome and xeroderma pigmentosum.

The combination of curettage of nBCC prior to the use of topical IM was investigated in two studies. In the first, IM was applied daily for 6–10 weeks after curettage, and this produced histologic clearance of 94% cases.³⁸ In the second study, curettage and electrodesiccation followed by IM once daily for 1 month after reduced the frequency of residual tumor and improved the cosmetic appearance.³⁹ Few recurrences have been reported during the short-term follow-up studies, although the results of the 5-year follow-up trials have not yet been published.

Actinic Keratoses

Actinic keratoses (AK) are the most common ultraviolet light-induced lesions and frequently occur on sun-exposed skin. AK is considered as *in situ* squamous cell carcinoma (SCC) that may progress to invasive SCC (iSCC). Although the exact rate of transformation of AK to iSCC is unknown, the majority of iSCC appear to arise from within AK. The treatment of AK provides an important opportunity to prevent the development of iSCC. Cryotherapy is the standard of care for AK, but it does not treat initially inapparent or subclinical AK and recurrences are frequent. IM is an effective and well-tolerated treatment for AK, and it is

approved by the FDA for the treatment of clinically typical, nonhyperkeratotic, nonhypertrophic AK on the face or scalp in immunocompetent adults. IM has to be applied once-daily, twice weekly (USA) or thrice weekly (Australia) for 16 weeks. Another option is the cycle dosing regimen approved in Europe and Australia, that consists of thrice weekly IM application for 4 weeks followed by a rest period of 4 weeks. The cycle dosing regimen may be repeated if any AK remains after completing an 8-week cycle, and the overall complete clearance rate is comparable to the 16-week treatment regimen, while decreasing drug exposure to the patient and decreasing the overall treatment time.⁴⁰

A recent trial demonstrated that IM applied once weekly for 24 weeks was convenient for patients and resulted in improvement of AK with minimal side effects.⁴¹

Subclinical AK lesions may become apparent in the treatment area during treatment with IM. Thus, the fact that IM effectively uncovers and treats subclinical lesions is considered an additional benefit of treatment with the drug. Although treatment rest periods are recommended if marked inflammation occurs, greater severity of erythema, erosions, and crusting appear to be associated with higher clearance rates. Fifty per cent of patients achieve complete clinicopathologic clearance of all AK lesions and an excellent cosmetic result.⁴² A randomized study compared IM, topical 5-FU and cryosurgery for AK, and the clearance rates for the treatment field at 12 months post-treatment were 73%, 33%, and 4%, respectively.⁴³ Thus, IM should be considered as a first line therapy for sustained treatment of AK. Furthermore, long-term follow-up data showed a low incidence of new AK lesions following treatment with IM. After a median follow-up period of 16 months IM continued to provide a long-term clinical benefit in a majority of patients.⁴⁴ IM can also be combined with other therapies for AK, and two RCT demonstrated higher AK clearance rates when IM was applied after cryotherapy or photodynamic therapy.^{45,46}

Immunosuppressed patients are a growing population at increased risk for developing AK and iSCC, thus resulting in significant morbidity and mortality. Two RCTs concluded that IM appears to be an effective alternative for the treatment of AK and cutaneous dysplasia in solid organ transplant recipients.^{47,48}

Other Squamous Intraepithelial Neoplasia

Bowen's disease is an *in situ* SCC of the epidermis and has a 3%-5% risk of developing into iSCC. A RCT revealed that 73% patients treated daily with IM for 16 weeks achieved complete resolution, with no relapse during the 9-month follow-up period.⁴⁹ However, more studies to define the ideal dosing regimen are required before it can be accepted as an approved therapy.

Anogenital intraepithelial neoplasia (AGIN) are generally HPV-associated tumors that may progress to iSCC. Surgery is the cornerstone treatment of AGIN, but

alternatives to surgery are needed because of considerable treatment-associated morbidity and high recurrence rates. Case series suggest that IM is highly effective, more convenient and minimally invasive for AGIN. A prospective follow-up study demonstrated that IM led to a decrease of human papillomavirus DNA and to a sustained clearance of anal intraepithelial neoplasia in HIV-infected men.⁵⁰ A RCT concluded that IM is effective in the treatment of high-grade (2 or 3) vulvar intraepithelial neoplasia.⁵¹ IM was well tolerated, relieved itching and pain, and did not influence health-related quality of life.

Other Cutaneous Malignancies

Open-labeled trials and case series suggest the usefulness of IM for actinic cheilitis, extramammary Paget's disease, lentigo maligna, melanoma metastasis, T cell cutaneous lymphoma and Kaposi sarcoma.

Actinic cheilitis (AC) occurs on the vermillion border of the lips, usually in a patient with significant sun exposure. AC requires early therapy to prevent its progression into iSCC. Topical therapy with IM may be an efficient, cosmetically more appealing alternative treatment than currently used destructive therapies.

Extramammary Paget disease (EMPD) is a rare skin neoplasm found in the genital, anorectal, or axillary area, which can be limited to the epidermis and can sometimes be associated with underlying carcinomas. Surgery is the gold-standard treatment, but case reports suggest that IM is an alternative to surgery.

Lentigo maligna (LM) is a melanoma *in situ* that most commonly appears on the sun-exposed skin of the head of elderly patients. Although LM has the potential for invasion, it often has a greatly protracted radial growth phase and may remain indolent for years. The current standard of care is surgical excision, but complete removal of LM may be difficult because of its occasional extensive subclinical extension. Complete regression of LM after IM treatment has been reported in open-labeled case series. However, without controlled evidence and prolonged follow up, the use of IM for LM must still be considered experimental.⁵² There are also case reports of the successful use of IM for dermal melanoma metastasis, but IM failed to prevent the progression of subcutaneous metastases.

Mycosis fungoides (MF) is the most common clinicopathologic subtype of primary cutaneous T-cell lymphoma. Treatment of MF with IM is well tolerated and associated with a histopathologic and clinical response rate of 50% in open-labeled studies.⁵³ Lymphomatoid papulosis, cutaneous CD30+ anaplastic large cell lymphoma, cutaneous follicle center lymphoma and cutaneous B-cell lymphoma have also been successfully treated with IM. As the long-term recurrence rates after treatment are unknown, patients should have long-term follow-up.

Kaposi sarcoma (KS) is a low-grade vascular neoplasm associated with human herpes virus type 8 infection. An

open-labeled trial demonstrated that IM had antitumor activity in about half the patients with classic and endemic KS and was generally well tolerated.⁵⁴ There are anecdotal reports of the efficacy of IM for immunosuppression-associated KS.

Finally, there are reports of the successful use of IM for keratoacanthoma and iSCC.

Vascular Tumors

Hemangioma of infancy is a benign vascular tumor characterized by presentation within the first weeks of life, rapid growth during the first year and variable degree of spontaneous involution over a period of several years. Active nonintervention remains the mainstay of therapy for most uncomplicated tumors, and the immune system is thought to play a role in the regression phase of hemangioma. Open-labeled studies suggest that IM may be a successful treatment option for superficial hemangioma and recurrent pyogenic granuloma.⁵⁵

Keloids

No effective treatment exists for permanent keloid removal. Case series suggest IM usefulness to prevent the recurrence of excised keloids. However, a recent RCT with 20 keloids failed to demonstrate a significant difference in keloid recurrence rates between the two treated groups. At 6 months, keloid recurrence rates were 37.5% in the IM group and 75% in the vehicle group ($p = 0.54$).⁵⁶

Other Skin Disorders

There are open-labeled case series and individual case reports of the successful use of topical IM for infiltrative BCC, trichoepitheliomas, epidermolytic acanthomas, porokeratosis of Mibelli, elastosis perforans serpiginosa, angiolympoid hyperplasia with eosinophilia, vulvitis circumscripta plasmacellularis, Zoon's balanitis, discoid lupus erythematosus, localized scleroderma, granuloma annulare, granuloma faciale, silicone granuloma, chronic interdigital tinea pedis and alopecia universalis. However, the role of IM in the treatment of these conditions remains unclear, and RCT are warranted.

SAFETY PROFILE

Studies on acute dermal toxicity, dermal irritation, dermal sensitization, and repeat-dose dermal toxicity have demonstrated that IM 5% cream is slightly irritating. IM does not enhance ultraviolet radiation-induced damage to human epidermal cells or DNA and has no detectable potential for inducing either photocontact allergy or phototoxicity in humans.⁵⁷ According to the results of five in vitro and three in vivo genotoxicity tests, IM showed no mutagenic or clastogenic potential. No appropriate or well-controlled studies

have been conducted in pregnant women, so safety of IM use during pregnancy remains uncertain and IM carries an FDA pregnancy C classification. IM should only be used in pregnancy if potential benefits surpass potential risks to the fetus. Furthermore, it is not known whether topical IM is excreted in breast milk.¹⁴

The most frequently reported adverse reactions are skin and application site reactions, although some patients develop systemic reactions. Typically, these reactions are more frequent and intense as dosing frequency increases, and decrease in intensity or resolve after cessation of IM therapy. Local skin reactions are frequent, generally mild, and well tolerated, and may extend beyond the application site onto the surrounding skin. However, treatment should be discontinued for some time in some patients because of the intensity of local reactions. Proper counseling on the related side effects is critical for maintaining patient compliance.

These skin reactions include: erythema, edema, induration, vesicles, pustules, erosion, excoriation, ulceration, weeping, exudate, flaking, scaling, dryness, scabbing, crusting, itching, soreness, and burning. Despite skin reactions, patients generally experience excellent cosmetic outcome. However, localized postinflammatory hyperpigmentation, hypopigmentation, and vitiligo may follow IM therapy, and these changes may be permanent.

The systemic reactions are uncommon and disappear rapidly on discontinuation of the drug. Systemic reactions that may be related to IM 5% cream are fatigue, fever, malaise, pain, myalgia, arthralgia, headache, nausea, diarrhea, and influenza-like symptoms. Rarely, IM may trigger or exacerbate inflammatory conditions such as psoriasis, aphthous ulcers, pemphigus, myasthenia gravis, and angioedema. Thus, IM should be used with caution in patients with pre-existing autoimmune conditions.

The effect of treatment with IM on the health-related quality of life (HRQL) of patients has been rarely studied. A RCT comparing IM and placebo in 52 women with vulvar intraepithelial neoplasia concluded that IM does not influence HRQL. In a repeated-measures analysis, no significant differences at baseline, at 4 weeks after treatment, or at 12 months were observed in self-reported HRQL, body image, or sexuality.⁵¹

CONCLUSION

A variety of factors affect the best treatment for a particular patient. The main aims of treatment are to cure the patient, to preserve function, to achieve an optimal cosmetic result, and to consider the needs and desires of the patient. The choice of therapy depends on clinical circumstance and medical practitioner experience. Moreover, patients should be educated about the available surgical and nonsurgical treatment options for their skin disease. The risks/benefits, postoperative requirements, potential complications, and long-term outcome should be discussed. The possible need

What We Know

- IM is a small synthetic imidazoquinoline heterocyclic amine of 240.3 Da (C14H16N4).
- IM is an immune response modifier that acts through toll-like receptor 7 to induce cytokine production and subsequent innate and adaptive cell-mediated immune response.
- IM induces frequent local skin inflammatory reactions, generally mild and well tolerated. Systemic reactions are uncommon and disappear rapidly on discontinuation of the drug.
- Meta-analysis of RCT has demonstrated the efficacy of IM for AGW, sBCC and AK, and these indications are approved in USA, Europe, and Australia.
- There is good evidence to support the use of IM in the treatment of AGW in HIV-positive patients, cutaneous leishmaniasis in combination with parenteral pentavalent antimony, nodular BCC, AK, and skin dysplasia in transplant recipients, Bowen's disease, high grade VIN and prevention of recurrence of shaved keloids, but these indications are currently off-label.
- Open-labeled trials and case reports suggest IM efficacy for many other skin conditions, but RCT are warranted.

for further treatment or long-term follow-up should also be outlined. Lastly, all patients must be made aware of the likely cosmetic/functional outcome, as well as the costs of the proposed treatment. Taking the above-mentioned into account, IM offers a topical, noninvasive, nonsurgical, home-based therapeutic option that has revolutionized the therapeutic management of cutaneous infections and skin cancer, empowering patients to participate in their own treatment.

IM is an immune response modifier drug, that applied topically induces production of several cytokines and chemokines, which promote both innate and adaptive cell-mediated immune responses. IM has frequent local side effects and uncommon systemic reactions that disappear rapidly on discontinuation of the drug. Patient selection and counseling are critical for optimizing compliance with respect to managing expectations and anticipated application-site reactions.

Imiquimod is currently approved by the FDA for the treatment of AGW, sBCC, and AK. Moreover, the use of IM has gradually expanded to various off-label skin conditions in the last decade. RCT have demonstrated IM efficacy for AGW in HIV-positive patients, cutaneous leishmaniasis in combination with parenteral pentavalent antimony, nodular BCC, AK, and skin dysplasia in transplant recipients, Bowen's disease, high grade VIN, and prevention of recurrence of shaved keloids. Based on the currently available data, topical IM appears to have a role

in treating these skin diseases if the benefit-to-risk ratio is favorable, although there are currently limited long-term follow-up data.

Open-labeled studies and anecdotal case reports suggest IM is a safe and effective across a broad range of cutaneous diseases. However, the role of IM in the treatment of these conditions remains unclear, and in the absence of RCT clinicians must consider the cumulative weight of smaller studies with their personal experience when assessing appropriateness of off-label IM use.

Topical Tar

61

Neil Sandhu, M.D., and Robert A. Schwartz, M.D., M.P.H.

SUMMARY

Coal tar and wood tar have been utilized in the field of modern dermatology for many years, dating back to ancient times. Tar is used to treat many dermatologic conditions, including chronic stable plaque psoriasis, scalp psoriasis, atopic dermatitis, and seborrheic dermatitis, either alone, or in combination therapy with other medications and/or phototherapy. Tar has been shown to be very effective in the clearing of lesions and prolonged remission times. However, many patients do complain of its odor, messy application and staining of clothing, but modified tar preparations have been made to increase their acceptability. Recent clinical studies do not support the possible carcinogenicity of tar. This article will review the current uses of tar in the treatment of selected dermatologic conditions as well as the pharmacology, formulations, efficacy, and adverse effects.

INTRODUCTION

Tar has been used in medicine since the ancient times, as described by Hippocrates.¹ Over 2000 years ago, Dioscorides, a Greek physician and pharmacologist, was one of the first physicians to use coal tar for dermatologic conditions. In 1681, therapeutic crude coal tar in dermatology was emphasized by Becher and Serle.^{2,3} In 1895, Professor Kaposi⁴ noted tar as being an important part of his pharmacopoeia. Through dry distillation, tar was obtained from coals, stones, and several kinds of wood including birch, beech, and *Juniperus oxycedrus*.

In the past, coal tar has been used to treat many different types of dermatologic conditions including scabies, sarcoidosis, pityriasis lichenoides chronica, and neurodermatitis. Coal tar is currently employed to treat chronic stable plaque psoriasis, scalp psoriasis, atopic dermatitis, seborrheic dermatitis, and occasionally neurodermatitis.^{3,5-7} Goeckerman was the first to describe the clinical efficacy of ultraviolet (UV) radiation in combination with coal tar for the treatment of psoriasis, allowing for long remission times and high clearing rates.⁸ Coal tar is considered the first line treatment in many parts of the world despite its lack of use in the western world.^{6,9} As evidenced by clinical experience and patient trials, tar is effective in treating many skin disorders. Currently, there are a few controlled

clinical trials. This is likely because of many factors, including a lack of interest by manufacturers, the introduction of newer and more lucrative therapeutic modalities, and the concerns regarding carcinogenicity. When treating patients, other tars, including wood tars, are also occasionally used instead of coal tar, but may not be as effective.¹⁰

PHARMACOLOGY OF TAR

Crude coal tar, wood tar (principally pine, beech, birch, and juniper) and shale (bituminous tars/ichthammols) are the three main types of tar.¹⁰ Wood and shale tars lack photosensitizing effects and contact sensitizing potential, unlike that of coal tar. Coal tar is heavier than and slightly soluble in water, resulting in a mildly alkaline solution with a naphthalene-like odor and a sharp, burning taste.¹¹ In the absence of air, coal tar is formed by heating coal. The gases that form are then allowed to cool into a brown-black liquid.² Ammonia is then removed, resulting in a product containing 10,000 compounds, including polycyclic aromatic hydrocarbons (PAHs), water, and carbon. This crude coal tar then undergoes fractional distillation. The oils that are then produced can be mixed in various topical vehicles, allowing for increased absorption of the coal tar.^{2,3} Depending on the type of coal used and temperature of the distillation, the final composition can vary greatly.¹² For example, coal tar has an increased content of phenols and tar acids at lower temperatures. In comparison, coal tar has an increased number of PAHs at higher temperatures.² At this time, there are no agreed upon chemical or biologic standards to determine the exact pharmacokinetics of coal tar given the variability expected in the final formulation.¹

Mechanism of Action

The mechanism of action of topical tar is not well understood. There are, however, several possible effects. These include suppression of DNA synthesis, which leads to a reduction of epidermal hyperproliferation in psoriatic skin¹² (Table 61-1). On the other hand, coal tar increases the mitotic rate-labeling index, causing an initial thickening of the epidermis in healthy skin.¹⁰ The variance in activity is likely attributed to coal tar correcting a defect in differentiation in psoriatic skin. Furthermore, antibacterial,

TABLE 61-1—Possible Mechanisms of Action of Coal Tar^{2,3,12}

Suppression of DNA synthesis
Reduction of epidermal hyperproliferation
Antifungal
Antibacterial
Antiparasitic
Antipruritic
Vasoconstrictive
Keratoplasic and antiacanthotic
Atrophogenic effect on epidermis
Photosensitizing effect
Inhibition of sebum secretion
Anti-inflammatory

antifungal, antiparasitic, antipruritic and anti-inflammatory effects have been documented with the use of coal tar.^{2,3} In addition, inhibition of sebum secretion was reported with the use of topical therapy in animal studies.²

Within the range of 330-550 nm in the UVA and visible light spectrum, coal tar possesses a photosensitizing effect, but the relevance of this is not fully understood and may be attributed to the tar components, specifically anthracene, 3,4 - benzpyrene, fluoranthene and pyrene.^{2,3,12} In mouse models, the use of coal tar with near UVA light has been shown to lead to suppression of DNA synthesis in normal and proliferating skin when compared to coal tar use alone.¹³ This has not been noted with UVB or UVC treatment.¹⁴ Given the phototoxic smarting reactions that UVA light causes, as well as the relatively necessary long exposure times, UVA light is not used.¹ Compared to tar and UVA light, tar and UVB light demonstrate increase efficacy in psoriasis therapy.¹⁰ The use of low-dose narrow-band UVB with a topical coal tar preparation (liquor carbonis detergens) has been shown to be an effective combination,¹⁵ but has not been proven to be preferable to broadband UVB with a topical coal tar preparation.

Formulations and Pharmacokinetics

Given its color, odor and ability to stain clothing, the use of tar has decreased in part because of concerns that the application is physically unappealing.¹⁶ A recent study compared both the tolerability and cosmetic acceptability of liquor carbonis distillate (coal tar) 15% solution versus calcipotriene cream in the treatment of plaque psoriasis. Patients were asked to rate the scent, drying time, staining, and dab-on applicator for the coal tar solution. Overall, patients reported the 15% coal tar solution as a cosmetically acceptable and tolerable treatment when compared to calcipotriene cream.¹⁷ Currently, crude coal tar (pix carbonis), coal tar ointment, and coal tar solution are the

only official USP preparations¹¹. Extracts of tar or alcoholic solutions have been used as plain solutions and/or incorporated into ointments. Topical tar solutions (liquor picis carbonis or liquor carbonis detergens- LCD) are prepared by mixing 50 g of polysorbate 80, 200 g of coal tar, and a quantity of alcohol sufficient to make 1 L. The final products usually contain different tar fractions; therefore, variance in the effectiveness of these formulations can be expected.^{1,18} Coal tar extracts are made using different solvents, which can include polyoxyethylene lauryl ether. Coal tar (1- 20%) extracts have been dissolved in gels, lotions, and shampoos in order to increase their cosmetic acceptability.² Because exposure to air increases the viscosity of these products, they should be stored in tight containers¹⁸ (Table 61-2).

Keratolytic agents, such as 5% salicylic acid, can be incorporated into these preparations to aid in the reduction of scaling.¹⁶ For difficult-to-treat palmar and plantar psoriasis, the use of tar with a corticosteroid cream is especially useful under occlusion.¹⁴ Many of these products can be found in pharmacies specializing in compounding. However, obtaining the compounded products can be extremely difficult.⁶ Currently, there are some commercially available compounded products (Table 61-3).

Efficacy is determined by both the strength of the tar as well as the vehicle in which it is dissolved. In one large study, investigators compared 1% coal tar lotion prepared with a liposomal base to 5% conventional coal tar extract in the treatment of patients with mild to moderate chronic plaque psoriasis. The total sign score (an assessment rating for erythema, induration and scaling) for 2 target plaques

TABLE 61-3—Selected Tar Products¹⁷

Products	Active ingredients	Dosage forms	Manufacturers
Coal tar solutions (LCD)			
Cutar	7.5% LCD (1.5% coal tar)	Lotion or mixed with water as soak	Summers Laboratories, Collegeville, PA
Psorigel	7.5% LCD (1.5% coal tar)	Gel	Healthpoint, Fort Worth, TX
Ionil-T	5% LCD (2% coal tar)	Shampoo	Healthpoint, Fort Worth, TX
Tarsum	10% LCD (2% coal tar) and 2% salicylic acid	Shampoo	Summers Laboratories, Collegeville, PA
Crude coal tar (pix carbonis)			
Estar	5% Coal tar	Gel	Bristol Myers Squibb, New York, NY
Coal tar extract			
T/Gel	2% (0.5% Coal tar)	Shampoo	Neutrogena, Los Angeles, CA
	4% (1% Coal tar)		
Coal tar distillate			
Doak tar	3% (1.2% Coal tar)	Shampoo	Doak, Nycomed USA, Melville, NY
Doak tar oil	2% (0.8% Coal tar)	Solution, mixed with water for soak	Doak, Nycomed USA, Melville, NY
Doak tar distillate	40%	Solution for compounding	Doak, Nycomed USA, Melville, NY
Tar blends			
Polytar	2.5% (0.5% Coal tar)	Soap (with povidone)	Steifel, Coral Gables, FL
	4.5% (0.5% Coal tar)	Shampoo	
	Both products contain a solution of crude coal tar, coal tar solution, juniper tar (cade oil), and pine tar		

LCD, liquor carbonis detergens = coal tar solution.

was significantly decreased in the 1% group. In addition, cosmetic acceptability of both products was not significantly different. The greater efficacy found in the lower strength product was attributed to the vehicle disrupting the architecture of the intracellular lipids, which allows for increased transport of the active ingredient into the epidermis.¹⁹

Furthermore, length of application has to be considered. In a paired comparison evaluating the use of short-term crude coal tar therapy in patients with chronic stable plaque psoriasis, 17 patients applied 30% crude coal tar treatment for 1 hour to one affected area and 5% crude coal tar treatment for 23 hours daily to another affected area for 21 days. Compared to plaques coated with the higher strength tar, the plaques covered with 5% crude coal tar showed significant improvement at days 14 and 21, as measured by severity scores assessing for erythema, scaling, and thickness.²⁰

Application of Tar

In 1895, Kaposi⁴ wrote, "The tar is usually applied in the following manner: the psoriatic patches having been cleared of their epidermis by soap in the bath, a thin layer of tar is rubbed in energetically once or twice a day, or at night

only, by means of a bristle brush, after which the patient dresses in flannel clothes. This procedure is repeated every day." In order to achieve a better effect, Kaposi described a tar bath in which the patient is first rubbed thoroughly with soap, then immediately has all affected skin painted with tar, which was left in place for 4-6 hours. However, he did note that acute tar toxicity was a potentially serious side effect.

Currently, tar can be used up to four times a day for skin disorders. Making sure that it is not applied to any bleeding or raw plaques, it is massaged into the skin and left on for at least 2 hours. Avoiding plastic wraps to prevent irritation, it can be wrapped in bandages. An emollient can be used 1 hour after the tar preparation is applied if the skin is excessively dry after treatment. For bath soaks, the tar is mixed with water. For about 30-45 days, the patient is to soak him or herself for approximately 15 minutes, once daily or even twice weekly. Tar should be removed from the body prior to ultraviolet radiation when administering phototherapy, which can be given 2 to 72 hours after the tar application.¹⁸ Tar shampoo, when used for the scalp, is used twice a week. It is applied to the scalp while hair is wet. Patients are instructed to stroke the hair in the direction of hair growth, followed by a rinse.

Pregnancy, Lactation, Child Use

Physicians should use caution when prescribing tar to a gravid patient, as the use of tar in pregnancy has not been studied. Overall, tar products are not generally prescribed in pregnant patients.⁶ Nursing mothers should also be informed about the lack of data regarding excretion of tar into the breast milk. In addition, the safety profile of tar in children has not been established. Clinical judgment should be used regarding tar use in children.¹⁸

Indications

Coal tar is used primarily in patients with chronic stable plaque psoriasis, scalp psoriasis, seborrheic dermatitis, atopic dermatitis, and occasionally neurodermatitis. If the psoriatic patient is sun sensitive or taking photosensitizing medications, if folliculitis or acne is evident in the area to be treated and in acute inflammatory psoriasis, tar should be avoided, as it may precipitate an erythroderma.^{18,21}

Chronic Stable Plaque Psoriasis

The original Goeckerman regimen had patients soak in crude coal tar for the majority of the day and night. After removal of the tar, this was followed by gradually increased exposure to UV radiation via a quartz mercury vapor lamp.²² This regimen required occlusive dressings and hospitalizations for 2 to 3 weeks, but did lead to a high clearing rate and long remissions.⁸ Because it is cheap, effective, and available, the original Goeckerman regimen is still used in most of the world for the treatment of chronic plaques psoriasis.²³ To make it more practical for outpatient treatment, many modifications have been made. Conflicting data has accumulated regarding the efficacy of this treatment, with several studies comparing tar to petrolatum in ultraviolet therapy showing no enhanced therapeutic benefit of the tar with erythemogenic doses of UV radiation.²⁴⁻²⁹

One modified Goeckerman regimen consists of the patient applying tar ointment at bedtime. After removing tar from body surfaces in the morning, the patient undergoes UV exposure. Good to excellent results in 95% of patients was shown in a study comprised of 123 psoriasis undergoing this regimen with daily UV irradiation and thrice-daily tar ointment application for an average of 20 days. These patients also demonstrated remission rates averaging 1.7 years with a range of 2 months to 8 years.³⁰ In addition, the remissions on tar therapy were longer than the spontaneous remissions experienced during the natural course of their disease. In a 21-day evaluation of the use of this modified ambulatory Goeckerman regimen on 162 severe psoriatic patients, all patients were hospitalized for 14 days. On day 14, about half of these patients were discharged to an outpatient setting. With 60% of patients still in remission 2 years after treatment, there was no

significant difference regarding the improvement of psoriasis in either group after discharge.³¹ Furthermore, studies have also shown that applying tar 2 hours prior to irradiation is equally effective as using overnight.³²

Several studies have compared the use of topical tar with other standard topical treatments of stable plaque type psoriasis. In one study of 40 patients, 1% coal tar preparation (Exorex)TM was compared with calcipotriol cream in patients with plaque-type psoriasis. Both topical medications were found to be comparably effective; however, cosmetic acceptability and tolerability was better for calcipotriol.³³ Furthermore, a study comparing topical 0.1% tazarotene gel with crude coal tar 5% ointment in patients with stable plaque psoriasis demonstrated comparable clinical efficacy.³⁴

Scalp Psoriasis

Scalp psoriasis affects 50% of psoriatic patients.³⁵ Particularly if pruritus is a main complaint, coal tar is effective in the treatment of scalp psoriasis. These coal tar preparations are usually mixed into a lotion or gel formulation. These can also be combined with a corticosteroid if needed.³⁶ Tar preparations are still an effective and cheaper alternative that extends the remission time if used as maintenance therapy in comparison to other treatments, including corticosteroids and calcipotriol in the treatment of scalp psoriasis³⁵. In addition, some tar preparations, such as gels, may not need occlusion, while shampoos may not be as effective without occlusion.³⁵ Adding salicylic acid can be helpful in removing thick scales, thus allowing for better topical absorption of tar.

In one large study, a gel containing coal tar was used in psoriatic patients for 5 consecutive days, followed by a vegetable oil soak on the 6th day. Eighty-three percent of patients cleared or showed marked scalp improvement. In addition, only 37.6% of them needed 2–4 courses. To assess for duration of remission, 72 patients that responded went on to either use a tar or non-tar shampoo twice a week. The use of a tar-containing shampoo allowed for a median remission time of 8 months, in comparison to those who used the non-tar shampoo relapsed in under half that time.³⁵

Seborrheic and Atopic Dermatitis

Few controlled clinical studies have been done to support the use of tar in the treatment of seborrheic and atopic dermatitis. However, tar has been used to treat these conditions for many years. Its use for these diseases dates back to ancient times and is cited in many texts.^{1,2,37-40}

To avoid possible side effects, including percutaneous absorption, local effects such as thinning of the skin, and in rare cases, adrenocortical function suppression, coal tar preparations in seborrheic dermatitis avoids the use of

corticosteroids.^{5,37} According to one pharmacologic study, coal tar gel use against *Malassezia* species, fungi isolated from seborrheic dermatitis patients, resulted in antifungal activity in vitro based on minimum inhibitory concentration measurements.⁴¹ The in vitro fungistatic effects against *Malassezia* species seen in coal tar have been found to be equivalent to ketoconazole gel.⁴²

The use of coal tar preparations has been shown to be beneficial in the treatment of atopic dermatitis. Crude coal mixed with a zinc paste base was applied 2 to 3 times a week in an outpatient analysis involving 18 atopic patients. They were then compared to others in an inpatient setting treated for the same condition with daily applications of the same treatment. Comparable improvements were shown in both groups, as measured by a visual scoring system.⁷

ADVERSE EFFECTS

Because of a chlorine-containing ingredient, tar is a follicular irritant, and tar folliculitis a common side effect of coal tar. This is usually evident on the lower extremities with tar concentrations greater than 2%.² Acneiform eruptions have also been noted with the use of tar; however, this differs from acne vulgaris because the main inducer in this case is chlornaphthalene. This is mainly seen in patches on the extensor surfaces of the arms, with pruritus as the main complaint. In addition, there is an association with dermatitis venenata of the fingers.³⁷ Adverse effects of tar can also include exacerbation of psoriasis and application site reactions, such as irritation, rash, burning, and stinging.¹⁹ Furthermore, allergic contact dermatitis, telangiectasias, atrophy, pigmentation, keratoacanthomas, and exfoliative dermatitis can also occur.^{2,3} These adverse effects are treated in the standard way. However, approaches beneficial for acne, folliculitis, and contact dermatitis are unlikely to be effective until the topical tar has been terminated or suitably modified. Kaposi⁴ described long ago tar intoxication, symptomatic of acute tar absorption. This includes symptoms such as nausea, vomiting, and black urine (Table 61-4). Unless it is actually ingested or absorbed in large amounts, the risk of tar intoxication is small. One should avoid using tar in erythrodermic psoriatic patients or extensively in a young child.

Carcinogenicity

Since 1775 when Sir Percival Pott linked chimney sweepers with an increased risk of scrotal cancer, there have been concerns raised about the carcinogenicity of coal tar. Small nodules that develop from cutaneous exposure to tar are known as tar keratoses. They may spontaneously regress or fall off, but have the potential to develop into a squamous cell carcinoma. In one study, 46 of 111 patients who were exposed to tar occupationally for 40 years, developed a cutaneous carcinoma.¹⁴ Topical tar treatment have resulted in percutaneous absorption, as measured by blood and

urine samplings in animal models.² Polycyclic aromatic hydrocarbons (PAHs), especially benzo(a)pyrene, are converted into the active form by inducible microsomal enzymes, which then bind to nucleotides of RNA and DNA, causing carcinogenic effects as seen in animal studies^{14,43} (Figure 61-1). However, there is no conclusive epidemiologic evidence supporting the human use of topical tar preparations leading to skin cancer.⁴⁴

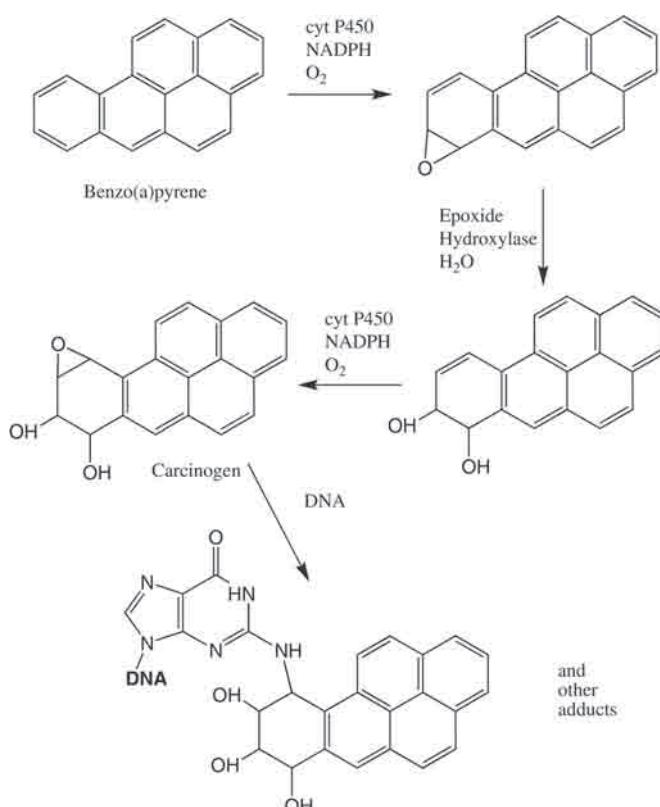

FIGURE 61-1 Mechanism of metabolic activation of benzo(a)pyrene leading to alkylation of DNA.

In a relatively small study of 23 patients, each underwent the Goeckerman regimen for an average of 17 days with an endpoint of determining the genotoxic effects.²³ Measurement of certain selected biomarkers including metabolites of PAHs, urinary thioethers, and chromosomal aberrations of peripheral lymphocytes were obtained. The results demonstrated that patients could be endangered at peak genotoxic exposure; however, these markers were not long lasting. These markers were not present after the 78th day of therapy. PAHs are primarily responsible for the genotoxicity in tar; however, UV light may as well be a contributing factor. Six males were treated for psoriasis with either topical pure coal tar or 4% coal tar-containing ointment in order to assess their genotoxic risk.⁴⁵ The frequencies of chromosome aberrations and sister chromatid exchanges in lymphocytes as well as urinary mutagenicity levels were related to the levels of exposure to coal tar. This lymphocytic circulation implies extracutaneous systemic carcinogenic risk. Furthermore, a recent study involving 13,200 patients with psoriasis and eczema showed no increased risk of non-skin or skin malignancies after coal tar treatment with a median treatment duration of 6 months.⁴⁶ However, more well-designed epidemiologic surveys should be performed to assess the risk of cutaneous and bladder cancer, lymphoma, and other malignancies after dermatologic use of coal tar as currently there is still no clear evidence of an increased risk of skin or internal cancers to date.

In a study examining the safety of tar in 719 psoriatics, compared to the general population, there was no increase in the incidence of skin cancer.⁴⁷ In two separate 25-year follow-up trials of 280 psoriatics and 426 atopic and neurodermatitis patients, treated with coal tar and UV radiation, there was no increased risk of skin cancer compared to the general population.^{45,48} The use of UV light appears to potentiate the carcinogenicity of coal tar; however, there has not been a consensus of epidemiologic studies to support this.²³ Overall, the risk of skin cancers in the general population and the prior use of other mutagenic agents needs to be considered when evaluating these concerns.

THE OTHER TARS

Wood tars are derived from the destructive distillation of pine, beech, birch, and juniper. They contain acetic acid or phenolcarbonylic acids, with a relative absence of toxic anthracene and pyridine derivatives.^{1,49} Wood tars have been used in the treatment of many different skin disorders, including psoriasis and atopic dermatitis. Wood tars have no photosensitizing effects.³ Wood tars have been shown to have an increased risk of irritation and allergic sensitization.^{2,10} In one study involving 1,883 patients, 5.4% of patients had wood tar sensitization. In those patients that had a combined allergy to wood and coal tar, cross-sensitization was determined to be the underlying cause.⁵⁰ Furthermore, a patient had exposure to topical pine tar only; however, she also showed a positive reaction to coal

tar, beech tar, birch tar, and juniper tar, supporting the finding that these reactions are a consequence of cross-sensitization and not prior exposure.⁵¹

Wood Tar

Polytar® is a tar blend of coal tar, juniper tar (cade oil), and pine tar and has been employed clinically for the treatment of psoriasis, seborrheic dermatitis, and eczema. In a 6-week, open label, noncomparative trial comprised of 910 patients, topical scalp treatment for seborrheic dermatitis was evaluated in patients using zinc pyrithione 1% mixed in a shampoo base and a tar blend 1% shampoo (Polytar®). Patients were advised to use the shampoo twice weekly for 4 weeks, followed by once a week for 2 additional weeks. Results showed a statistically significant decline in mean dandruff score, with an 84.8% reduction at 6 weeks. Furthermore, mean scores of itching and erythema were statistically decreased.⁵² In another 4-week study with 162 patients in treating moderate to severe scalp psoriasis, tar blend 1% shampoo (Polytar®) was compared to clobetasol propionate 0.05% shampoo (Clobex®). Decreasing erythema, plaque thickening, pruritus, desquamation, and the total and global severity scores were significantly more effective with the corticosteroid shampoo. Patients also preferred the corticosteroid shampoo in regards to cosmetic acceptability in comparison to the tar shampoo.⁵³ Side effects of tar blend shampoos are similar to those of coal tar used alone when topically applied. However, adverse effects such as fever, hypotension, renal failure, and hepatotoxicity have been reported if accidentally ingested.⁵⁴

Shale Tar

Obtained from the destructive distillation of stones that contain fossilized fish, shale tar is composed of 20% sulfur. It has less photosensitizing effects and contact dermatitis potential in comparison to wood or coal tars.³ Shale oil is derived from sedimentary rock. It is further distilled into pale and dark shale oil by different processing methods.⁵⁵ In 1882, the dark shale oil was described in the treatment of skin disorders by Unna; however, it is the pale sulfonated shale oil (PSSO) that is now preferred in the treatment of skin disorders.⁵⁵ Shale tar has been shown to have antibacterial, antimycotic, analgesic, antipruritic, and anti-inflammatory properties. Enhanced proliferation and growth factor expression of keratinocytes, as well as the stimulation of wound healing (epithelialization) have been demonstrated in vivo.⁵⁵ Shale tar is used in the treatment of psoriasis, seborrheic dermatitis, and atopic dermatitis.^{55,56} The anti-inflammatory effect of 0.5% hydrocortisone cream is comparable to 4% shale oil.⁵³

In a randomized, controlled, multicenter, observer-blinded trial comprised of 119 patients evaluating the efficacy of PSSO in the treatment of venous leg ulcers, approximately half of the patients received a topical application of 10%

What We Know

- Tar has been used for centuries and is a proven, effective treatment modality for many skin disorders, including psoriasis, atopic dermatitis, and seborrheic dermatitis. With conflicting evidence in epidemiologic and human studies, there are concerns regarding its carcinogenicity.
- Tar is used in many countries and is considered a first line treatment because of cost savings and availability.
- Tar is a pharmacologic agent that has shown significant efficacy in psoriasis, atopic dermatitis, and seborrheic dermatitis.
- Tar should be considered a key component in the armamentarium of drugs for the treatment of many skin disorders.

PSSO to the site daily for 20 weeks. The other half of patients received a topical vehicle for the same period. As measured by photoplanimetry, the ulcer size was significantly reduced in the PSSO group compared to vehicle, with a cumulative relative reduction in ulcer area greater in the PSSO area as early as 6 weeks into treatment. However, at the end of the study period, there were no significant differences in granulation and complete epithelialization.⁵⁶

Michael Krathen, M.D., and Alice B. Gottlieb, M.D., Ph.D.

As our understanding of disease mechanisms and clinical experience with these medications continue to grow, so will the prevalence of biologic use. Biologic medications can be loosely defined as bioengineered agents, generally monoclonal antibodies, or soluble cell surface proteins, which are produced in living organisms and interact with cell signaling pathways to improve disease outcomes. Within the scope of dermatology, biologics modulate several fundamental pathways of the adaptive immune system. These powerful agents can dramatically alter the disease activity of psoriasis, autoimmune blistering disease, and a host of other inflammatory conditions. Caution and prudent patient selection must be addressed, however, given the increased risk of infection and malignancy identified in some agents.

TNF-ALPHA BLOCKING AGENTS

Tumor necrosis factor (TNF)-alpha is a potent immunoactivator, which is principally released by cells in the

macrophage/monocyte lineage, along with multiple other cell types, in the early stages of inflammation^{1,2}. The release of TNF-alpha is important in propagating the host response in combating various viral, bacterial, and parasitic infections. Both exogenous (e.g., lipopolysaccharide) and endogenous (e.g., interleukin 1 β and interferon γ) mediators can stimulate TNF-alpha release². Downstream effects are numerous, including endothelial cell activation (allowing for selected and upregulated leukocyte migration and transport), neutrophil activation, macrophage, and NK cell killing, and NF-kappa beta pathway upregulation^{1,2}. Elevated levels of TNF-alpha have been identified in numerous diseases including Crohn's disease, rheumatoid arthritis (RA), psoriasis, psoriatic arthritis, septic shock, and bacterial meningitis²⁻⁵. Inhibition via TNF-alpha blockers is effective in treating psoriasis, Crohn's disease, rheumatoid arthritis, and various other inflammatory diseases (Table 62-1)⁶⁻⁸. There are currently five TNF-alpha blockers on the market in the United States, only three of which are approved for dermatologic use (see Table 62-1).

TABLE 62-1—Tumor Necrosis Factor Inhibitors and Indications(9)

TNF blocker	FDA-approved indications: Dermatology	FDA approved indications: Nondermatology	Off-Label Dermatologic Uses
Infliximab(10)	Severe chronic plaque psoriasis	Crohn's disease Ulcerative colitis Psoriatic arthritis Rheumatoid arthritis Ankylosing spondylitis	Pyoderma gangrenosum Hidradenitis suppurativa Cutaneous sarcoidosis Behçet's disease Wegener's granulomatosis Pityriasis Rubra Pilaris Dermatomyositis
Etanercept (10)	Moderate to severe chronic plaque psoriasis	Psoriatic arthritis Rheumatoid arthritis Ankylosing spondylitis Juvenile idiopathic arthritis	Pyoderma gangrenosum Hidradenitis suppurativa
Adalimumab (10-12)	Moderate to severe chronic plaque psoriasis	Psoriatic arthritis Rheumatoid arthritis Ankylosing spondylitis Juvenile idiopathic arthritis Crohn's disease	Cutaneous sarcoidosis Pyoderma gangrenosum Dissecting cellulitis Granuloma Annulare Behçet's disease
Golimumab	None	Psoriatic arthritis Rheumatoid arthritis Ankylosing spondylitis	No studies as of 5/09
Certolizumab	None	Crohn's disease	

No generics currently exist for any of the TNF-alpha inhibitors. Although the TNF-alpha blockers exhibit class effect, differences exist in efficacy, safety, and mechanism of action.

ETANERCEPT

Etanercept is a dimeric fusion protein which links a portion of the human extracellular TNF-binding receptor to the human Fc portion of IgG1⁶. In addition to TNF alpha, this soluble receptor molecule also neutralizes lymphotoxin A². Etanercept has been approved by the FDA for treatment of psoriasis, psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis, and juvenile idiopathic arthritis⁶. Off-label uses are numerous. The relevance of added lymphotoxin A blockage is unknown; in one case of rheumatoid arthritis, treatment with etanercept showed improvement, although prior treatment with infliximab (TNF alpha inhibition alone) was ineffective¹³.

Dosing

Etanercept is delivered subcutaneously through syringes or auto-injectable pens. The psoriasis dosing varies per indication and age (Table 62-2).

Efficacy

Psoriasis

A number of trials have proven efficacy for etanercept use in psoriasis. A Phase III randomized double-blind dose reduction study (*n*=583) evaluated the use of etanercept up to 24 weeks in adults with chronic plaque psoriasis,

involving at least 10% body surface area (BSA)¹⁴. Forty nine percent of subjects treated with 50 mg twice a week (BIW), 34% treated with 25 mg BIW, and 3% of placebo patients achieved a psoriasis area and severity index (PASI) score of 75% or greater (PASI 75) at 12 weeks. All subjects from weeks 12 to 24 were transitioned to 25 mg BIW; at 24 weeks 54% of the 50 to 25 mg BIW group, 45% of the continuous 25 mg BIW, and 28% of the placebo to 25 mg BIW group achieved PASI 75. No neutralizing antibodies formed during the study, although antietanercept antibodies developed in about 1% of participants. Although the dose-reduction group (50 mg to 25 mg BIW) showed little change in PASI 75 at 24 weeks, an earlier study showed progressive improvement in treating from 12 to 24 weeks with etanercept at 50 mg BIW¹⁵. For the 50 mg BIW group in the latter study, the PASI 75 at week 12 was 49% and 59% at week 24.

Another Phase III randomized, double-blind trial of etanercept (*n*=591) with open-label extension, demonstrates long-term efficacy of 50 mg BIW dosing in moderate to severe chronic plaque psoriasis¹⁶. All patients after week 12 were converted to 50 mg BIW therapy. Peak PASI 75 scores were achieved at week 48 with subsequent decline; posthoc analysis showed that the PASI 75 declined by approximately 10% in those with at least 90% compliance. Again, nonneutralizing antietanercept antibodies were found but had no impact on efficacy or safety outcomes. Adverse event rates were similar for the etanercept/etanercept group at 12 and 96 weeks, suggesting extended exposure does not change the drug's toxicity. Nine malignancies and 14 nonmelanoma skin cancers were detected during the study. Although the standardized incidence ratios (SIRs) for these malignancies were not significantly different from age- and sex-matched cohorts from the general population, at least three were considered possibly related to etanercept by the investigator.

TABLE 62-2—TNF Inhibitor Dosing Schedule for Psoriasis

	Adults (FDA label usage)	Children (Off-Label Use)
<i>Etanercept</i>		
- Initiation	50 mg sq twice weekly × 3 months	Psoriasis, Ages 4-17 years
- Maintenance	50 mg sq once weekly	0.8mg/kg (up to maximum 50 mg) once weekly (19, 23) 25 mg or 0.4 mg / kg twice a week (23-25)
<i>Adalimumab</i>		
- Initiation	80 mg sq first dose, 40 mg sq second dose 1 week later	No studies in psoriasis Juvenile Idiopathic Arthritis, ages 4-17 years(8)
- Maintenance	40 mg sq every other	Dosing: 15 to < 30 kg: 20 mg every other week < 30 kg: 40 mg every other week
<i>Infliximab</i>		
- Initiation	5 mg /kg at weeks 0, 2, 6	Case Reports in Psoriasis, Ages 13 and 14
- Maintenance	5 mg/kg every 8 weeks after 3 rd initiation dose; adjust dose and frequency depending upon clinical efficacy and tolerance	3.3 to 5 mg/kg at weeks 0, 2, 6 (26, 27) 3.3 to 5 mg/kg every 8 weeks after 3 rd initiation dose (26, 27) Crohn's Disease (ages 6-17)(7) 5 mg/kg at weeks 0, 2, 6, 10 weeks 5 mg/kg every 8 or 12 weeks

One patient experienced worsened congestive heart failure (CHF).

Dosing of 50 mg once weekly (QW) is supported by a 12 week double-blind, placebo-controlled trial ($n=268$) followed by a 12 week open label conversion study¹⁷.

A large randomized open label study ($n=2546$) demonstrated that etanercept therapy can be interrupted without risk and resumed with good effect¹⁸. Although the continuous group (50 mg BIW followed by 50 mg QW) showed improved outcomes, interrupted therapy subjects were only followed for a maximum of 8 weeks after reinitiation and may have reached similar efficacy if followed over time.

Children and Adolescents

Etanercept use in children with psoriasis has been investigated as well. A 48-week treatment-withdrawal-retreatment study ($n=211$) of etanercept in children and adolescents age 4-17 demonstrated good efficacy¹⁹. Subjects were treated with 0.8 mg/kg etanercept up to 50 mg QW \times 12 weeks initially; 57% of etanercept and 11% of placebo patients achieved PASI 75 at 12 weeks. Weight-based dosing, as opposed to maximum dosage, was considered more effective. Similar to the above retreatment study by Moore et al. efficacy of retreatment in subjects who lost PASI 75 was consistent with response rates seen at similar time intervals during initial treatment phase. Infectious and noninfectious adverse events were similar in placebo and treatment groups. No cancers, deaths, demyelination events, opportunistic infections, or tuberculosis were reported.

Off-Label Indications

HIDRADENITIS SUPPURATIVA

An open-label, uncontrolled Phase II study ($n=10$) evaluated the use of etanercept 50 mg QW for 12 weeks in hidradenitis suppurativa (HS)²⁰. A decrease in fistulas, Sartorius score, visual analog scale, and patient-reported pain was reported. The Sartorius score decreased greater than 50% in six subjects at week 12 and seven subjects at week 24. In contrast, another Phase II study investigating use of etanercept 50 mg QW for HS demonstrated minimal improvement²¹. Quality of life index scores, physician global assessment scores, lesion counts, and patient pain scores showed no difference from baseline at 12 weeks in the latter study. Perhaps higher doses of etanercept will show benefit in the future.

NEUTROPHILIC DERMATOSES

Case reports indicate that etanercept may be helpful in pyoderma gangrenosum, although the more potent TNF-alpha inhibitors infliximab and adalimumab may be more effective¹⁰. Reports also indicate the usefulness of etanercept in Sweet's¹⁰.

GRANULOMATOUS DISEASE

There are limited data, mostly in the form of case reports, to support the use of etanercept in cutaneous sarcoidosis, granuloma annulare, and necrobiosis lipoidica¹⁰.

BULLOUS DISEASE

Case reports have shown benefit for etanercept in mucous membrane and cutaneous pemphigoid, allowing for prednisone tapering in otherwise resistant disease¹⁰.

AUTOIMMUNE CONNECTIVE TISSUE DISEASE

A pilot study of 10 patients with systemic sclerosis treated with etanercept 25 mg BIW for 6 months showed improvement in clinical outcomes, including the Rodnan skin core and digital ulceration¹⁰. Etanercept in a bleomycin-induced murine model of scleroderma showed a reduction in dermal sclerosis, collagen accumulation, and burden of myofibroblastic cells²². Future human studies are required to further substantiate these results. Case reports detailing improvement in dermatomyositis and Behcet's disease have been reported as well¹⁰.

Other reported uses in dermatology for etanercept include acute and chronic graft versus host disease (GVHD), SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis), multicentric reticulohistiocytosis, erythema annulare centrifugum, and Hailey-Hailey disease¹⁰.

INFliximab

Infliximab is a chimeric monoclonal IgG1 antibody that neutralizes TNF-alpha through high affinity binding of soluble and transmembrane forms of TNF-alpha, thus preventing binding of TNF-alpha and its receptor⁷. The constant region of the monoclonal antibody is human, whereas the variable region is murine⁷. Infliximab is FDA approved for the following indications: severe chronic plaque psoriasis, Crohn's disease, ulcerative colitis, psoriatic arthritis, rheumatoid arthritis, and ankylosing spondylitis (See Table 62-1). As with etanercept, the off-label uses are numerous.

Dosing

Infliximab is available only through intravenous infusion. Treatment is performed at outpatient infusion centers. Dosing schedules for psoriasis are listed in Table 62-2.

Efficacy

Psoriasis

A Phase III, double-blind, placebo-controlled study ($n=378$) evaluated the efficacy and safety of infliximab, administered 5 mg/kg at weeks 0, 2, and 6 and then every 8 weeks until

week 46, in moderate to severe plaque psoriasis²⁸. At week 24, the PASI 75 was 82% versus 4% for placebo, but efficacy tapered somewhat with a PASI 75 of 61% at week 50. Nail psoriasis, as measured by the NAPSI score, was also significantly improved as compared to placebo. Anti-infliximab antibodies, which were detected in 19% of subjects at week 66, decreased the efficacy of infliximab. Three serious infections and three hypersensitivity reactions were noted in the treatment group. There were no demyelinating events, tuberculosis or serious opportunistic infections, new onset CHF, or major hematologic events (aplastic anemia, pancytopenia, agranulocytosis).

A study evaluating comparative dosing of 3 mg/kg or 5 mg/kg and continuous versus intermittent dosing showed improved PASI 75 scores with both the 5 mg/kg and continuous groups²⁹. Safety data in this study revealed the following: two cases of tuberculosis, 12 malignancies (10 with nonmelanoma skin cancer who were previously treated with ultraviolet light therapy), elevations in alanine and aspartate aminotransaminases, and two patients with a lupus-like syndrome. No demyelinating events were seen. Anti-infliximab antibodies were correlative with risk of infusion reaction. This study concluded that the ideal dosing regimen was 5 mg/kg administered with an every 8 week maintenance dosing instead of the as-needed regimen.

The impact of infliximab on health-related quality of life (HRQoL) in psoriasis has been evaluated. In a double-blind, randomized, placebo-controlled study (n=835), infliximab (either 3 or 5 mg/kg) was shown to improve Dermatology Life Quality Index (DLQI) and Short-Form Health Survey 36 (SF-36) at 10 weeks. HRQoL correlated with disease severity, the presence of psoriatic arthritis, and depression. Even accounting for these comorbidities, infliximab significantly improved the physical and mental health components of the SF-36 and the DLQI. Similar improvements in the DLQI and SF-36 were noted in another double-blind, randomized, placebo-controlled study evaluating infliximab in chronic plaque psoriasis (REF: 16704649).

There are no prospective studies evaluating the use of infliximab in children and adolescents with psoriasis or psoriatic arthritis. Several cases have been reported supporting the efficacy of infliximab at doses ranging from 3.3 to 5 mg/kg in children with psoriasis³⁰. Infliximab has been used successfully in pediatric Crohn's disease, as evidenced by a Phase III, randomized, open-label study in pediatric subjects with moderate to severe Crohn's disease³¹. Large, prospective, controlled and randomized studies are needed to further assess the efficacy and safety of infliximab in the pediatric population.

Off-Label Indications

GRANULOMATOUS DISEASE

Infliximab has been shown to be one of the most effective antigranuloma medications on the market. The

antigranuloma effect of infliximab has been especially important in the treatment of sarcoidosis. As will be discussed, adalimumab also shows efficacy in granulomatous disease, whereas the evidence for etanercept is less straightforward; perhaps underlying differences in these medications can explain both the increased risk of *Mycobacterium tuberculosis* (TB) reactivation and improved clearance of granulomas with adalimumab and infliximab. Although no prospective studies have been performed, the dramatic responses seen in numerous cases seem to indicate efficacy¹⁰. Cases of successful treatment of granuloma annulare and necrobiosis lipoidica with infliximab have also been reported¹⁰.

HIDRADENITIS SUPPURATIVA

Several case reports and case series document improvement in HS with 5 mg/kg dosing of infliximab¹⁰.

Other disease which have responded to infliximab in the form of case reports or case series include the following: pyoderma gangrenosum, subcorneal pustular dermatosis, Wegner's granulomatosis, dermatomyositis, Behcet's disease, acute and chronic GVHD, pityriasis rubra pilaris, SAPHO syndrome, multicentric reticulohistiocytosis, toxic epidermal necrolysis, and atopic dermatitis^{10,32}.

ADALIMUMAB

Adalimumab is a recombinant fully human monoclonal IgG1 anti-TNF-alpha antibody administered by subcutaneous injection⁸. It is approved by the FDA for the following indications: rheumatoid arthritis, juvenile idiopathic arthritis, psoriatic arthritis, ankylosing spondylitis, Crohn's disease, and plaque psoriasis (See Table 62-1).

Efficacy

Psoriasis

Like etanercept and infliximab, adalimumab has been shown in several Phase III studies to be effective in the treatment of plaque psoriasis. Although concern about subject selection with respect to extension studies has been raised³³, adalimumab has proven long-term (up to 2 years) efficacy. Several studies have evaluated adalimumab in plaque psoriasis.

A multicenter, randomized, double-blind, placebo-controlled study (n=148) evaluated the safety and efficacy of adalimumab in moderate to severe plaque psoriasis³⁴. After 12 weeks of study receiving either adalimumab 40 mg QW or every other week or placebo, subjects were allowed to continue adalimumab at initial doses or start adalimumab 40 mg every other week. At 12 weeks, 53% and 80% of patients in the every other week and weekly dosing groups, respectively, achieved PASI 75, whereas only 4% of the controls achieved this same level of improvement. Mean PASI improvement continued out to the end of the study,

at 60 weeks. Nine percent of subjects withdrew because of an adverse event. The most common side effects include injection-site reaction, nasopharyngitis, and upper respiratory tract infections. Four malignancies were discovered in the trial in treatment subjects, including two with malignant melanoma, and one each with breast carcinoma and gastric adenocarcinoma. No lymphomas or nonmelanoma skin cancers were detected. One case of pulmonary coccidiomycosis and two cases of TB (one latent, one conversion) were identified. Hepatic transaminases were elevated greater than threefold in two patients and were withdrawn from the study.

Another double-blind, placebo-controlled randomized trial ($n=1212$) investigated adalimumab (40 mg every other week for 15 weeks) in moderate to severe plaque psoriasis³⁵. PASI 75 scores were achieved in 70% of treated patients at 16 weeks compared with only 7% of controls. PASI 75 scores may be elevated because of subject selection bias in that responders were preferentially continued into the open-label portion of the study³³. Six cases of nonmelanoma skin cancer and one case of TB were identified; no cases of lymphoma, demyelinating disease, or lupus were identified.

The safety, efficacy, and impact on quality of life (QOL) of adalimumab was addressed in a double-blind, placebo-controlled randomized-controlled study in a cohort of Japanese patients with moderate to severe plaque psoriasis ($n=169$)³⁶. Similar to the other studies mentioned, PASI 75 scores for the 40 mg every other week groups (one with 80 mg loading dose, and one without) were around 60%. Another group, which received 80 mg every other week, showed a significantly improved 81% PASI 75 at weeks 16 and 24 in comparison to the 40 mg groups. With respect to safety, there were no significant differences in the number of serious adverse events, severe adverse events, or adverse events leading to premature discontinuation of the drug. Differences in injection site reactions and mild elevations in hepatic aminotransferase levels were noted in the treatment groups. Significant improvements in the Dermatology Life Quality Index (DLQI) and the Short Form 36 Health Study (mental and physical components) were noted for all treatment groups.

Children and Adolescents

No studies exist in which children with psoriasis have been treated with adalimumab. Given successful treatment of juvenile idiopathic arthritis with adalimumab, prospective and controlled studies will likely follow.

Off-Label Uses

As with etanercept and infliximab, off-label uses of adalimumab are numerous and growing. Cases of improvement after treatment with adalimumab in sarcoidosis,

pyoderma gangrenosum, multicentric reticulohistiocytosis, dissecting scalp cellulitis, and granuloma annulare have been reported¹⁰⁻¹².

HIDRADENITIS SUPPURATIVA

Six subjects with refractory severe HS were treated with 40 mg every other week adalimumab for 24 months³⁷. The number of affected regions, fistulas, and nodules were reduced significantly at 1 year.

GOLIMUMAB

Golimumab, a novel human IgG1κ monoclonal antibody which specifically targets TNF-α, has been approved by the FDA in the treatment of rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis³⁸. The application of golimumab (50 or 100 mg dosed every 4 weeks) for use in psoriasis was partially investigated in a randomized, placebo-controlled, double-blind trial designed to assess its efficacy in a cohort of psoriatic arthritis patients ($n=405$)³⁹. Methotrexate was administered concomitantly. Although the primary outcome was the American College of Rheumatology 20% improvement criteria for arthritis (ACR20), PASI scores were followed in parallel for up to 24 weeks. PASI 75 scores at 14 weeks were 40% and 58% for the 50 and 100 mg doses, respectively; at 24 weeks scores continued to improve in a dose-dependent fashion with PASI 75 obtained by 56% and 66% in the 50 and 100 mg groups, respectively. Importantly, the study population has slightly less severe skin disease with lower affected body surface area and PASI scores than those seen in psoriasis studies, so psoriasis specific trials will help determine the role of golimumab in the dermatologic armamentarium. The most frequent adverse events in the treatment group were nasopharyngitis and respiratory tract infection. No cases of tuberculosis were identified. Three malignancies were discovered during the treatment phase in the 100 mg golimumab group, including two cases of basal cell carcinoma and 1 case of prostate cancer. Anti-golimumab antibodies were detected in 4.6% of patients and had no apparent effect on outcome, although the numbers for detecting a difference were low in the study; no subjects who took methotrexate at baseline developed antibodies.

CERTOLIZUMAB

Certolizumab is a Pegylated Fab' fragment specific for binding TNF-α⁴⁰. Since it lacks an Fc domain, it does not fix complement or cause antibody-dependent cell-mediated cytotoxicity in vitro⁴⁰. The fact that a TNF blocker lacking an Fc component has both efficacy and increased TB reactivation demonstrates that the Fc component does not account for differential safety or efficacy properties among the TNF blockers. Certolizumab does not bind

TABLE 62-3—Pharmacokinetics of TNF Alpha Inhibitors(2, 38, 40)

lymphotoxin A (TNF- β)⁴⁰. Currently, it is approved by the FDA for refractory moderate to severe Crohn's disease in adults. Two studies investigating the use of certolizumab in psoriasis have been completed (Clinical Trials.gov identifiers NCT00329303 and NCT00245765), although published data is lacking currently (clinicaltrials.gov).

PHARMACOKINETICS/ PHARMACODYNAMICS

Table 62-3 demonstrates comparative pharmacokinetic data for etanercept, infliximab, and adalimumab. The half-life of adalimumab is the longest of the three approved TNF inhibitors for psoriasis, allowing for only twice a month injections. Intravenous bolus of infliximab results in high maximum concentration and demonstrates 100% bioavailability (See Table 62-3); these particular pharmacokinetic variables may account for the quick and robust clinical response to infliximab therapy. Golimumab and certolizumab also show long half-lives; they are currently marketed as once-monthly subcutaneous medications. Whether this dosing schedule works in psoriasis is unknown.

With respect to binding avidity, etanercept binds to 2 TNF-alpha subunits in a 1:1 ratio, whereas both adalimumab and infliximab can bind up to two per single drug molecule (2:1 ratio)^{2,41}. It has been suggested that this low ratio allows for safer titration of etanercept than either adalimumab or infliximab, which can effectively neutralize more TNF molecules per unit drug².

SAFETY

Although the risks of therapy vary with each TNF- α inhibitor, the general safety concerns of the drug class include the following: malignancy, susceptibility to infection, demyelinating disease, heart failure, and more common benign side-effects including injection site reactions.

Malignancy

As the field of cancer immunology expands, more will be understood in the complex relationship between cancer

antigenicity and the host response. Currently, immunosurveillance by the host, particularly by natural killer cells, is thought to play a protective role in the body's fight against malignancy⁴². Immunosuppression is considered a risk factor in the development of new malignancies, the most obvious example being the increased risk of melanoma and nonmelanoma skin cancer in solid organ transplant recipients⁴³. To date there are little data which conclusively link the use of TNF- α inhibitors with malignancy. In examining 13,001 patients with rheumatoid arthritis over approximately 49,000 patients years of treatment, Wolfe and Michaud showed that the 49% who received biologics (infliximab, etanercept, adalimumab, and anakinra) had an increased risk of developing nonmelanoma skin cancer (OR 1.9, 95% confidence interval (CI) 1.2-1.8) and possibly increased risk of melanoma (OR 2.3, 95% CI 0.9-5.4)⁴⁴. In this same study, no increases in the rates of hematologic, lung, colon, or breast malignancy were detected. In contrast, a meta-analysis of nine randomized-controlled trials ($n=3,493$) which investigated the use of either infliximab or etanercept for rheumatoid arthritis showed a pooled 3.3 OR (95% CI 1.2-9.1) of malignancy (mostly nonmelanoma skin cancer and lymphoma); higher doses of TNF- α inhibitors was associated with increased odds ratio as well⁴⁵. Large studies in dermatology evaluating the risk of malignancy and TNF- α inhibitor use have not been performed.

Despite lack of conclusive data regarding TNFs and malignancy, the FDA added a black box warning regarding risk of lymphoma and other malignancies in children and adolescents on anti-TNF α therapy⁴⁶. An FDA analysis identified 48 malignancies in children and adolescents on TNF blocker therapy. The reporting rate of lymphoma in the infliximab and etanercept cohorts (adalimumab and golimumab were not assessed for this analysis) was significantly elevated from background; data regarding other TNF blockers was too sparse for further analysis. Additionally, the FDA noted that almost all patients were on concurrent immunosuppressives. Conservative management includes counseling patients about current data and the as of yet unknown risk of neoplasia.

Infection

The use of TNF- α inhibitors is associated with increased risk for infection with *Mycobacterium tuberculosis* (TB)² along with other intracellular infections, including *Histoplasma capsulatum*, *Listeria monocytogenes*, and *Leishmania donovoni*⁹. The FDA released a MedWatch Alert in 2008 concerning the delay in diagnosis and treatment of pulmonary and disseminated infection with histoplasmosis, blastomycosis, and coccidiomycosis in patients on TNF- α inhibitors⁴⁷. The risk for TB infection may be elevated in patients on infliximab and adalimumab in comparison to etanercept². Nonetheless, all patients starting and continuing on TNF- α inhibitor therapy should be screened for TB (see monitoring, below). Furthermore, the risk of serious infections for patients taking infliximab and etanercept for rheumatoid arthritis has been shown to be increased in comparison to placebo patients (OR 2.0, 95% CI 1.3-3.1); similar to risk of malignancy, a dose-response relationship was noted⁴⁵.

Given the increased risk for infection on therapy, vaccination against certain pathogens may be beneficial in certain patients before initiation of anti-TNF- α therapy if possible. Although host immune response against infections is likely blunted, data show that both influenza and pneumococcal vaccines are likely effective during adalimumab therapy⁴⁸. The National Psoriasis Foundation does not explicitly recommend a vaccination protocol, but does recommend vaccination before initiation of anti-TNF- α therapy if the decision has been made to vaccinate⁴⁸. The 2008 American College of Rheumatology (ACR) recommendations for rheumatoid arthritis patients include vaccination with influenza, pneumococcus, and Hepatitis B (if HBV risk factors such as intravenous drug use, multiple sexual partners in the previous 6 months, health care worker are present) vaccines⁴⁹. Both groups recommend against the use of live vaccines in these patients.

The use of TNF inhibitors in patients with certain existing viral and bacterial (mycobacterial) infections should be avoided or done so cautiously. Reactivation of HBV has been noted in patients on infliximab and adalimumab but not etanercept⁵⁰⁻⁵². Although chronic HBV infection is not an absolute contraindication to TNF inhibitor therapy, careful monitoring of liver function tests and HBV DNA levels is a must; pretreatment with appropriate antivirals may prevent reactivation, although data is limited^{50,53}.

Whereas TNF has been shown to control viral replication in HBV, TNF does not seem to play as significant a role in controlling HCV⁵⁰. One case series of HCV-infected RA patients ($n=31$) treated with etanercept, infliximab, and adalimumab supports the use of anti-TNFs in HCV-infected patients provided liver enzymes and HCV viral loads are monitored regularly⁵⁴. In this study, four patients experienced elevation in viral load without hepatotoxicity and one patient discontinued anti-TNF use because of persistently elevated alanine aminotransferase

without viral load elevation. A recent consensus paper by the National Psoriasis Foundation recommends TNF inhibitors, particularly etanercept, along with PUVA and other systemics like acitretin as a second line medication for patients with HCV⁵⁵. Magliocco and Gottlieb reported three patients with psoriasis, psoriatic arthritis, and HCV who were successfully treated with etanercept without a worsening in their liver function or viral load⁵⁶. In fact, a Phase II randomized, placebo-controlled trial ($n=50$) indicates that adjuvant etanercept use in combination with interferon and ribavirin for chronic hepatitis C may help establish virologic clearance and normalize hepatic transaminases; furthermore, etanercept recipients experienced fewer or equivalent side effects for nearly all adverse effects⁵⁷.

Demyelinating Disease

Case reports indicate that anti-TNF- α therapy can initiate or uncover underlying demyelinating disease. The following peripheral nerve disorders have been reported with anti-TNF- α therapy: Guillain-Barré syndrome, Miller Fisher syndrome, chronic inflammatory demyelinating polyneuropathy, multifocal motor neuropathy with conduction block, mononeuropathy multiplex, and axonal sensorimotor polyneuropathies⁵⁸. Nonetheless, some authors have indicated the incidence of demyelinating disease is not elevated during anti-TNF- α therapy⁵⁹. If a strong family history of multiple sclerosis or other demyelinating disease is present, it may be best to avoid anti-TNF- α therapy until this risk is further characterized. Cessation of anti-TNF- α therapy is generally regarded as the best approach toward treatment, although some have more recently advocated that stopping the withdrawal is not always necessary for neuropathy control⁶⁰.

Hepatotoxicity

Elevations in serum aspartate and alanine aminotransaminase (AST and ALT), which are usually but not always reversible, have been reported with TNF-inhibitors, particularly infliximab^{9,48}. Although the sequelae of such elevations is unclear, the medical board of the National Psoriasis Foundation has recommended withholding treatment if either the AST or ALT is equal to or greater than five times the normal limit⁴⁸. It may also prudent to recheck serologies for hepatitis B in previously exposed patients. HBV reactivation has been reported in patients with antibodies to both hepatitis core and surface antigens (HBsAb and HBcAb) with negative HBsAG (surface antigen)⁵⁰.

Hematologic Toxicity

Rarely, the following hematologic side effects have been noted with the anti-TNF- α agents: anemia, leukopenia, neutropenia, thrombocytopenia, pancytopenia, and

aplastic anemia⁴⁸. Although infrequent, monitoring the CBC regularly throughout treatment is sensible (see monitoring, below).

Heart Failure

New onset or worsening of existing congestive heart failure (New York Heart Association Class III-IV) leading to death and hospitalization has been noted at high doses of infliximab (10 mg/kg)⁷. The package inserts for all five TNF inhibitors warn patients of these risks^{6-8,38,40}.

Infusion Reactions: Infliximab

Of all the TNF-inhibitors, infliximab is the only one administered intravenously. Infusion-related hypersensitivity reactions, including hypotension, urticaria, and/or dyspnea may occur, most commonly during or within first 2 hours of treatment⁷. Emergency treatment for hypersensitivity reactions, including appropriate staff and medications, should be readily accessible in infusions centers.

Delayed infusion reactions have been reported, particularly when infliximab is readministered in patients who have developed anti-infliximab antibodies and the interval between restarting therapy and the previous dose was 6 months or longer⁷. Most of these reactions were noted in a cohort of Crohn's patients upon reinitiation of infusions; 3 to 12 days after infusion, affected patients experienced myalgia and/or arthralgia, fever, rash, facial, hand, or lip edema, dysphagia, urticaria, sore throat, and headache⁷.

Injection site reactions: Etanercept, Adalimumab, Certolizumab, Golimumab

The most common side effect of the injectable anti-TNF agents is an injection site reaction, defined as redness, swelling, itching, or bruising at the site of injection. Approximately 15 - 20% (adalimumab 19%; etanercept 14%) of subjects in trials have experienced injection site reactions. Generally the reactions are mild to moderate, lasting about 3-5 days with decreasing frequency over time⁶.

MONITORING

A consensus statement from the Medical Board of the National Psoriasis Foundation addresses appropriate laboratory monitoring when initiating biologics in psoriasis⁴⁸. Appropriate laboratory tests at baseline include complete blood count (CBC) with platelet count, liver function tests (including serum alanine and aspartate aminotransaminases), hepatitis B and C panels, and a tuberculin skin test (PPD) or other appropriate screening test for tuberculosis. The frequency of monitoring varies, although checking a CBC and LFTs every 3 months may be appropriate given

reports of leukopenia, neutropenia, pancytopenia, and fatal hepatitis⁷. Drug induced thrombocytopenia has also been noted with TNF-alpha inhibitor therapy^{7,61}. If bruising or excessive bleeding is noted on therapy, prompt evaluation of a CBC with platelet count is indicated.

A consensus group published guidelines in 2008 regarding TB and biologics in dermatology⁶². First, all patients should be screened for TB risk before initiating immunosuppressive therapy. Second, screening should commence yearly after initiation of TNF-alpha inhibitors given the increased risk of reaction. Third, a 5 mm or greater induration in a tuberculin skin test should be considered positive in immunosuppressed patients. Fourth, if a patient is found to have latent TB, immunologic therapy can be started 1 to 2 months after initiating therapy with isoniazid, although the preference is to complete full course of therapy before starting the biologic. Finally, active TB must be treated with a full four-drug regimen before initiating biologic therapy.

KEYS TO PRESCRIBING

Neutralizing autoantibodies have been detected in the following TNF-inhibitors: infliximab, adalimumab, certolizumab, and golimumab^{7,8,38,40}. The level of antibody production varies according to the particular drug, disease indication, and length of therapy. The prevalence of antidirug antibodies is lowered with concomitant use of methotrexate. Because of the development of neutralizing antibodies, restarting the same TNF-inhibitor after cessation of previous therapy may lead to higher drug failure rates; thus, reinitiating therapy with another agent may be more beneficial. Alternatively, starting the TNF-inhibitor once the patient is already on a stable dose of methotrexate can reduce the development of neutralizing antibodies and may lower long-term treatment failures. Efficacy over the long term may be reduced secondary to development of neutralizing antibodies.

TNF-flared psoriasis has been reported in patients taking anti-TNFs for psoriasis (plaque, pustular, erythrodermic), ankylosing spondylitis, rheumatoid arthritis, inflammatory bowel disease, and Behcet's disease⁶³. A recent review of TNF-induced psoriasis identified infliximab as the culprit agent in the majority of cases (55.1%) followed by etanercept (27.6%) and adalimumab (17.3%)⁶⁴. Most patients were being treated for rheumatoid arthritis (50.4%) followed by ankylosing spondylitis (16.1%), Crohn's disease (13%), psoriasis (6.9%), psoriatic arthritis (3.1%), ulcerative colitis (1.5%), and Behcet's disease (6.9%)⁶⁴. In this review, palmar-plantar eruptions were the predominant morphology identified (40.5%), followed by plaque (33.1%), and guttate (10.2%). The time interval between starting the TNF-inhibitor and the onset of the psoriasisform eruption has ranged from 15 days to 20 months⁶³. This phenomenon is a class effect; switching to another TNF blocker is unlikely to resolve the flare.

The most effective management is to stop the TNF blocker and initiate an alternative systemic therapy⁶⁴.

Patients should be free from severe illness or infection when initiating therapy. If a patient experiences severe illness or infection while on therapy already, skipping the next dose—if in close proximity to illness—is prudent.

Drug-induced lupus has been reported with TNF-inhibitors. Although the development of autoantibodies (ANA and dsDNA) is relatively common during therapy, drug-induced lupus (DIL) is not⁶⁵. When it occurs, anti-TNF-induced lupus (ATIL) presents differently than classic cases of DIL. ATIL presents more like classic systemic lupus erythematosus with serositis, myositis, nephritis, CNS involvement, cutaneous eruptions, and positive anti-nuclear and anti-dsDNA antibodies than DIL. Antihistone antibodies may be present, but are not present nearly as often as in DIL⁶⁵.

USTEKINUMAB: IL-12/23 INHIBITORS

Greater understanding of the pathogenesis of psoriasis, psoriatic arthritis and the recently characterized Th17 cell has led to the development of the IL-12/23 inhibitor ustekinumab⁶⁶. Ustekinumab is a human IgG1 antibody, which specifically targets the shared p40 subunit of IL-12 and IL-23⁶⁷. Although it has not yet been approved by the US FDA (as of this writing), ustekinumab (also known as CANTO 1275) has been studied in psoriasis, psoriatic arthritis, Crohn's disease, and multiple sclerosis^{68–72}.

Efficacy

Psoriasis

The safety and efficacy of ustekinumab for use in moderate to severe plaque psoriasis was evaluated in the PHEONIX 1 trial, a Phase III, double-blind, randomized, placebo-controlled, multicenter study ($n=766$)⁷³. Approximately half of the subjects had tried biologics (TNF inhibitors) before the study. Subjects received either 45 or 90 mg of ustekinumab at weeks 0, 4, and then every 12 weeks; placebo patients underwent crossover after the first two placebo doses (weeks 0 and 4) with subsequent treatment with either 45 or 90 mg of ustekinumab. At 12 and 28 weeks, 67.1% and 71.2%, respectively, of the 45 mg group reached PASI 75; the 90 mg group showed similar response at week 12 (66.4%) and, like the 45 mg group, continued to improve at week 28 (78.6%). The PHEONIX 2 study, also a multicenter, randomized, placebo-controlled, Phase III study evaluating the use of ustekinumab in moderate to severe plaque psoriasis, showed very similar results to PHEONIX 1⁷⁴.

Follow-up studies for both PHEONIX 1 and 2 evaluated how ustekinumab treatment affects health-related quality of life (HRQoL) in psoriasis. In the PHEONIX 1 study, HRQoL was assessed by the DLQI (Dermatology Life

Quality Index) and SF-36 tools. Significant improvements in both the DLQI and SF-36 were noted at week 12 in the ustekinumab groups and were sustained at least through 1 year of maintenance therapy. Interestingly the improvements in SF-36 were no longer significant if adjusted for PASI and physicians general assessment (PGA) scores, which may indicate how directly quality of life in psoriasis is impacted by the physical manifestations of disease. In the PHEONIX 2 study, the Hospital Anxiety and Depression Scale in addition to the DLQI were evaluated. Similar to the PHEONIX 1 data, the DLQI outcomes in PHEONIX 2 showed significant improvement at week 12 compared to placebo and correlated well with PASI scores. At 12 weeks, a smaller proportion of ustekinumab-treated subjects experienced symptoms of mild to severe anxiety and depression versus baseline, whereas the placebo groups demonstrated an increase over the same time interval.

A head to head comparison trial of ustekinumab versus etanercept for the treatment of moderate to severe plaque psoriasis ($n=903$) demonstrated improved PASI 75 and PGA scores over a 12 week period. In this multicenter, investigator-only blinded study, subjects were randomized to receive either ustekinumab (45 or 90 mg monthly injections) or high-dose etanercept (50 mg twice weekly) for 12 weeks. At week 12, PASI 75 scores for ustekinumab 45 mg, ustekinumab 90 mg, and etanercept were 67.5, 73.8, and 56.8%, respectively. The percentage of subjects achieving PGA scores of clear or minimal disease at week 12 for these respective groups, were 65.1%, 70.6%, and 49%. After 12 weeks, the etanercept group was crossed-over to receive higher-dose (90 mg monthly) ustekinumab. Of the etanercept nonresponders at 12 weeks (PGA ≥ 3), 48.9% achieved PASI 75 after cross-over to 90 mg monthly ustekinumab.

In addition to psoriasis, ustekinumab has been shown to effectively treat psoriatic arthritis in a Phase II multi-site, double-blind, placebo-controlled, randomized cross-over study ($n=146$)⁷². At 12 weeks, 42% of subjects treated with either 90 mg or 63 mg of ustekinumab weekly for 4 weeks achieved the ACR20, whereas only 14% of the placebo-treated group reached this same cut-off. Furthermore, the improvement in joint disease was durable in that about three-quarters of those who met ACR20 at week 12 still met these criteria at 36 weeks, 33 weeks after the last ustekinumab injection. In addition to the arthritis outcomes, significant improvements in PASI 75 and DLQI scores were also noted in the treatment group at 12 weeks.

Safety

The most commonly reported adverse events in the PHEONIX 1 and 2 studies include the following: respiratory tract infection, nasopharyngitis, headache, and arthralgia. Several serious infections were reported in the treatment groups (herpes zoster, lower extremity cellulitis, "viral

syndrome", osteomyelitis in a diabetic with a foot ulcer, gastroenteritis, appendicitis, and diverticulitis). No significant laboratory abnormalities were noted. Several new malignancies were noted during the study period, including lentigo maligna, breast cancer, transitional cell carcinoma, prostate, thyroid, colon cancer, squamous cell carcinoma of the tongue. Cardiac disorders, including angina and coronary artery disease, were also included in the list of serious adverse events reported. Antibodies to ustekinumab developed in approximately 5% of patients by week 76.

A double-blind, randomized, placebo controlled, cross-over study investigated the use of ustekinumab in psoriatic arthritis ($n=146$)⁽⁷²⁾. Safety data from this study indicates that infections and striking abnormalities in hematologic and chemistry tests were similar in the placebo and drug treatment groups up to week 12. Several serious adverse events in ustekinumab treated subjects were reported: syncope, respiratory-tract infection, hemorrhage, stroke, congestive heart failure/myocardial infarction/hypertension, chest pain, gastric ulcer hemorrhage, and abdominal pain/back pain.

ALEFACEPT: LFA-3/CD-2 T-CELL ACTIVATION

Alefacept is a human LFA-3 fusion protein which inhibits antigen-presenting cell-T-cell interactions and causes antibody-dependent T-cell cytotoxicity^{66,75}. This dimeric fusion protein consists of the extracellular CD-2-binding portion of LFA-3 (leukocyte function antigen-3) linked to the Fc portion of human IgG1⁷⁵. By binding to CD2 on T cells, alefacept blocks the costimulatory signal for CD45RO+ memory effector T cell activation. Activated T cells populations are depleted as well because the Fc portion of alefacept enables natural killer cell recognition (via the FcR).

Dosing

Although alefacept has been evaluated both for intravenous and intramuscular (IM) administration, current product labeling recommends once weekly IM injections for 12 consecutive weeks⁷⁵. A repeat course can be administered, provided T-cell counts are stable and the medication is otherwise being tolerated.

Efficacy

The main dermatologic use of alefacept is for psoriasis.

Psoriasis

Alefacept was the first biologic drug treatment developed specifically for a dermatologic disease⁶⁶. Alefacept and efalizumab (withdrawn from the US market because of safety concerns) were designed to specifically affect the T-cell

arm of psoriasis pathogenesis. Efficacy in comparison to the TNF inhibitors is likely reduced, although long-term comparisons are difficult to make because of study design and preferential short-term follow-up³³. A multicenter, Phase III, placebo-controlled, randomized, double-blind study investigating the use of IM alefacept (either 10 mg or 15 mg once weekly for 12 consecutive weeks), demonstrated efficacy in moderate to severe chronic plaque psoriasis ($n=507$)⁷⁶. PASI scores continued to improve after the 12-week treatment phase, likely a result of prolonged pathogenic T-cell depletion. Throughout this study, 33% and 28% of the 15 mg and 10 mg groups, respectively, achieved PASI 75.

The combination of narrow band UVB and alefacept for psoriasis has been promoted in several studies⁷⁷⁻⁷⁹. Nonetheless, the added value of nbUVB cannot properly be assessed given the lack of large properly controlled studies.

Alefacept has also been evaluated for palmoplantar pustular (30 mg/week)⁽⁸⁰⁾, scalp⁸¹, and nail⁸² psoriasis. Despite reported improvements, these were open-label, uncontrolled studies; more rigorous studies are required before definitive claims of efficacy can be made. Other off-label uses include alopecia areata and lichen planus⁸³.

Other Diseases

Pyoderma Gangrenosum has also been reported to respond to alefacept in one open-label study⁸⁴. A double-blind, randomized, placebo-controlled study ($n=45$) demonstrated no efficacy for alefacept in the treatment of chronic and severe alopecia areata for more than 12 weeks.

Safety

A pooled analysis of 13 alefacept trials ($n=1869$, 2589 person-years of treatment) characterized the most likely side effects, which include the following: headache, upper respiratory tract infection, influenza, and pruritus⁸⁵. In this same analysis, no cases of opportunistic infection, tuberculosis, or deaths related to infection were reported. Similar to the rate of serious infections, the malignancy risk does not appear to be elevated beyond baseline⁸⁶. One of the major considerations of therapy is the risk of dose-dependent reductions in circulating CD4+ and CD8+ T-cells during therapy⁷⁵. The product insert recommends checking T-cell counts every 2 weeks during the treatment stage and withholding further treatment if the CD4+ T-cell count drops below 250 cells/ μ L. Nonetheless, in the systemic review by Goffe et al. the infection rate did not correlate with reduced circulating CD4+ T-cells⁸⁵).

ANTI-B-CELL THERAPIES

Rituximab is a CD-20 specific monoclonal humanized antibody which targets pre-B and mature B lymphocytes⁸⁷. It is

currently approved by the US FDA for treatment of rheumatoid arthritis and Non-Hodgkin's Lymphoma (NHL), but it has been used in a variety of dermatologic conditions⁸⁸. Nonetheless, no randomized, double-blind studies of rituximab exist for these off-label uses.

Dosing

Rituximab is administered as an intravenous infusion. The off-label uses of rituximab in dermatology have generally followed the NHL dosing, which is 375 mg/m². The frequency and duration of treatment varies widely. The approved dosing for rheumatoid arthritis is two separate 1000 mg infusions administered 2 weeks apart in combination with methotrexate. The initial infusion rate is generally initiated at 50 mg/hour. If the patient is tolerating the infusion well, the rate can be increased 50 mg/hour each 30 minutes up to a maximum of 400 mg/hour. Subsequent infusions can initiate and proceed at faster rates⁸⁷.

Efficacy

The most well studied off-label dermatologic uses of rituximab include the treatment of pemphigus vulgaris (PV) and other autoimmune blistering diseases.

Despite the lack of rigorously controlled large studies, it is evident that rituximab can improve PV and even induce long-lasting remissions. Several different treatment algorithms have been proposed in treating PV. Ahmed et al. published a series of 11 patients with pemphigus vulgaris with greater than 30% body surface area involvement⁸⁹. Patients were initially administered 2 cycles of rituximab (375 mg/m²) once a week for 3 weeks along with intravenous globulin (IVIG, 2 g/kg) on the fourth week; once monthly IVIG and rituximab was then administered for the 4 subsequent months. Sustained remission was noted in 9 of 11 patients with a mean of 31.1 months. Anti-desmoglein autoantibodies decreased after rituximab therapy in the nine patients with durable response, an important finding which has been repeated in other studies as well⁹⁰. Deletion of autoreactive B cells with subsequent down-regulation of desmoglein-specific CD4+ T-cells has been implicated in the ultimate response to therapy⁹⁰. Another study by Joly et al. reported the use of once weekly rituximab (375 mg/m²) for 4 consecutive weeks in 21 patients; 18 patients (86%) were disease-free at 34 months, eight of whom were weaned completely from corticosteroids⁹¹.

Good clinical outcomes have been reported in pemphigus foliaceus, paraneoplastic pemphigus, bullous pemphigoid, and epidermolysis bullosa acquisita (EBA); importantly, several deaths from severe bacterial, viral, and fungal infections have been reported in these patient populations⁹². A recent review of 71 patients with PV, pemphigus vegetans, EBA, paraneoplastic pemphigus, pemphigus foliaceus, and combined bullous pemphigoid and GVHD

showed complete or partial response to rituximab in 94% of patients⁹³.

Numerous studies report marked improvement, including clearance, of primary cutaneous B-cell lymphoma after treatment with rituximab^{94,95}. The European Organization for Research and Treatment of Cancer and the International Society for Cutaneous Lymphoma consensus recommendations for management of cutaneous B-cell lymphomas includes rituximab (intravenous and intralesional) as first line treatment option for primary cutaneous follicular cell lymphoma and diffuse large cell lymphoma, leg type, particularly if the patient has very extensive skin lesions⁹⁶.

Several retrospective and prospective case series published support the use of rituximab in steroid-refractory chronic graft versus host disease⁹⁷. Small studies or case reports show improvement with rituximab in atopic dermatitis ($n=6$)⁹⁸, cutaneous lupus erythematosus (including SCLE⁹⁹, lupus profundus¹⁰⁰, and cutaneous manifestations of SLE¹⁰¹), and cutaneous vasculitis¹⁰². Although case reports show benefit of treating dermatomyositis with rituximab, an open label trial evaluating both muscle and skin symptoms ($n=8$) showed no significant difference in outcomes at 24 weeks¹⁰³.

Safety

Most reported safety data for rituximab pertains to patients treated for systemic lymphoma, either as mono- or combination therapy. In non-Hodgkin lymphoma (NHL) patients, the most common adverse reaction is the infusion reaction. A type-1 hypersensitivity-like reaction including hypotension, urticaria, and bronchospasm may occur within the first 30 to 120 minutes of treatment; supportive measures and either slowed or interrupted infusion is recommended⁸⁷. Similar reactions have been seen in rheumatoid arthritis (RA) patients as well. Serious infections may occur at increased frequency during treatment. Although these occurred fewer than 5% and 2% in NHL and RA patients, respectively, signs, and symptoms of infection should be sought out and managed proactively⁸⁷. A review of pemphigus patients treated with rituximab also indicated an increased risk of infection during treatment, although many were prescribed additional immunosuppressants⁹². A separate review of 71 patients with autoimmune blistering disease identified six patient deaths, four of whom were treated for paraneoplastic pemphigus, one with PV, and another with a combination of bullous pemphigoid and GVHD; most of these deaths were attributed to sepsis, congestive heart failure, or pneumonia⁹³.

A major concern of rituximab remains the potential risk of developing progressive multifocal leukoencephalopathy (PML), a deadly brain infection caused by the JC virus. Although causation remains unproven, the US FDA has issued several warnings regarding the risk of infection and death¹⁰⁴. Physicians supervising therapy with rituximab should monitor for progressive and gradual

impairments in speech, vision, motor function, and overall cognition¹⁰⁴.

Intravenous immunoglobulin (IVIG) coadministration, in addition to facilitating disease improvement, may also be necessary to help reduce infectious complications⁹². In the previously mentioned review of 71 patients treated with rituximab for autoimmune blistering disease, none of the six who died were treated with concomitant IVIG⁹³.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin, comprised of pooled polyclonal IgG derived from the human blood donor serum, is not approved for any dermatologic condition. Nonetheless, it has been used off-label in a variety of disorders. Despite the use in dermatology and other disciplines of medicine, its precise mechanism of action is unknown; potential mechanisms providing benefit in autoimmune and other disease is discussed in a recent review¹⁰⁵.

Efficacy

Autoimmune Diseases

Interestingly, IVIG works well in the short-term management of autoantibody diseases including autoimmune blistering disease and the ANCA vasculitides. As discussed above, IVIG has been shown to work well, in conjunction with rituximab, in the treatment of pemphigus vulgaris. A recently completed randomized, double-blind, placebo-controlled study evaluated the treatment with one cycle of IVIG in patients with either pemphigus vulgaris or foliaceus ($n=61$)¹⁰⁶. At baseline, patients were unable to lower the oral daily prednisone dose below 20 mg and 10-35% of patients were on concomitant immunosuppressants. The time to escape from protocol (defined as increasing the steroid dose or supplementation with another immunosuppressant) was significantly longer in the 400 mg/kg/day group than placebo. Pemphigus activity scores and IgG autoantibody titers to desmoglein 1 and 3 were lower after 85 days of follow-up in both treatment groups (200 or 400 mg/kg/day \times 5 days). Given the short follow-up, long-term outcomes are unclear. This data is further supported by the initial work of Ahmed, who reported the use of successive cycles of IVIG in patients with oral and cutaneous pemphigus vulgaris and foliaceus^{107,108}.

Successful treatment of other autoimmune blistering disorders with IVIG, including bullous pemphigoid (BP), have also been reported¹⁰⁹. In this study, 15 subjects with refractory severe BP were prospectively treated with repeated cycles of 2 g/kg IVIG. The interval between cycles was set at 4 weeks initially and spaced out to 16 weeks before termination of therapy (upon clearance). The total number of cycles ranged from 10 to 18. After discontinuing IVIG therapy, patients were followed for a mean of 20 months without relapse or recurrence of pemphigus or serious long-term side effects from IVIG.

Vasculitis

Intravenous immunoglobulin is beneficial in the short-term management of various autoantibody driven diseases. Limited data support the use of IVIG in ANCA vasculitis, including Wegner's, microscopic polyangiitis, and Churg-Strauss. Good data, including randomized-controlled trials, indicate that IVIG can eliminate fever in the vast majority of patients with Kawasaki disease and reduces the risk of coronary artery aneurysm¹¹⁰.

Although a mortality benefit was previously described in high-dose IVIG-treated toxic epidermal necrolysis (TEN) patients, subsequent data are inconclusive. An initial noncontrolled, retrospective, multicenter study of IVIG in TEN showed a mortality of only 12%¹¹¹. The proposed mechanism of action is that IVIG blocks Fas-Fas-ligand-induced epidermal apoptosis cascade. A retrospective analysis of 281 patients with Stevens-Johnson syndrome/TEN was completed as part of the EuroSCAR study¹¹². Neither IVIG nor corticosteroids were found to have any mortality benefit.

Safety

Thromboembolic complications, including deep venous thrombosis, myocardial infarction, and ischemic stroke, may occur in up to 13% of IVIG-treated patients¹¹³. Renal insufficiency, aseptic meningitis, congestive heart failure, and hemolytic anemia, may be induced as well with therapy^{9,114,115}. IgA-deficient individuals who produce anti-IgA antibodies may experience anaphylaxis when administered IVIG¹¹⁴. Serum immunoglobulin classes should be evaluated in advance of treatment to safeguard against this life-threatening complication. Patients should also be prescreened for infectious hepatitis and HIV. Baseline evaluation including renal and liver function tests, complete blood count, rheumatoid factor, and cryoglobulins is also recommended¹¹⁴.

DENILEUKIN DIFTITOX

Denileukin diftitox is a recombinant fusion protein, which combines active diphtheria toxin with the membrane translocation domain of IL-2¹¹⁶. Cells that express the IL-2 receptor are selectively targeted for cell death. Denileukin diftitox is approved by the FDA for the treatment of persistent or refractory cutaneous T-cell lymphoma (CTCL) whose malignant cells express the CD-25 component of the IL-2 receptor¹¹⁷.

Efficacy

Denileukin diftitox was assessed in a Phase III study ($n=71$) for the treatment of stage Ib-III CTCL (Cooperative Group Staging; patients with greater than 10% body surface area excluding visceral involvement). Subjects had failed at least

one prior therapy and at least 20% of lymphocytes in the skin had to stain positively for CD-25 on immunohistochemistry. The study dosing included two randomized groups of 9 or 18 µg/kg/d and administered for 5 consecutive days approximately every 3 weeks. Thirty percent of subjects experienced subjective response and 10% achieved either complete pathologic or clinical response.

Safety

Denileukin diftitox is administered through intravenous infusion. Approved dosing is 9 or 18 mcg/kg/day over 30 to 60 minutes for 5 continuous days every 3 weeks for 8 total cycles¹¹⁷. Infusion reactions, including fever, nausea, rigors, vomiting, diarrhea, and pruritus, occur commonly, especially during the initial two infusions; rare post-marketing reports of death after infusion have been reported. Capillary leak syndrome may occur at any point during therapy and has been reported to occur in up to 32.5% of patients. To reduce likelihood of developing capillary leak syndrome, serum albumin levels should be monitored and treatment withheld if lower than 3 g/dL. Loss of visual acuity and color vision has been reported as well.

ABATACEPT

Abatacept is a soluble fusion protein, which inhibits T-cell costimulation. This protein links the extracellular domain of CTLA-4 (cytotoxic T-lymphocyte-associated antigen 4) with a modified Fc portion of human IgG1. The CTLA-4 region binds CD80 (B7-1) and CD86 (B7-2) on antigen presenting cells, thus blocking the CD28 driven co-stimulatory activation of T-cells¹¹⁸. Abatacept is approved for juvenile idiopathic arthritis and rheumatoid arthritis. Limited data support the use of abatacept in psoriasis.

Efficacy

A Phase I dose-escalation study evaluating the use of abatacept in a cohort of chronic plaque psoriasis in patients ($n=43$) with 10-49% body surface area has been conducted¹¹⁹. One hour infusions were given on days 1 and 3 and then at weeks 3 and 5, with doses ranging from 0.5 to 50 mg/kg. Forty six percent of subjects demonstrated a 50% or greater improvement in their Physician's Global Assessment of disease activity.

Safety

Abatacept is administered as an intravenous infusion. As with other infusions, hypersensitivity, anaphylaxis, and anaphylactoid reactions may rarely occur¹¹⁸. Coadministration with a TNF-inhibitor may increase the risk for infection and should be avoided. Pretreatment screening for TB is recommended. Avoidance of live

vaccines is recommended during treatment and up to 3 months after discontinuation. The rates of both lung cancer and lymphoma may be elevated in patients who undergo therapy with abatacept¹¹⁸. In the Phase I study of psoriasis patients mentioned above, the most common adverse events were uncomplicated respiratory tract infection (16%) and transient headache (16%)¹¹⁹.

OMALIZUMAB

Omalizumab is a humanized monoclonal IgG1κ antibody which binds to human IgE¹²⁰. Treatment can lower IgE levels and prevent IgE-mediated inflammatory pathways, including mast and basophil cell activation¹⁰. It is currently approved by the US Food and Drug Administration for treatment of moderate to severe persistent asthma. Approved dosing is 150 to 375 mg administered subcutaneously every 2 to 4 weeks¹²⁰.

Efficacy

Several case series have evaluated the use of omalizumab in atopic dermatitis¹⁰. One study of 3 adults with severe atopic dermatitis treated with omalizumab showed no improvement after twice monthly injection of 450 mg for 4 months¹²¹. In contrast, 100% (3/3) of pediatric patients with atopic dermatitis showed improvement during treatment at doses up to 450 mg every other week¹²². Importantly, these children were all shown to have positive radioallergosorbent testing reaction to aeroallergens; none of the three adults in the former study were demonstrated to have positive radioallergosorbent testing. Furthermore, treatment in the pediatric study was supplemented by topical corticosteroids, topical calcineurin inhibitors, oral mast cell stabilizers, and oral antihistamines. More rigorous studies are required before omalizumab therapy can be recommended for atopic dermatitis.

Improvement in a patient with solar urticaria and another with cholinergic urticaria has been reported after treatment with omalizumab^{123,124}. Clinical trials are ongoing to evaluate the use of omalizumab in bullous pemphigoid and chronic idiopathic urticaria¹²⁵.

Safety

Anaphylaxis, in some cases life-threatening, has been reported after administration of omalizumab in up to 0.2% of patients (based on postmarketing surveillance)¹²⁰. Otherwise, omalizumab appears to be a relatively safe and well-tolerated drug. The most commonly reported adverse events include injection site reactions (45%), viral infections (23%), upper respiratory tract infection (20%), sinusitis (16%), headache (15%), and pharyngitis (11%)¹²⁰. Malignant neoplasms have been observed in 0.5% of omalizumab patients compared with 0.2% of controls in studies of asthma or allergic disorder patients¹²⁰.

What We Know

- Biologic medications are an increasingly important and powerful treatment option in dermatology.
- Biologics for psoriasis offer the hope for safe and effective long-term maintenance of clearance.
- Data support the off-label use of TNF-alpha inhibitors in a variety of dermatoses, including hidradenitis suppurativa, granulomatous diseases, and neutrophilic disorders.
- Biologics blocking IL-12/IL-23 are highly effective in psoriasis and may also be effective in psoriatic arthritis.
- Rituximab/IVIG are useful in recalcitrant autoimmune blistering disorders.
- Biologics may be useful in the treatment of cutaneous lymphoma, systemic and cutaneous vasculitis, severe refractory atopic dermatitis, and many other disease entities.

Topical Immunomodulators

63

Marta Grazzini, M.D., Riccardo Rossi, M.D., and Torello Lotti, M.D.

INTRODUCTION

The advent of new topical agents such as topical calcineurin inhibitors (TCIs) has broadened the range of drugs available to dermatologic diseases. This increase in therapeutic choices offers clinicians an array of more physiologic pathways and mechanisms of action through which treatment can be accomplished and more options for combination therapies. The most rational approach to utilize when deciding which agents to combine in a multidrug regimen is to consider the mechanisms of action of the drug categories commonly used to treat skin disease. These classes include topical corticosteroids, vitamin D₃ analogs, Retinoids, and TCIs. In this chapter, we will cover topical immunomodulator, focusing in particular on the most commonly used ones: tacrolimus and pimecrolimus; sirolimus will be mentioned too.

The US Food and Drug Administration (FDA) approved pimecrolimus in December 2001 as a short-term and intermittent long-term therapy for mild to moderate atopic dermatitis. In January 2006, the prescribing information and indication were revised because of the report of cases of skin malignancy in patients using pimecrolimus cream 1. Nowadays pimecrolimus is indicated as second-line therapy for the short-term and noncontinuous chronic treatment of mild to moderate atopic dermatitis in adults and children aged 2+ years who do not respond to other treatments or for those for whom the use of those treatments is not advisable¹.

Tacrolimus, initially named FK506², was isolated in 1987 from a product of *Streptomyces tsukubaensis*. It is a macrolide lactone produced for the prevention of organ rejection after an allogenic liver or kidney transplant. Topical tacrolimus was introduced in 1999 in Japan, and then in the United States in December 2000 for the short-term and noncontinuous treatment of moderate to severe atopic dermatitis. In March 2005, the FDA issued an alert to health care professionals, advising them to use tacrolimus as well as pimecrolimus, only as directed and only after other eczema treatments had failed, because of possible cancer risk.³

Sirolimus, also known as rapamycin⁴, is a macrocyclic lactone produced by the organism *Streptomyces hygroscopicus*. It was originally identified as an antifungal agent but was later found to have potent immunosuppressive

activity. For this reason, it was initially used as an immunosuppressive drug in transplant patients. Sirolimus shares a homology with tacrolimus, and acts through the specific binding of a family of cytosolic immunophilins known as FK-binding proteins (FKBP). However, the sirolimus-FKBP complex does not act on the nuclear factor of activated T cells or on calcineurin in the manner of tacrolimus⁵.

MECHANISM OF ACTION AND PHARMACOKINETICS

The actions of Tacrolimus and Pimecrolimus likely are similar (Table 63-1). They are both complex macrocyclic compounds that bind to the intracellular protein macrophilin-12 (FK506-binding proteins) and function as macrolactam immunomodulators, thereby inhibiting the activity of the calcineurin.

The therapeutic effects of tacrolimus and pimecrolimus are related to the activation of T lymphocytes. The typical interaction of the antigen with the T-lymphocyte receptor determines an increase of calcium in the cytosol that forms complex with the calcium-binding protein, calmodulin, which then activates calcineurin. When calcineurin is activated it catalyzes the dephosphorylation of a number of substrates, including N phosphorylated NF-AT (NF-AT) that are supposed to go to the nucleus to regulate the genes transcription.

TABLE 63-1—Topical Pimecrolimus and Tacrolimus: Comparison Between the Two Drugs in Terms of Mechanism of Action and Pharmacokinetics¹⁴

	Pimecrolimus	Tacrolimus
Principal Cellular targets	T cells, mast cells	T cells, mast cells
Cytokines inhibited	IL-2, IL-3, IL-4, IL-5, IFN- γ , TNF- α	IL-2, IL-3, IL-4, IL-5, IFN- γ , TNF- α
Blockade of dendritic cell functions	+	-
Apoptosis of dendritic cells	+	-
Skin penetration	+	++

Tacrolimus can prevent this signaling through the production of a complex with macrophilin-12 and calcium-calmodulin. This complex inhibits calcineurin activity, thereby preventing the dephosphorylation of NF-AT and inhibiting its ability to regulate the transcription of genes.

Tacrolimus can suppress the transcription of a number of genes, that produce interleukin-2 (IL-2), interleukin-3 (IL-3), interleukin-4 (IL-4), interleukin-5 (IL-5), interleukin-12 (IL-12), interferon-gamma (IFN- γ), tumor necrosis factor-alpha (TNF-a), and granulocyte-macrophage colony-stimulating factor (GMCSF), which are relevant in the pathophysiology of several skin disease including atopic dermatitis, vitiligo and psoriasis⁶. As far as pharmacokinetics is concerned, during the clinical development program, systemic exposure to topically applied pimecrolimus and tacrolimus was investigated in short-term and long-term studies to assess systemic percutaneous absorption of topically applied drugs.

The results of these studies⁷ demonstrate that treatment with pimecrolimus cream 1% results in minimal systemic exposure to pimecrolimus during treatment for up to 1 year. The highest pimecrolimus blood concentrations measured in adults was 4.6 ng/mL, while in pediatric patients was 2.6 ng/mL. These levels were lower than the mean peak concentration found in adult psoriatic patients treated for 28 days with a well-tolerated oral dose of 30 mg pimecrolimus twice daily.

Tacrolimus is largely metabolized in the liver by the cytochrome P450 enzyme system via monodemethylation and/or hydroxylation. The drug is then excreted through the bile, which displays most of its metabolites. Less than 1% of the drug is excreted unchanged in the urine.

Sirolimus, like tacrolimus, and pimecrolimus, is a potent inhibitor of T-cell activation, but its mechanism of action is different. Sirolimus inhibits the IL-2 receptor-mediated signal transduction pathway with no effect on calcineurin activity. Instead, the FKBP12/sirolimus complex binds to and inhibits the kinase activity of mTOR, a central kinase that transduces signals from the IL-2 receptor and other growth factor receptors to cell cycle regulators, including p70S6 kinase. TOR proteins play a crucial role in coordinating the equilibrium between protein synthesis and breakdown in response to nutrient availability. Essentially, TOR proteins act on downstream proteins responsible for controlling translation of mRNAs encoding proteins that regulate the cell cycle⁸. These include translation inhibitors, eukaryotic translation initiators (eIF4GI) and ribosomal S6 kinases (S6Ks). A noncytotoxic dose of sirolimus inhibits primary and metastatic tumor growth by interfering with angiogenesis. It induces a decrease in the production of vascular endothelial growth factor (VEGF) and blocks stimulation of vascular endothelial cells by VEGF. This may also be relevant to its mechanism of action in psoriasis, as angiogenic factors are important to the development of disease. Therefore, it can be expected that sirolimus will have a different safety profile, without nephrotoxicity,

neurotoxicity, or hypertension. Preclinical in vitro and in vivo studies have demonstrated that combination treatments of topical sirolimus and oral cyclosporin can result in a synergistic effect and the reason for this is because the two drugs are active in different steps of the cell-mediated immune response.

ANIMAL MODELS: EFFECTIVE AND SAFETY

Sirolimus, pimecrolimus and tacrolimus have been tested in numerous animal studies designed expressly to further explore the toxicity of the molecule and increase drug exposure to observe toxic effects.

Animal models have also been studied in order to evaluate the effectiveness of topical pimecrolimus and tacrolimus. Meingassner et al.^{9,10} made several investigations of allergic contact dermatitis in mouse, rat, and pig models in which topical calcineurin inhibitors showed a very high level of activity. In pig models, a statistically significant anti-inflammatory effect was observed at concentrations as low as 0.04%. Pimecrolimus had no effect on skin texture or thickness and showed an overall effectiveness close to that of potent corticosteroids for the treatment of autoimmune skin disease¹¹.

Neckermann et al.¹² studied the effectiveness of systemic and topical pimecrolimus on hypomagnesemic hairless rats compared to its vehicle. The use of topical pimecrolimus was effective with suppression of the inflammation in five rats treated but at the concentration used in this study, it did not appear to have a systemic effect.

In dermal carcinogenicity studies related to lymphomas performed on mice, systemic immunosuppression was only observed in the mice treated with a high systemic exposure to pimecrolimus.¹³ No evidence of lymphoma was observed until systemic exposure to the drug was 66 times the average systemic exposure measured at the maximum recommended dose of topical pimecrolimus in humans. Concerning tacrolimus, no evidence of lymphoma was observed in analogous murine toxicology studies until systemic exposure to the drug was 26 times the average systemic exposure at the maximum recommended dose of topical tacrolimus estimated from human studies.

In animal models and in humans sirolimus has shown a relevant immunosuppressive activity in a number of diseases. In a murine model of tetradecanoylphorbol acetate-induced ear edema, sirolimus inhibited the edematous response in a dose-dependent manner. In addition, neutrophil infiltration and epidermal influx were significantly inhibited in this model. Sirolimus has been demonstrated to reduce keratinocyte proliferation in a dose-dependent manner. As the proliferative state of keratinocytes and neutrophil infiltration of the epidermis are characteristics of psoriasis, these studies suggest that sirolimus might have a role in the treatment of psoriasis. Topical application of 1.2% sirolimus in a pigskin model of allergic contact dermatitis was ineffective.

TABLE 63-2—Efficacy of Topical Pimecrolimus and Tacrolimus in Inflammatory Skin Diseases

	Pimecrolimus	Tacrolimus	Sirolimus
Atopic Dermatitis	Established efficacy	Established efficacy	-
Vitiligo	Likely beneficial	Likely beneficial	-
Psoriasis	Established efficacy (intertriginous psoriasis)	Established efficacy (intertriginous psoriasis)	Likely beneficial
Seborrheic Dermatitis	Likely beneficial	Likely beneficial	-
Lupus Erythematosus	Likely beneficial	Likely beneficial	-
Alopecia Areata	Possibly beneficial	Possibly beneficial	-
Oral Lichen Planus	Likely beneficial	Likely beneficial	-
Pyoderma gangrenosum	Possibly beneficial	Possibly beneficial	-
Chronic Hand Dermatitis	Possibly beneficial	Possibly beneficial	-
Chronic actinic dermatitis	Possibly beneficial	Possibly beneficial	-
Ichthyosis linearis circumflexa	Possibly beneficial	Possibly beneficial	-

Established efficacy: High-quality meta-analyses, systematic reviews of randomized-controlled trials with a very low risk of bias.

Likely beneficial: Case-control or cohort studies with a high risk of confounding.

Possibly beneficial: Nonanalytic studies.

Topical application of up to 2% sirolimus ointment was ineffective also in a guinea-pig contact dermatitis model, although suppression of keratinocyte proliferation was observed⁹

EFFICACY

Efficacy of tacrolimus, pimecrolimus, and sirolimus has been evaluated in atopic dermatitis, vitiligo, psoriasis, and other skin disease including seborrheic dermatitis, lupus erythematosus, alopecia areata, and others (Table 63-2).

ATOPIC DERMATITIS

Atopic dermatitis (AD) is the most common inflammatory skin disease in children, affecting more than 15% of children in the United States.

Several clinical trials showed efficacy and safety of pimecrolimus in treatment of AD^{14–16}. AD improved after a few days of twice-daily topical application of pimecrolimus and multiple clinical trials have demonstrated an improvement of the eczema area severity index (EASI). The treated patients also showed a significant decrease in the number and severity of flares and a lower dependence on corticosteroids in infants as young as 3 months with atopic dermatitis.

In two independent 6-week randomized-controlled trials, treatment with pimecrolimus 1% cream twice daily significantly decreased the symptoms of AD in children, as well as adolescents as compared to its emollient vehicle. At week 6, 35% of pimecrolimus-treated patients were classified as clear or almost clear of disease according to the investigator global assessment (IGA). The drug showed

a rapid onset of action, with therapeutic effects observed by day 8 and further improvement thereafter¹⁷. The baseline disease severity had no effect on treatment outcome¹⁸. Hanifin et al.¹⁹ reported an improvement of the diseases in children and adults affected by AD treated with topical tacrolimus. A marked reduction in pruritus was seen within 3 days of therapy. Hanifin et al. concluded that tacrolimus ointment therapy is a rapidly effective and safe treatment for the management of atopic dermatitis in both pediatric and adult patients who were followed for up to 4 years.

A randomized-controlled trial compared pimecrolimus cream 1% with tacrolimus ointment 0.03% in pediatric patients with moderate to severe AD. 170 patients (2–17 years) were enrolled into two groups (pimecrolimus vs. tacrolimus). The therapies were applied twice daily until complete clearance of disease or until week 6. As far as efficacy was concerned, there were no statistically significant differences in terms of efficacy between the treatment groups in the proportion of patients achieving clinical success. However, IgA response rates resulted slightly higher in the tacrolimus group²⁰.

VITILIGO

Different treatment options for vitiligo are available. Calcineurin inhibitors seem to represent a useful alternative for vitiligo in particular for locations on the head and neck. The use of Pimecrolimus allows the dermatologist also to avoid the side effects of currently available therapeutic options such as topical steroids. Calcineurin inhibitors can be used alone or in combination treatment.

The additional use of UVB-narrow band phototherapy increases the efficacy of calcineurin inhibitors according

to our experience,²¹ but its long-term safety is no yet clear, in particular regarding the photo-carcinogenic effect. Ostovari et al.²² however, observed that there is a lack of efficacy of tacrolimus in the absence of UV-B exposure.

Grimes et al.²³ for the first time described the efficacy of tacrolimus in vitiligo while Lan et al.²⁴ reported that tacrolimus promotes melanocyte and melanoblast growth and creates a favorable milieu for cell migration via keratinocytes. Kanwar et al.²⁵ reported more than 75% repigmentation in 57.9% and 50% to 75% repigmentation in 26.3% of children treated with topical tacrolimus (0.3%) in vitiligo.

In a double-blind half-side trial comparing topical tacrolimus to clobetasol in 20 children with vitiligo, Lepe et al.²⁶ reported that the two agents were equally effective.

Long-term stability of repigmentation and efficacy of combination therapies among calcineurin inhibitors and other topical agents in vitiligo, however, remain to be further investigated.

PSORIASIS

Topical treatment of psoriasis is usually restricted to the mild form of the disease because the thick scaling seems to inhibit the drug's penetration into the skin. The use of calcineurin inhibitors in psoriasis treatments originated from the observation of seven psoriatic patients that were undergoing organ transplant and had been treated with systemic tacrolimus therapy. This treatment resulted in a dramatic improvement of psoriasis with complete remission in 4 weeks.

Several reports showed the efficacy of calcineurin inhibitors in plaque-type psoriasis.^{27–30} Recently, a task force of the National Psoriasis Foundation Medical Board was convened to evaluate treatment options for this disease³¹. This study group recommended low- to mid-potency topical steroids as first-line, short-term treatment. Calcipotriene (calcipotriol), pimecrolimus, and tacrolimus, for long-term therapy when it is possible.

Zonneveld et al.³² reported that topical tacrolimus instead is ineffective in chronic plaque psoriasis because of poor absorption.

A study³³ conducted using topical sirolimus on 24 patients for 6 weeks showed that topically applied sirolimus penetrates the skin and may have some antipsoriatic and immunosuppressive activity.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis (SD) is a chronic inflammatory disorder that mainly affects the seborrheic region. SD is a chronic relapsing skin disorder that presents with erythema, scaling, and pruritus.

While ketoconazole is often used, pimecrolimus has been used successfully in SD³⁴. The efficacy of pimecrolimus in the treatment of seborrheic dermatitis has been

compared with a potent corticosteroid in an open-label clinical trials and randomized trials.^{35–37} The efficacy of the two different treatments in reducing symptoms of the disease was approximately comparable, but relapses were observed more frequently and were more severe in the corticosteroid group than in the pimecrolimus. Moreover, Koc and colleagues showed that pimecrolimus had also a comparable efficacy profile to that of ketoconazole, but side effects appeared more frequently in the pimecrolimus group than in the ketoconazole group³⁴.

LICHEN PLANUS

Oral lichen planus (OLP) is considered an autoimmune disease of unknown etiology that affects the mucosae, especially the oral cavity. Existing clinical trials have shown that topical corticosteroids are often effective in the management of oral lichen planus. However, tacrolimus has recently been shown to be an effective treatment of OLP. Vente et al.³⁸ treated six patients with erosive oral lichen planus with 0.1% hydrophilic tacrolimus ointment and all reported rapid relief of pain and burning. Radfar et al. compared the effectiveness of clobetasol and tacrolimus in the topical management of OLP,³⁹ and they found tacrolimus to be as useful as clobetasol in the treatment of OLP.

A number of other studies demonstrated the utility of tacrolimus 0.1% and pimecrolimus for the treatment of OLP.^{40–47} Moreover, Donovan et al.⁴⁸ successfully treated the refractory oral lichen planus associated with hepatitis C with tacrolimus.

A recent group case report⁴⁹ conducted in seven patients affected by erosive oral lichen planus, showed good activity of sirolimus in the treatment of this disease with negligible absorption and side effects.

OTHER SKIN DISEASES

There is a long list of small series and case reports documenting the use of pimecrolimus and tacrolimus in various inflammatory skin conditions that warrant further validation.

A few number of clinical trials^{50,51} have shown the potential efficacy of pimecrolimus and tacrolimus in lupus erythematosus where, however, the gold standard of topical treatment remains the high-potency corticosteroid. In our experience, calcineurin inhibitors represent an excellent alternative for treatment of lupus erythematosus where local corticosteroids are contraindicated.

Thiers⁵² tried topical tacrolimus 0.3% in a boy with alopecia areata who subsequently progressed to alopecia totalis. We suppose that the failure of the treatment (in two single cases) relates to an insufficient penetration of the ointment formulation in skin. Since then, however, several animal studies^{53,54} have been performed regarding this concept without consistent result.

Tacrolimus has been suggested for the ulcers of pyoderma gangrenosum.⁵⁵ Reich et al.⁵⁶ successfully treated such lesions with 0.1% tacrolimus ointment twice daily, obtaining clearance within 3 weeks. Marzano et al.⁵⁷ suggested that topical tacrolimus monotherapy could represent a first-line treatment for PG that fulfills the following criteria: localized disease, idiopathic form, and recent onset with negative microbiologic tests on PG lesions.

In an open label study,⁵⁸ performed in patients affected by chronic hand dermatitis, pimecrolimus induced a complete or almost complete clearance in 30% of patients after 22 days of continuous therapy, including overnight occlusion. The authors found that twice-daily topical treatment with pimecrolimus cream 1% resulted in low pimecrolimus blood levels, was well tolerated as well as safe and effective.

A few case reports,^{59–61} describe successful treatments of chronic actinic dermatitis with topical tacrolimus and pimecrolimus have been reported. One case of ichthyosis linearis circumflexa in a 20-year-old man was treated successfully using topical tacrolimus.^{62,63}

It is our opinion that these studies appear promising but require further validation through randomized and double-blind studies in a large sample size and with a significant follow-up period.

SAFETY PROFILE

During the development program, a number of clinical studies were conducted in patients treated with tacrolimus and pimecrolimus for up to 2 years, with no clinically relevant systemic side effects and no clinically significant treatment-related laboratory abnormalities. In studies,^{64–66} all data show that the risk of consistently systemic exposure after topical application of tacrolimus and pimecrolimus is very low risk and the maximum blood concentration in most patients is below the limit of quantification.

In all these clinical studies, application site reactions such as burning sensations and pruritus was the most frequently reported treatment-related adverse event (Table 63-3). These reactions were always short events of mild or moderate severity, which occurred during the first week of the treatment period and often disappeared by the second or third week of treatment.²⁰ The burning sensation, which

is generally experienced as a feeling of warmth or heat, has been reported by 18–59% of patients in clinical trials. Application-site pruritus and erythema were reported by at least 10% of patients in clinical studies and usually temporary. The burning sensation, pruritus, and erythema occurred more frequently in adults than in children.

In the clinical studies, the incidence of application-site side effects seemed to be related to the severity of disease. Compared to patients with less severe disease, more patients with severe disease or with >75% of their body surface area affected reported these events.^{19,67}

In a study conducted with patients that applied either pimecrolimus cream 1% or tacrolimus ointment 0.03% twice daily to all skin lesions until complete clearance and upon recurrence for 6 weeks. Application site reactions were less common in pimecrolimus-treated patients than in tacrolimus-treated patients. In particular, erythema or irritation of the skin was reported by 8% of patients treated with pimecrolimus cream 1% and by 19% of patients treated with tacrolimus ointment 0.03%.

Two 6-week studies⁶⁸ conducted in children with mild to severe AD did not reveal significant differences in the incidence of application site reactions between patients treated with either tacrolimus ointment 0.1% or tacrolimus ointment 0.03% and those treated with pimecrolimus cream 1%.

Common nonapplication site side effects are seen during treatment with tacrolimus ointment include influenza-like symptoms, headache, allergic reaction, and asthma⁶⁹.

Special concern was raised for the development of the skin viral infections. The cutaneous viral infection may be caused by local immunosuppression induced by calcineurin inhibitors. During the studies, the infectious disease (ID) rates for total skin infections and the infection disease rates for total bacterial, fungal and parasitic skin infections were similar in patients treated with pimecrolimus cream 1%, and in patients who received the vehicle. In children, the ID rate of total viral skin infections was instead significantly increased in patients treated with pimecrolimus cream 1% in comparison with placebo⁷⁰.

Occurrence of recurrent skin tags, rosacealike granulomatous eruptions, rosaceiform dermatitis, mucosal hyperpigmentation, tinea incognita, molluscum contagiosum, in addition, verruca vulgaris have been reported.

TABLE 63-3—Incidence of Common Application-Site Adverse Events in Clinical Trials^{55,61}

	Tacrolimus 0.03% ointment (%)		Tacrolimus 0.1% ointment (%)		Pimecrolimus cream 1%	
	Children	Adults	Children	Adults	Children	Adults
Burning sensation	18-43	45-46	19-34	23-59	13.4	25.9
Pruritus	13-41	20-46	11-32	15-46	-	5.5
Erythema	2-8	2-25	1-8	4-28	3.1	2.1

Risk of Malignancies

There is a theoretic concern that topical immunomodulatory therapy with tacrolimus and pimecrolimus may increase the risk of cancer, even if there is no consistent evidence to suggest an increased risk of cutaneous or visceral cancer.

Systemic use of calcineurin inhibitors in transplant patients is associated with lymphoma and skin cancer,⁷¹ however, this association seems related to the immunosuppressive effect of the systemic level of these drugs apparently determined by the administration of high doses for prolonged periods.

There is no clear evidence to suggest that there is a systemic immunosuppression in patients with AD or other skin disease treated with topical calcineurin inhibitors; some data could instead suggest the opposite. In fact, in a study where infants and young children received pimecrolimus cream 1% intermittently for up to 2 years, the incidence rate of common noncutaneous childhood infections declined over time and throughout the second year of treatment. This is a relevant finding because an increased incidence of systemic infections is considered a reliable indicator of immunocompetence^{72,73}.

Arellano et al.⁷⁴ performed a nested case-control study in the PharMetrics database to evaluate the association between topical immunosuppressants and lymphoma in a cohort of patients with atopic dermatitis, but did not find an increased risk of lymphoma in patients treated with topical calcineurin inhibitors.

A recent and up to date report of the largest cohort study conducted to evaluate the association between calcineurin inhibitors and cancer, did not observe an increase in overall cancer rates among subjects with atopic dermatitis, or eczema who were exposed to either topical tacrolimus or pimecrolimus⁷⁵. However, they found that the use of topical tacrolimus might be associated with an increased risk of T-cell lymphoma.

Currently there is no evidence that suggests a relationship between the development of skin cancer according to the dose of drugs administered or to the duration of the treatment. To date more than 21,000 patients have been treated with topical calcineurin inhibitors in clinical trials and if there is an increased risk of malignancies, the long-term use of those drugs in population should give rise to an increasing number of malignancies⁷⁶.

CONCLUSION

Topical calcineurin inhibitors appear to be an effective and safe treatment option for the treatment of AD and may work well in several other inflammatory skin diseases such as psoriasis and seborrheic dermatitides, in particularly when lesions are localized on the face or skin folds. They should be used as an alternative topical agent in instances of failure of conventional therapy. It is our opinion that the

What We Know

- Topical calcineurin inhibitors has broadened the range of drugs available to dermatologic disease
- The most common used ones are tacrolimus and pimecrolimus
- They are both immunomodulators that complex macrocyclic compounds that bind to the intracellular protein macrophilin-12.
- This complex inhibits activity of calcineurin, thereby preventing the dephosphorylation of NF-AT and inhibiting its ability to regulate transcription of genes.
- The therapeutic effects of tacrolimus and pimecrolimus are related to the activation of T lymphocytes.
- Efficacy of calcineurin inhibitors has been evaluated in atopic dermatitis, vitiligo, psoriasis, seborrheic dermatitis, lupus erythematosus, alopecia areata, and others.
- Several clinical trials showed efficacy and safety of pimecrolimus and tacrolimus in treatment of AD.
- Calcineurin inhibitors seem to represent a useful alternative for vitiligo in particular for location in the head and neck.
- In clinical studies for up to 2 years, there were no clinically relevant systemic side effects and no clinically significant treatment-related laboratory abnormalities.
- There is a theoretic concern that topical immunomodulatory therapy with tacrolimus and pimecrolimus may increase the risk of cancer.
- There is no evidence to suggest an increased risk of cutaneous or visceral cancer associated to topical application of calcineurin inhibitors.

studies conducted on calcineurin inhibitors, appear to be promising but require further validation with randomized and double-blind studies in a large sample size, and with a significant follow-up period

INTRODUCTION

Hypnosis consists of intentional trance induction, deepening, work, maintenance, and termination. Medical hypnotherapy can reduce suffering, promote healing, or help the person alter a destructive behavior pattern. The natural trance state has been used since ancient times to assist in healing.

Each of us experiences the absorption that occurs with mild spontaneous trances daily while watching television or a movie, reading a book or a magazine, or playing a computer game. After appropriate training, a person may intensify this trance state in himself or herself or in another individual, and use this heightened focus to promote mind-body interactions that help to lessen suffering or to enhance healing. The trance state may be induced by using deep slow breathing, relaxation, guided imagery, meditation techniques, self-hypnosis, or hypnosis induction techniques. While people vary in their ability to enter the trance state, most can obtain some benefit from hypnosis.

Reaching agreement on a precise definition of hypnosis has been challenging. Marmer¹ described hypnosis as a psychophysiologic tetrad of altered consciousness, consisting of narrowed awareness, restricted and focused attentiveness, selective wakefulness, and heightened suggestibility. For a more extensive discussion of the definitions and theories regarding hypnosis, see the texts by Crasilneck and Hall² or Barabasz and Watkins.³ Myths abound about hypnosis that tend to overrate, underrate, or distort the true capabilities and nature of hypnosis.

With respect to dermatology, hypnosis may help decrease pain and pruritus in the skin; intervene in psychosomatic aspects of skin diseases; and lead to the resolution of some skin diseases, including verruca vulgaris. In some cases, suggestion without formal trance induction may be sufficient. Sulzberger and Wolf⁴ reported on the successful use of suggestion to treat verrucae vulgaris.

MECHANISMS OF ACTION

While clearly defining hypnosis has been somewhat elusive, there are demonstrable observable changes in functional magnetic resonance imaging (fMRI),⁵ positron emission (PET),⁶ and electroencephalogram (EEG)⁷ in the trance state compared with the normal alert state. One way that

hypnosis may make suggestions more effective is by inhibiting competing negative or distracting thoughts, so that the focus can be solely on the suggestion.⁸ This reciprocal inhibition of thoughts competing with the suggestion can enhance positive reconditioning, by reducing the resistance to change and increasing the focus of attention, while pairing a more desirable conditioned stimulus and response to an unconditioned stimulus. When that unconditioned stimulus is then encountered in real every day life, the new subconscious conditioning (learning) can inhibit old undesirable dysfunctional conditioning (learning), resulting in pattern interrupt and changed responses to the stimulus.⁸

Hypnosis can allow conscious regulation of blood flow and other autonomic functions that are not usually under conscious control. The relaxation response occurring with hypnosis affects the neurohormonal systems that regulate many body functions. Hypnotized volunteers in studies have been able to significantly decrease immediate sensitivity flare reaction of the histamine prick test. The effect of hypnotic suggestion on delayed cellular immune responses was shown to have significant effect on the size of erythema and on palpable induration in one study but no significant effect in other studies⁹.

Braun¹⁰ reported that different allergic responses, dermatologic reactions, and effects on seizure disorders, pain control, and healing occurred in the same individual who had multiple personality disorder (now called dissociative identity disorder), depending on the specific personality present at the moment, demonstrating how much influence the mind can have on physiologic reactions and disease processes. The report also described differences in physiologic responses and disease conditions for selected individuals in hypnotic trance compared to their normal waking state.

Hypnosis may be used to promote healthy behaviors, to decrease situational stress, to reduce needle phobias, to control harmful habits such as scratching, to provide immediate and long-term analgesia, to reduce symptoms such as itching related to diseases, to speed recovery from surgery, and to enhance the mind-body connection to accelerate healing. Skin diseases that have a psychosomatic aspect often respond especially well to hypnosis. Griesemer,¹¹ who was both a dermatologist and a psychiatrist, during 1 year in his practice, recorded the occurrences of emotional triggering of dermatoses in his patients. As a result he developed an emotional triggering index for

various skin diseases, with 100 indicating an every single time emotional influence and zero, indicating no emotional influence on the skin disease.

The responsiveness of skin diseases to hypnosis are also noted in the somewhat outdated book by Scott¹² and in the chapter on the use of hypnosis in dermatologic problems in the text by Crasilneck and Hall.² Koblenzer¹³ also mentions some uses of hypnosis for common dermatologic problems. Grossbart and Sherman¹⁴ discuss mind-body interactions in skin diseases and include hypnosis as recommended therapy for a number of skin conditions in an excellent resource book for patients.

MODES OF MEDICAL HYPNOTHERAPY

Hypnosis is a tool, not a therapy in and of itself. It can be used to help locate and correct psychologic and behavioral roadblocks to healing. Processes that can be enhanced by hypnosis include supportive ego-strengthening therapy, direct suggestion, symptom substitution, psychosomatic hypnoanalysis, and posthypnotic suggestion⁹.

Induction of the hypnotic state in adults is achieved by methods that focus attention, soothe, and/or produce monotony or confusion. The hypnotic state can be induced in children by having the child make-believe that he or she is watching television, a movie, a play, a computer game, or by using some other distractive process that uses the imagination.

Deepening the hypnotic state is achieved by methods that continue to focus attention and soothe and/or produce monotony or confusion. Examples include descending stairs with a numerical count, watching a whirling wheel, floating, and going to a safe place and enjoying the sights, sounds, pleasant odors, and tactile feelings.

Trance maintenance can be obtained by methods that continue to soothe and focus attention. The patient usually maintains some awareness and is able to speak to answer questions without coming out of trance.

Trance work can include simply relaxing and being where the patient would rather be during a dermatologic procedure, or supportive ego strengthening, direct suggestions, symptom substitution, psychosomatic hypnoanalysis, and posthypnotic suggestions.

Relaxation and being where the patient would rather be during a dermatologic procedure is useful for reducing anxiety and reducing any pain associated with the procedure. It includes suggestions to the patient to go in their mind where they would rather be such as at a beach, in a forest, taking a trip, enjoying a hobby, floating, or doing some other enjoyable activity.

Supportive ego-strengthening therapy while in a hypnotic state includes positive suggestions of self-worth and effectiveness. The strengthened ego is better able to repress or confront discordant elements that inhibit healing.

Direct suggestion during hypnosis is frequently used to decrease discomfort from pain, pruritus, burning sensations,

and anxiety. Direct suggestion may produce sufficiently deep anesthesia in highly hypnotizable patients to permit cutaneous surgery with no other anesthetic. Direct suggestion can also be used to reduce repetitive behaviors of skin scratching or picking, nail biting or manipulating, and hair pulling or twisting. Undesirable psychophysiological events such as hyperhidrosis, blushing, and some types of urticaria can sometimes be controlled through direct suggestion. Some skin lesions such as verrucae can even be induced to resolve by using direct suggestion.

Suggestions may be made for symptom substitution. Symptom substitution reconditions the subconscious mediated by hypnosis to replace a negative habit pattern with a more constructive one. For example, scratching can be replaced by another physical activity, such as stiffening the elbows and making a fist until the urge to scratch passes. Stress relievers can be substituted for scratching including athletic activities, artwork, verbal expression of feelings, journaling of feelings, or meditation.

Psychosomatic hypnoanalysis may help patients deal with chronic psychosomatic dermatoses that are nonresponsive to other simpler approaches. LeCron's^{15,16} list of the seven most common factors causing emotional difficulties and illnesses, namely conflicts, motivation, the effect of suggestion, organ language, identification, self-punishment, and the effect of past experiences is a good starting point for exploration in hypnoanalysis. Ewin and Eimer¹⁷ provide a scripted method of detecting and neutralizing the emotional impact of sensitizing or precipitating events. They use ideomotor finger signaling to elicit significant memories that may be preverbal or nonverbal. Results are likely to be much more rapid than with standard psychoanalysis. Only well-qualified and appropriately licensed practitioners should perform hypnoanalysis.

The author reported on the successful use of psychosomatic hypnoanalysis in dermatology¹⁸. The author slightly modified Ewin's mnemonic for LeCron's 7 key factors to the mnemonic COMPASS, as follows: Conflict, Organ language, Motivation, Past experiences, Active identification, Self-punishment, and Suggestion. There is a diagnostic value of screening for psychosomatic factors related to skin disorder triggering or exacerbation using psychosomatic hypnoanalysis. If the focused history and ideomotor questioning for all seven COMPASS factors is negative, it is unlikely that there is a significant psychosomatic component. With one or two COMPASS factors positive, appropriate reframing suggestions may be sufficient, but with more factors positive, more intensive psychotherapy would be appropriate.

Posthypnotic suggestion is often included toward the end of the session, and further strengthening of the effects can be obtained by recording an MP3 or CD that the patient can repeatedly use for self-hypnosis later. The patient should not use the recording while operating a motor vehicle. It often takes 20 to 40 repetitions before a behavioral or attitudinal change is likely to be permanent.

Trance termination may be obtained by suggesting a realerting, with, or without count up, and usually incorporating suggestions for continued relaxation and ease for the rest of the day while becoming fully alert and awake. With self-hypnosis, patients will come out of trance spontaneously either to the alert state or by falling asleep, depending upon the circumstances and the patient's desires.

SEARCH METHODS

A search was conducted using Ovid EBM Reviews - Cochrane Database of Systematic Reviews searching for hypnosis and Ovid MEDLINE 1950 to December 2009 searching for hypnosis and the various skin disorders below with extension of the search by tracing article references back to the 1920s for treatment. Of particular interest were randomized controlled trials (RCT) and nonrandomized controlled trials (NRCT), with case series (CS) and case reports (CR) also included for completeness.

EVIDENCE FOR TREATMENT EFFECTIVENESS

The studies reporting effectiveness of various hypnotherapy treatments were rated in terms of the strength of the scientific evidence according to the American College of Cardiology and American Heart Association (ACC/AHA) guidelines grading schema¹⁹. This involves 3 classes of recommendation 1, 2 and 3, and 3 strengths of evidence A, B, C. Recommendation class 1 is for treatments for which there is evidence or general agreement that the treatment is effective. Class 2 is for treatments where there is a divergence of evidence or opinion about the effectiveness of treatment. Class 3 is for treatments where there is evidence or general agreement that the treatment is not effective. Evidence strength level A is strong evidence based on the results of multiple randomized trials or meta-analyses of such trials. Level B is moderate evidence based on evidence from a single randomized trial or from nonrandomized studies. Level C is weak evidence based on expert opinion, case studies, or standards of care.

EFFICACY OF HYPNOTIC RELAXATION DURING DERMATOLOGIC PROCEDURES AND SURGERY

Many dermatologic procedures can produce pain or anxiety in patients. Skin procedures that may be somewhat painful but usually do not require a local anesthetic include moderate depth chemical peels, cryodestruction of skin lesions, curettage of molluscum, excision of skin tags, extrusion of comedones, incision and expression of milia, laser treatment of vascular lesions, strong microdermabrasion, and sclerotherapy. Dermatologic procedures that usually require a local anesthetic include electrodesiccation

and curettage, incision and drainage of an abscess, laser ablation of skin lesions, liposuction, punch biopsy, shave biopsy, surgical excision, and surgical repair. Cutaneous procedures that may require conscious sedation include deep chemical peels, dermabrasion, laser resurfacing, and extensive liposuction. Adding hypnotic relaxation and/or hypnotic analgesia may benefit the patient during all of these procedures.

Recent experimental evidence has helped to localize the active sites of the mechanisms of pain relief during hypnosis. Faymonville et al. found that pain reduction mediated by hypnosis was localized to the activated mid-anterior cingulate cortex, as observed by using subtraction positron emission tomography (PET).⁶

Freeman et al.⁷ observed significantly greater high theta (5.5-7.5 Hz) activity at parietal and occipital sites, during both hypnosis and waking relaxation in persons who were highly hypnotizable (based on the Stanford Hypnotic Susceptibility Scale, Form C or SHSS:C scores). This was carried out in an electroencephalographic (EEG) study of hypnosis effects versus distraction effects on cold pressor pain, compared with persons who were less hypnotizable. Freeman et al. also found that in persons who were highly hypnotizable, hypnosis provided significantly greater pain relief than distraction or waking relaxation. These individuals also had significantly greater pain relief via hypnosis than those who were less hypnotizable. These PET and EEG studies support state-based theories rather than sociocognitive theories of hypnosis.

Montgomery et al.²⁰ in a meta-analysis of hypnotically induced analgesia found that hypnosis relieved pain in patients with headache, burn injury, heart disease, cancer, dental problems, eczema, and chronic back problems. Their study also quantified the magnitude of hypnoanalgesic effects. For most patients, hypnotic suggestion relieved pain regardless of its type. While light and medium trance states are sufficient for most purposes, a deep trance state is required for hypnotic anesthesia for surgery.

Faymonville et al.²¹ randomly assigned 60 patients undergoing plastic surgery with adjunctive conscious sedation either to a control group with stress-reducing strategies or to a hypnosis group. In the hypnosis group, the intraoperative and postoperative anxiety and pain were significantly lower and significantly smaller amounts of medication were required for conscious sedation.

Mauer et al.²² evaluated 60 patients who underwent hand surgery and received either standard treatment or standard treatment with adjunctive hypnosis. The hypnosis group had significantly decreased perceived pain intensity, expression of perceived pain, and anxiety compared to those of control subjects. Patients in the hypnosis group also had significantly fewer medical complications and a more rapid postoperative recovery rate.

Montgomery et al.²³ studied 20 women having excisional breast biopsies who were randomized to standard care versus preoperative hypnosis. They found brief

10 minute hypnosis to be effective in reducing postsurgery pain and distress both before surgery and after surgery.

Defechereux et al.²⁴ reported a prospective randomized study of thyroid and parathyroid procedures performed using hypnosis, local anesthesia, and minimal conscious sedation compared to similar surgery performed under conventional anesthesia. They found that patients in the hypnoanesthesia group had significantly less inflammatory response, hemodynamic dysregulation, postoperative pain, postoperative fatigue, and convalescence time compared with the control group. Bleeding, operative times, and surgical comfort were similar in both groups.

Liossi et al. conducted a prospective, randomized, controlled trial to compare the efficacy of a local anesthetic (EMLA), EMLA plus hypnosis, or EMLA plus attention in children receiving venipuncture. Children in the EMLA-plus-hypnosis group reported less anticipatory anxiety and less procedure-related pain and anxiety. They were rated as demonstrating less behavioral distress during the procedure than patients in the other two groups. In addition, parents whose children were randomized to the EMLA-plus-hypnosis group experienced less anxiety during their child's procedure than parents whose children had been randomized to the other two groups²⁵.

Lang et al.²⁶ conducted a large prospective randomized trial of adjunctive nonpharmacologic analgesia for invasive percutaneous vascular radiologic procedures in three groups: (1) standard intravenous conscious sedation care, (2) structured attention with conscious sedation, and (3) guided self-hypnotic relaxation with conscious sedation if needed. Pain scores increased linearly with time in the standard group and in the structured attention group, but remained flat in the hypnosis group. Anxiety scores decreased over time in all three groups but more so in the hypnosis group. Conscious sedation drug use was significantly higher in the standard group, intermediate in the structured attention group, and lowest in the self-hypnosis group. Hemodynamic stability was significantly higher in the hypnosis group than in the other two groups. Length of procedure times were significantly shorter in the hypnosis group than in the standard group. Individual imagery was quite varied from one patient to another²⁷.

Lang et al.²⁶ concluded that hypnosis was superior in reducing pain and anxiety, in maintaining hemodynamic stability, and in shortening the procedure time compared with standard care, and the results of the structured attention group were in between those of the hypnosis group and the standard care group. Multiple RCT evidence has demonstrated that hypnosis for procedural pain and anxiety is definitely beneficial in invasive radiology as well as plastic surgery, hand surgery, neck surgery, and breast biopsy in adults, and venipuncture in children, evidence class 1A.

Lang and Rosen,²⁸ performed a cost analysis of standard intravenous conscious sedation compared to intravenous conscious sedation that included self-hypnotic

relaxation using the data from the above study. The average cost per case associated with standard care sedation was \$638 compared to an average cost of \$300 per case for hypnosis augmented sedation. The cost savings averaged \$338 per case.

Allowing the patient to choose his or her own self-guided imagery seems to permit most individuals to reach a state of relaxation during procedures. The author has used a technique similar to the invasive radiologic studies modified for dermatology with good success in dermatologic surgery.²⁹ The eye-roll induction is most commonly used by the author, and this method works quickly for most patients. The author is currently conducting a RTC in hypnotic relaxation for dermatologic surgery. Hypnosis for procedural pain and anxiety is probably beneficial in dermatology procedures, with evidence class 1C.

EFFICACY OF HYPNOTHERAPY FOR SPECIFIC DERMATOLOGIC CONDITIONS

Information about the effectiveness of hypnosis on specific dermatologic conditions has in the past largely been based on one or a few uncontrolled cases. In recent years, a few RCT have produced more reliable information. Unfortunately, RCT results are still not available for most of the disease categories. The list of dermatologic conditions below for which hypnosis has been utilized is not all-inclusive, but it does include most of the dermatologic conditions for which hypnosis has been shown to be reasonably helpful in reducing symptoms or in improving aspects of the condition. They are arranged in order based on the strength of scientific evidence for the effectiveness of hypnosis, starting with the strongest RCT evidence, followed by NRCT, CS, and CR⁹. Dermatologic conditions supported by only one or a few case reports are listed in alphabetical order toward the end of this section, starting with acne excoriée. References not included here can be found in reference 9.

Randomized-Controlled trials

Verruca Vulgaris

The report by Sulzberger and Wolf⁴ on the efficacy of suggestion in treating warts has since been confirmed numerous times. Numerous case series reports attest to the efficacy of hypnosis in treating warts.^{30,31} Ewin reported a case series of warts resistant to other measures including hypnosis where 33 of 41 cleared following psychosomatic hypnoanalysis.³² Several RCT have been performed that demonstrated significant clearing of warts using hypnosis. Spanos et al³³ in a well-conducted randomized-controlled study serves as a typical example, and found that 53% of the experimental group had improvement of their warts 3 months after the first of five hypnotherapy sessions, while

none of the control group had improvement. Hypnosis can be successful as a therapy for warts, evidence class 1A, and hypnoanalysis also can be useful, evidence class 1C.

Psoriasis

Excess stress is often a factor in the onset, exacerbation, and prolongation of psoriasis. Hypnosis and suggestion have been reported to have a positive effect on psoriasis. In a typical case report, 75% clearing of psoriasis was reported by using a hypnotic sensory-imagery technique. Extensive, severe psoriasis of 20 years' duration showed marked improvement in another case by using sensory imagery to replicate the sensations in the patient's skin that he had experienced during sunbathing. Yet another case of severe psoriasis of 20 years' duration fully resolved with a hypnoanalytic technique.

Tausk and Whitmore³⁴ performed a small randomized controlled trial using hypnosis as adjunctive therapy for psoriasis, with significant improvement in individuals who were high hypnotizables as rated by SHSS:C. Hypnosis can be useful as adjunct therapy for resistant psoriasis, especially if an emotional factor is significant in the triggering of the psoriasis, evidence class 1B.

Nonrandomized Controlled Trials

Atopic Dermatitis

Stewart and Thomas³⁵ treated with hypnotherapy 18 adults with extensive atopic dermatitis whose conditions had been resistant to conventional treatment. In a NRCT, they used relaxation, stress management, direct suggestion for nonscratching behavior and for skin comfort and coolness, ego strengthening, posthypnotic suggestions, and instruction in self-hypnosis. The results were statistically significant for reduction in itching, scratching, sleep disturbance, and tension compared with controls. Topical corticosteroids use decreased from the original amount for each patient by 40% at 4 weeks, 50% at 8 weeks, and 60% at 16 weeks, evidence class 1B. For resistant atopic dermatitis, hypnosis can also reduce the required amount of other conventional treatments.³⁶

Case Series

Alopecia Areata

Gupta et al³⁷ noted a strong correlation between high stress reactivity and depression in patients with alopecia areata. Not all reports of hypnosis for alopecia areata have produced positive results. Willemson et al³⁸ utilized hypnotherapy for 21 patients, of whom nine had alopecia universalis and 12 had extensive alopecia areata. All patients had significantly lower anxiety and depression after

hypnotherapy. Complete scalp hair regrowth occurred in nine patients, including four with alopecia universalis and 2 with ophiasis. Over 75% scalp hair regrowth occurred in another 3 patients. Five patients had a significant relapse of alopecia, evidence class 2C.

Urticaria

Two individual cases of urticaria responding to hypnotic suggestion were reported in a study. An 11-year-old boy had an urticarial reaction to chocolate that could be blocked by hypnotic suggestion so that hives appeared on only one side of his face in response to that hypnotic suggestion. A case series study of hypnosis with relaxation therapy utilized for 15 patients with chronic urticaria of an average duration of 7.8 years showed that within 14 months, six patients' conditions had cleared and eight had improved, with decreased medication requirements reported by 80% of patients. One patient's condition did not improve, evidence class 2C. Ewin¹⁷ described a case where psychosomatic hypnoanalysis uncovered a history in a medical student who had urticaria to chocolate. As a young boy he had gone to a local zoo with his parents and happened to be looking at the python cage at feeding time. He was horrified to see a python swallow a bunny rabbit. The next morning for Easter he got an Easter basket containing a chocolate bunny. That was when the urticaria to chocolate began. Once the medical student became aware of his own childhood memories and processed them as an adult, along with posthypnotic suggestions that it would be safe for him to eat chocolate without reacting, he could eat chocolate with no reaction.

Individual Case Reports

Acne Excoriée

Hollander³⁹ reported success in controlling the psychogenic picking aspects of acne excoriée in two cases, by using posthypnotic suggestion that the patient was to remember the word scar whenever she wanted to pick her face and to refrain from picking by saying scar. The excoriations resolved but not the underlying acne. The author has also used this technique successfully, along with suggestions that natural with slight imperfections is really more beautiful than something artificially perfect, evidence class 1C.⁴⁰

Congenital Ichthyosiform Erythroderma

Several cases of remarkable clearing of congenital ichthyosiform erythroderma of Brocq following direct suggestion for clearing under hypnosis have been reported. For example, Kidd⁴¹ reported improvement in a 34-year-old father and his 4-year-old son. Not all cases have responded so well, however, evidence class 2C.

Dyshidrotic Dermatitis

A reduction in the severity of dyshidrotic dermatitis has been reported with hypnotherapy treatment. Greisemer's¹¹ data indicate a significant psychosomatic component for dyshidrosis; therefore, hypnosis has biologic plausibility as a therapy. Not all reports have been positive, evidence class 2C.

Erythema Nodosum

Resolution of erythema nodosum of 9-year duration occurred in a 44-year-old woman after hypnoanalysis¹⁸. Five of the seven key COMPASS factors were positive in this case. Because so many factors were positive, the patient was referred for psychotherapy but failed to follow up on the psychotherapy, evidence class 1C.

Erythromelalgia

One case report exists of successful treatment of erythromelalgia in an 18-year-old woman using hypnosis alone followed by self-hypnosis. Permanent resolution occurred. Not all cases respond, evidence class 2C.

Furuncles, Recurrent

Jabush⁴² described a 33-year-old man with recurrent multiple furuncles since age 17 years old that contained *Staphylococcus aureus*. The furuncles were unresponsive to multiple treatment modalities. He noted that the patient had a negative self-image. Use of hypnosis and self-hypnosis with imagined sensations of warmth, cold, tingling, and heaviness resulted in dramatic improvement over 5 weeks, with full resolution of the recurrent furuncles. The patient also improved his self-image substantially. The hypnosis was hypothesized to have helped in some way to normalize the immune response of the body to the bacteria. While conventional antibiotic therapy is the first line of treatment for furuncles, in unusually resistant cases with significant psychosomatic overlay, hypnosis may help to end the recurrent cycles of infection, evidence class 1C for recurrent furuncles with psychosomatic overlay.

Glossodynia

When oral pain has a psychogenic component, hypnosis may be effective. Even with purely organic disease, hypnosis may temporarily relieve pain, evidence class 1C.⁴³

Herpes Simplex

Reduction in the frequency of recurrences of herpes simplex following hypnosis has been reported along with lessening of discomfort from herpes simplex eruptions.⁴⁴

In patients with an apparent emotional trigger factor, hypnotic suggestion may be useful as a therapy for reducing the frequency of recurrence, evidence class 1C for lessening of discomfort.

Hyperhidrosis

Hypnotherapy and autogenic training may be useful as adjunctive therapies for hyperhidrosis but have variable success, evidence class 2C.

Ichthyosis Vulgaris

A 33-year-old man who had ichthyosis vulgaris that tended to be better in the summer and worse in the winter began hypnotic suggestion therapy in the summer and was able to maintain the summer improvement throughout the fall, winter, and spring. Other cases have not had significant improvement, evidence class 2C.

Lichen Planus

The pruritus and the lesions may be reduced in selected cases of lichen planus by using hypnotherapy, but results are mixed, evidence class 2C.

Neurodermatitis

Several cases of neurodermatitis or psychogenic excoriations have reportedly resolved by using hypnotherapy. The neurodermatitis remained resolved, with up to 4 years of follow-up.⁴⁵ Iglesias⁴⁶ reported 3 cases of neurodermatitis that failed to respond to direct suggestion under hypnosis but that responded to hypnoanalysis with ideomotor signaling followed by reframing, evidence class 1C.

Nummular Dermatitis

A reduction of pruritus and resolution of lesions have been reported with the use of hypnotherapy for nummular dermatitis, with mixed results, evidence class 2C.

Postherpetic Neuralgia

In some individuals, the pain of acute herpes zoster and postherpetic neuralgia can be reduced by hypnotherapy, with mixed results, evidence class 2C.

Pruritus

The intensity of pruritus may be modified and improved by hypnosis. For example, a man with chronic myelogenous leukemia had intractable pruritus, which improved with hypnotic suggestion. Hypnotherapy evidence for reducing

pruritus including that in atopic dermatitis is evidence class 1B.

Rosacea

Rosacea, especially the vascular blush component, has been reported to improve in selected cases of hypnotherapy for resistant rosacea, but not in others, evidence class 2B.

Trichotillomania

Several cases of successful adjunctive treatment of trichotillomania with hypnosis have been reported. Hypnotherapy for trichotillomania is evidence class 1C⁴⁷.

Vitiligo

Hautmann and Panconesi⁴⁸ described the psychoneuroendocrinimmunologic aspects and mechanisms of vitiligo. Occasional cases of vitiligo have improved by using hypnotic suggestion, but most do not, evidence class 3C.

SAFETY PROFILE FOR HYPNOSIS

In appropriately selected patients, hypnosis can decrease or eliminate symptoms, and in some cases, it can induce lasting remissions or cures of skin diseases. Discussing this option with patients allows the dermatologist to gauge the patient's receptiveness to hypnotherapy. The time requirements for screening patients, educating them about realistic expectations for results from hypnosis, and performing the hypnotherapy are generally no longer than those for screening, preparing, and educating patients about cutaneous surgery and then performing it.

Many dermatologists choose to refer patients with complex psychosomatic dermatologic problems to competent specialists in hypnotherapy. Dermatologists who prefer to refer patients to hypnotherapists may obtain referrals and information from the American Society of Clinical Hypnosis www.asch.net or similar professional organizations. Dermatologists who prefer to learn how to use hypnosis themselves may obtain appropriate training through the same organizations.

The advantages of medical hypnotherapy for dermatologic diseases include the ability to obtain a response where other treatment modalities have failed, the ability to reduce relapses, and the ability of patients to self-treat and gain a sense of control when taught self-hypnosis reinforced by using audio recordings. Hypnosis is nontoxic and cost-effective. Providing this treatment can result in pleased and grateful patients.

The disadvantages of medical hypnotherapy in dermatology include the training required, the low hypnotizability of some patients, the negative social attitudes still prevalent about hypnosis, and the lower reimbursement

rates per unit time for cognitive therapies such as hypnosis when compared to procedural therapies such as cutaneous surgery. An occasional patient can experience a mild post-hypnotic headache.

TRAINING IN MEDICAL HYPNOTHERAPY

The American Society of Clinical Hypnosis offers weekend, regionally held, 20-hour courses in beginning, intermediate, and advanced hypnosis. Information may be obtained from its web site www.asch.net, which also provides online registration for the courses. Other organizations also offer training both in the United States and abroad. Once the practitioner has obtained the necessary basic training, mentors are available.

LEGAL ASPECTS OF PRACTICING MEDICAL HYPNOTHERAPY

In some states in the United States such as Florida, the practice of hypnotherapy is limited to licensed practitioners. The training requirements depend on the type of license. Outside of the United States, most jurisdictions have their own laws or statutes that dictate who may legally practice hypnosis.

As with all medical practice, informed consent is crucial before proceeding with medical hypnotherapy. Although the informed consent does not need to be in writing, informed consent should be well documented in the patient's chart if no written form is signed by the patient.

In some states, prior hypnosis may be considered to taint the accuracy of the memory with respect to legal testimony given by patients if they are plaintiffs, victims, or witnesses. If the area to be addressed by medical hypnotherapy might be open to future litigation, the credibility of the patient's testimony may suffer. When applicable, this potential legal issue should be included in the informed consent discussion.

Exploring repressed memories is a legally risky issue because of legal claims by patients that hypnotherapists have created false memories. Only adequately trained physicians, psychiatrists, and psychologists who know how to avoid asking leading questions should venture into this area.

This information is not warranted to be legally correct. Conferring with a qualified attorney to obtain legal advice is recommended to obtain correct information for a specific jurisdiction.

PATIENT SELECTION FOR MEDICAL HYPNOTHERAPY

Suitable patients for hypnosis are mentally intact, not psychotic or intoxicated, motivated, not resistant, and preferably moderately or highly hypnotizable, as rated

What We Know

- Hypnosis for procedures has strong supporting evidence, as does hypnosis for warts and for atopic dermatitis. RCT and NRCT for most dermatologic conditions have yet to be performed, with only the weaker evidence of CS and individual CR to support the use of hypnotherapy in those situations. Similarly, psychosomatic hypnoanalysis has only CS and individual CR to support its use in dermatology.

by the Hypnotic Induction Profile⁴⁹ or by the Stanford Hypnotic Susceptibility Scale and its variants. However, for dermatologic procedures, a moderate or high degree of hypnotizability is not critical to the success of self-guided imagery for relaxation and discomfort reduction.

Hypnotherapy for dermatologic disorders generally works best in moderately to highly hypnotizable patients who are appropriately motivated and who have dermatoses that have a large psychosomatic component or are otherwise known to be responsive to intervention with hypnosis. Starting initially with simple, easy cases is best, referring the more complex cases to those with more experience.

CONCLUSION

Hypnotherapy for dermatologic disorders or procedures can be effective, cost-effective, nontoxic, and gratifying in many cases. For some patients it appears to work miracles and for others to fail completely, while most results lie somewhere in between. A key factor in producing positive results is the specific type of hypnotherapy chosen. Careful selection of the cutaneous disease process, the patient, and the provider, as well as appropriate use of hypnosis, can decrease suffering and morbidity from skin disorders with minimal adverse effects.

Photodynamic Therapy

65

Riccardo Rossi, M.D., Marta Grazzini, M.D., and Torello Lotti, M.D.

INTRODUCTION

Topical photodynamic therapy (PDT) use in dermatologic practice is thoroughly discussed and debated in the scientific literature because although the concept is simple, the multiple parameters involved make it complex, and more studies and research are required to determine the optimal parameters for the treatment of approved as well as off-label indications. Various photosensitizing agents and their different uses in delivery and incubation times, such as being combined with various parameters relating to light, are used. The only FDA-approved (Food and Drug Administration) indication of ALA (5-aminolevulinic acid)-PDT and MAL (methyl aminolevulinate)-PDT is the treatment of actinic keratoses (AKs). MAL-PDT is approved for AK, superficial/nodular basal cell carcinoma (s/n BCC) and Bowen's Disease (BD) in 22 European countries, as well as New Zealand and Australia, where it is marketed under the trade name Metvix® (Photocure, Oslo, Norway and Galderma, Paris, France) and has recently been launched under the name Metvixia® in USA. Levulan® (DUSA Pharmaceuticals Inc.) is the other proprietary drug (ALA 20% solution in an alcohol-water-surfactant vehicle) that has been approved but only for actinic keratoses in the United States and Canada (although not in European countries). Different from the US, ALA is not yet in the pharmacopeia of any European country and can be produced and commercialized only as a chemical reagent. Therefore, its use is subject to the rules and specific authorizations of local ethics committees and national health regulatory authorities.

Currently, there is not enough information to decide whether ALA-PDT is more or less effective, safe, or tolerated than MAL-PDT. ALA-PDT has never been evaluated with randomized-controlled studies and this makes comparison of the results obtained from various studies extremely difficult. In addition, even if ALA has been used in many studies as an occlusive medication at a standard concentration (20%) therefore the type and modality of preparation and conservation of the drug, time of application, emission spectrum, and dosage of irradiated light were very different. ALA/MAL PDT has been investigated in the off-label treatment of a number of other neoplastic, infectious, and inflammatory skin conditions with variable and often contrasting results. The use of ALA/MAL-PDT

in these indications must follow all the rules and authorizations specified by the local Ethics Committees.

The literature was screened by using the top sources (Cochrane Library, the Medline and Embase databases, primary, and secondary journals) for finding the best evidence about treatment for the most recent and definitive studies especially for registered indications that are first discussed and followed by a review that covers the type of scientific study, efficacy in human studies, treatment regimen, longevity/recurrence rates and safety profile.

MECHANISM OF ACTION AND PHARMACOKINETICS

Basically, photodynamic action requires the presence and interaction of three components: a photosensitizer, light (at wavelengths that are absorbed by the photosensitizer) and oxygen. Various light wavelengths, exposures, and intensities are then used to activate the agent. This light-activated molecule interacts with oxygen and leads to the formation of a highly reactive singlet oxygen. With low-light and low-drug doses, cell viability may be obtained while other traits (cytokine formation, receptor expression) may be altered. With higher doses of light and drug, the disruption of cell membranes and organelles causes necrosis. At an intermediate combination of light and drug, cells may undergo apoptosis. The most effective wavelength (which allows for a deeper penetration into the skin) in ALA/MAL-PDT was found to be 635 nm red light and its efficacy is proportional to the light energy rate (W/cm^2) and the energy density or fluence (J/cm^2) used.¹ The topical material (with no intrinsic photosensitizing properties) is converted in the mitochondria to light-absorbing PpIX (in the absence of light, PpIX is metabolized fully to a photodynamically inactive heme over 24 to 48 hours) that accumulates in neoplastic cells or in the endothelium of newly formed vessels of tumor parenchyma while sparing the surrounding healthy tissue. This selectivity is based on photosensitizer size and lipophilic/hydrophilic characteristics, electric charge and unspecific protein binding characterizing some pharmacokinetics differences from ALA (polar hydrophilic molecule) and MAL (more lipophilic molecule) (Table 65-1).^{2,3} In addition to MAL and ALA, other photosensitizers such as benzoporphyrins, phthalocyanines, and porphycenes

TABLE 65-1—Pharmacokinetics Differences from ALA and MAL

Pharmacokinetics	
ALA	Polar hydrophilic molecule. Penetrates cells through a transmembrane active mechanism Na^+/Cl^- -dependent β -amino acid, including glycine and gamma aminobutyric acid (GABA) transporters. This system is energy, pH, and temperature dependent. It is saturable and slow and only slightly accelerated in tumor cells.
MAL	Lipophilic methyl ester of 5-ALA. Penetrates cell membranes with active mechanisms but also by passive transmembrane diffusion. This mechanism does not require energy and is faster. The system is unsaturable; it is very efficient in normal cells but even more efficient in neoplastic cells. MAL is quickly demethylated to ALA in the cytoplasm so that the subsequent metabolic passages are the same.

have been used after local application in some pilot studies. Compared to PpIX, these molecules are characterized by a higher absorption coefficient, improved bioavailability and an absorption peak in the range of distant red ($\lambda > 660$ nm) or near infrared ($\lambda = 700-850$ nm) regions that allows them to be activated even as deep as the hypodermis. Their use is still experimental and reserved to selected researcher groups.

A photosensitization mechanism is initiated by the absorption of light by a photosensitizer (P) which generates an excited state of P with two main kinds of competing pathways: a type-1 mechanism where the excited state of the photosensitizer interacts directly with the substrate molecule. The reaction proceeds by electron or hydrogen atom transfer and leads to the formation of reactive oxygen species (ROS: hydrogen peroxide, superoxide radical anion and hydroxyl radical) which oxidize a wide variety of biomolecules causing biologic damage and a type-2 mechanism where the photosensitizer reacts with molecular oxygen to produce a highly reactive oxygen intermediate that easily initiate further reactions. Both type-1 and type-2 reactions cause oxidation of biomolecules in the cell but 1O_2 is regarded as the main mediator of phototoxicity in PDT. The reactive oxygen proceeds to destroy the target cell by direct effects with necrosis but especially apoptosis with lipids, amino acids, and protein oxidation; vascular effects with damage to endothelial cells by platelet activation and release of proaggregatory agents from leucocytes

that leads to ischemia and eventual tumor necrosis and induction of innate and adaptive immune responses, with up-regulation of inflammatory mediators and infiltration of neutrophils, lymphocytes and macrophages that contribute to the damage of tumoral tissue.³

The precise mechanisms (at a cellular level) underlying the efficacy of topical PDT in the treatment of NMSC (nonmelanoma skin cancer) are not fully known. Both apoptosis and necrosis have been described as occurring after topical PDT and the importance of each phenomenon may be influenced by an intracellular localization of the photosensitizer and illumination parameters.^{4,5}

TREATMENT MODALITY AND SAFETY PROFILE

First, it is important to note general exclusion criteria, which were implemented by all reviewed studies. PDT should not be used in patients with any type of photosensitivity, a photosensitizing disease, or even recently tanned skin. Patients with a previous erythema or an inflammation at the treatment site must have had a complete resolution of these conditions prior to treatment or re-treatment.

ALA and MAL are contraindicated for patients with cutaneous sensitivity at 400-450 and around 630 nm, porphyria, allergies to porphyrins or sensitivity to any components of the ALA/MAL solution. Both ALA/MAL are classified as FDA Pregnancy Category C and are not approved for use in children. We summarized (Table 65-2) the most important steps beginning with a preliminary visit to response evaluation as well as safety and management of complications that reflect the most important and recent guidelines. For this reason, the authors suggest finding more details and protocol algorithms from the most important guidelines in order to find also some practical pearls of wisdom.⁶⁻¹⁴ Moreover, you can find in this text, categorized by all relevant cutaneous diseases, the safety profile in addition to the efficacy date.

EFFICACY

Actinic Keratosis

Actinic keratosis (AK) is an important feature of chronic sun damage and helps to identify a population at risk of developing an invasive squamous cell carcinoma (SCC), either from a pre-existing AK or from the surrounding skin. Patients with diffuse signs of photocarcinogenic AKs may experience difficult therapeutic management, especially if those subjects are chronically photoexposed because of professional or lifestyle reasons. In these cases, lesions are usually widespread and tend to recur. It is impossible to predict which AK will evolve into an invasive SCC but it is certain that AK is being recognized increasingly as an early clinical manifestation of a biologic continuum that may ultimately lead to invasive SCC. As it is currently impossible

TABLE 65-2—Multistep Treatment Modality of PDT

STEP 1 <i>Preliminary visit</i>	I. Disclose a personal or familiar history of porphyria or other relevant photosensitivity disorders. II. Documented allergy to the photosensitizer or compounds of the vehicle III. Exclusion criteria IV. In cases of dubious diagnosis, punch biopsy is performed. V. Compilation of the patient's clinical history and the flow chart and measurement of the two diameters of the lesions to be treated. Preoperative photographs are helpful to adequately assess the treatment result and to monitor long-term responses. VI. Evaluate the possible presence of other lesions in other sites, which may require treatment. VII. Inform the patient about the PDT method, possible side effects, and available alternative therapies. VIII. Written consent form.
STEP 2 <i>Preparation of the lesion</i>	I. Scales and crusts may be gently removed, if a keratolytic has not been used, with a curette without local anesthesia. II. In case of bleeding, apply 1% tranexamic acid or 5% acetic acid or 20 vol. hydrogen peroxide or gauze under light pressure until bleeding has stopped. If hemostasis does not occur, postpone treatment to the following day. III. Apply MAL/ALA cream extending the application to 5 mm outside visible margins of the lesion in such a way as to cover the lesion by 1-2 mm. IV. Cover the treated area with polyethylene or adhesive tape, paying particular attention to sensitive areas (around the eyes) and curved zones (around the nose). In these cases, it is advised that the medication be reinforced with a bandage to guarantee the best adherence of the medicine to the skin and to avoid a loss of photosensitization. V. Cover the occlusion to avoid passage of light and the possible deactivation of the PpIX by using gauze and adhesive bandage. VI. The patient can rest for 3 h for MAL while awaiting illumination but should not stay in environments under 15°C. The FDA-approved incubation period for 5-ALA PDT treatment of actinic keratoses is 14-18 hrs, as directed on the package insert for 5-ALA. However, short-incubation times of 1, 2, and 3 hours have been used for treatment of AK. VII. This kind of preparation can be reduced to one step, whereas new patch formulation should highlight relevant clinical results with long-term efficacy. (See AKS paragraph).
STEP 3 <i>treatment</i>	I. The patient should lie down in the most comfortable position possible. II. Remove the bandage (depending on the photosensitizer and the incubation period chosen). III. Both the patient and physician should wear protective glasses. IV. Observation with Wood's light is useful for evaluating the true extension of the lesion to be treated. V. Illumination phase. The three major sources in the USA are the BLU-U (with a delivered dose of 10 J/cm ² for 16 min and 40 s), the pulsed dye laser (PDL) and the intense pulsed light (IPL). A red light (broadband and LED light) is used to a lesser extent in the USA and more commonly in Europe. In this case, the recommended dose is 37 J/cm ² for the LED lamps and 75-100 J/cm ² for filtered halogen lamps. VI. The patient may experience a heating or burning sensation during the first minutes of treatment; in this case, the treatment may be interrupted and restarted a few minutes later. VII. Ask the patient about the intensity of pain (expressed in a VAS—visual-analog scale from 1-10) and report this value on the patient's chart.
STEP 4 <i>After treatment</i>	I. The skin (erythematous or erythemato-edematous, and sometimes exudative) should be medicated with antibiotic cream and covered with gauze. II. The patient should continue this medication for the next few days. III. The patient should be advised not to use steroid creams or cosmetics until the skin is healed. IV. The treated area can be washed daily with water and a delicate detergent. V. The patient may experience a mild burning sensation in the treated area for up to 24 hrs after treatment. If this is intense, the patient may take an oral analgesic. VI. The patient must not expose him/herself to sunlight or UV light until complete re-epithelialization. Serohematic crusts may form in the treated area but should not be removed. VII. It is important to re-evaluate the patient 7 days afterwards and on that occasion, to decide whether further treatment is necessary.
STEP 5 <i>Response evaluation (approved indications)</i>	I. For AKs , a single treatment is sufficient in most cases. Nevertheless, a second treatment may be given, if at follow-up, the lesion has not been removed clinically. If after two sessions the patient has not obtained a complete response, an alternative therapy should be recommended (see AK paragraph for more details). II. All patients with BCC should receive two treatments, 7 days apart. A third treatment can be administered if the lesion is still clinically evident after 1 month of time. Schedule the clinical follow-up at 3 months following treatment and then every 6 months. If the lesion has not completely disappeared after three treatments, the patient should undergo alternative treatment (see BCC paragraph for more details). III. For BD , 1-4 treatments are necessary with the same protocol used for AKs and BCCs (see BD paragraph for more details).

(Continued)

TABLE 65-2—Multistep Treatment Modality of PDT (*Continued*)

STEP 6 <i>Safety and management of complications</i>	<ul style="list-style-type: none"> I. Unlike topical chemotherapy, topical PDT application is not a protracted treatment, with skin contact lasting a few hours to a day, rather than for many weeks or months. Consequently, morbidity and side effects with PDT are diminished relative to those with topical chemotherapies (5-fluorouracil, imiquimod, diclofenac sodium). II. Treatment-associated discomfort is also usually limited, with burning, pruritis, desquamation, crusting, edema, erythema, and pain diminishing within 24 hours of treatment. III. In most cases, symptoms and signs clear entirely within 1-2 weeks. IV. Usually the last manifestations to be resolved are mild erythema and edema limited to the treated region, which is followed by a minimally noticeable, dry necrosis that lasts no more than 3 weeks from the time of treatment. V. Pigment changes, where present, are temporary. VI. Scarring, ulceration, or infection are not reported. On the other hand, consistently satisfactory cosmetic results are regularly noted by investigators. VII. Decreased symptoms may be achieved with concurrent cold air analgesia at the time of initial treatment. VIII. Emollient with a bland moisturizer for several days after treatment and a strict avoidance of light for 48-72 hours after treatment is sufficient to induce rapid resolution of edema and erythema. IX. It is not yet known if PDT can induce malignant transformation. Studies have shown no carcinogenic potential or even delayed onset of neoplasia.
--	---

to determine which lesions will transform, there is a growing recognition of the role of prevention, (e.g., sunscreen), as well as the importance of treating all existing lesions.

Immunosurveillance can modulate the progression of AKs towards neoplastic lesions in single subjects. Grafted or immunocompromised patients usually have widespread AKs with a more rapid progression towards malignancy resulting in areas of field cancerization.^{15,16}

In the treatment of AKs, the new concept of “field cancerization” is very important. This concept was developed in order to explain the growth of multiple primitive tumors and their local recurrence following treatment. Recent studies at a molecular level have supported a cancerogenic model in which the development of a field of genetically modified cells plays a key role. The diagnosis and treatment of epithelial carcinomas, therefore, should not be limited to the single lesion but should also be extended to the field in which it developed, and in which genetic alterations and an initial, gradual replacement of normal cells may already be active. This consideration becomes particularly important when choosing the most appropriate AK treatment, in order to guarantee that the area surrounding the documented lesion may be adequately treated and a therapy such as PDT may be particularly well suited.¹⁷

The aims of this therapy are to eradicate clinically evident and subclinical lesions, as well as the small foci or transformed clonuses, prevent the evolution of an invasive SCC, determine a longer remission, and increase the interval between treatment sessions.

AK was the first FDA-approved indication for the use of PDT in skin cancer management and a large body of evidence now exists to support the use of photodynamic therapy for the treatment of AK (Figures 65-1a and 65-1b).

The treatment of actinic keratosis has been shown to be efficacious in large, multicenter randomized and controlled studies, with a local application of MAL, followed by red light exposure, and in two multicenter randomized, placebo-controlled studies, with ALA followed by blue

light.^{18,19} Comparative studies have demonstrated that a single MAL-PDT session is more efficacious than a placebo and as efficacious as cryotherapy or topical chemotherapy

FIGURE 65-1 (A) Diffuse grade II/III actinic keratosis of the face. (B) Result after 2 PDT sessions.

with 5-fluorouracil. The percentage of responses was much higher with two separate PDT sessions. In multicenter randomized clinical studies, the clearance rate was 69% if a single treatment session was delivered²⁰ and 83% (vs. 28.7% with the placebo),²¹ 91%^{22,23} and 89%,²⁴ respectively, if a second treatment was delivered 1 week apart. Similar results (89%) were obtained by repeating the treatment after 3 months in patients who had not attained complete remission after the first treatment session.²⁵

In all studies carried out, healing was achieved without scarring and the cosmetic effect was deemed "excellent" by the majority of patients and doctors and definitely better in comparison to cryotherapy or 5-fluorouracil.^{12,20,22–24,26–28} Compared to cryotherapy, two PDT sessions had a superior efficacy to one freeze-thaw cycle, whereas one PDT session was as effective as a double freeze-thaw cycle. Similar efficacy has been demonstrated comparing ALA-PDT with 5-FU but PDT was better tolerated.^{20,23,29}

The skin location of AKs can influence the results. MAL and also ALA-PDT are effective in clearing AKs on the face and scalp; clinical results (87% vs. 76%) and cosmetic outcome (77% vs. 50%) significantly favored PDT when compared to cryotherapy.³⁰ Cosmetic outcomes (excellent or good) of 96%, 97% and 98% were reported.^{20,23,24} Kaufmann et al.³¹ however, showed lower efficacy with MAL-PDT (78%) on the extremities when compared to cryotherapy (88%).

Four studies report the inferiority of response of acral AKs in comparison with facial lesions with weighted clearance rates of 44% (105 of 240) compared with 91% (286 of 315)^{32–35} and scalp lesions (93%) responded better than did facial (87%) lesions.³⁶

Before cream application, a careful lesion preparation with debridement using a sharp dermal curette is suggested for hyperkeratotic lesions because grade 1 lesions had slightly higher complete response rates than grade 2 lesions (89% vs. 80%), and large lesions (diameter >20 mm) had a poorer response compared to smaller lesions.³⁶ In a recent paper, Van Der Geer³⁷ shows that a pretreatment of AKs on the dorsum of the hands with diclofenac 3% gel can improve the PDT efficacy.

A reduced MAL (160 mg/g) incubation period (1 vs. 3 h), in an open, randomized, parallel-group multicenter study showed for lesions on the face and scalp, complete response rates of 78% for thin AKs and 74% for moderately thick AKs after 1 hour versus 96% and 87% after 3 hours incubation, but recurrence rates at 1 year after two treatments were similar (19% with 1 h vs. 17% with 3 h).³⁸

In a double-blinded randomized clinical trial, Wiegell et al.³⁹ highlighted nondifferences in response rates or adverse events, comparing 16% and 8% MAL-PDT to home-based daylight exposure in two symmetrical areas of 30 patients with mostly thin-grade AKs of the face or scalp (complete response rate after 3 months was 76.9% for 16% MAL and 79.5% for 8% MAL), but longer follow-up is necessary. A variety of incubation times and light sources

were used in the numerous studies in the literature but a standardized protocol exists that has shown excellent clinical and cosmetic results.^{6–8,10–14} New developments will contribute to the optimization of this treatment modality, new methods of alleviating pain are of high interest, especially when large areas are treated and a new formulation might contribute to a wider acceptance of the treatment.⁴⁰ Two randomized-controlled phase III studies have investigated the efficacy and safety of a patch (self-adhesive, 4 cm² in size with 8 mg 5-ALA per patch, 4 h application with neither lesion preparation nor bandaging) in comparison with placebo-PDT and cryosurgery in 449 patients with mild to moderate AK lesions of the head and face. The results after 12 weeks showed promising results and 5-ALA patch-PDT proved to be superior to the placebo-PDT (82% vs. 19% and 89% vs. 29%) and to cryotherapy (77%).⁴¹ The use of a 5-ALA patch could improve PDT handling because the patch is applied directly on the lesions without preparing them by curettage; occlusive dressing and light protection are not necessary. However, bigger patches to treat large areas of AK should be evaluated, considering the new concept of field cancerization.

Actinic cheilitis is a subtype of actinic keratosis localized to the lip that mainly involves the lower lip after long-term exposure to the sun. In this critical localization, common therapeutic modalities for actinic keratoses are more difficult to apply, and cure rates of many of these treatments are limited. The major therapeutic approaches include surgical excision (vermilionectomy), cryotherapy, electrodesiccation, CO₂ laser ablation, 5-fluorouracil cream, and 5% imiquimod cream. PDT could be considered a new therapeutic option. The first report about PDT treatment for actinic cheilitis using 5-ALA as topical photosensitizer was published about 9 years ago. From 1996 to date, few papers have indicated an improvement in porphyrin sensitization of the epithelial tissue by using MAL/ALA PDT in actinic cheilitis.^{24,42} From a practical perspective, MAL-PDT can be suitably and safely integrated into clinical practice. Berking et al.⁴³ observed a complete clinical cure in 47% (7/15) and a partial cure in another 47% (7/15) of the treated patients, with excellent cosmetic outcomes and patient satisfaction in most cases. More recently, Rossi et al.⁴⁴ showed the same excellent results with complete response in five patients after two PDT sessions, with a period of 14 days between the first and the second applications, and without recurrences after a 30-month follow-up period.

Severe adverse events have not been reported, however, pain, burning and/or itching in the irradiated areas during and/or sometimes after treatment, especially those localized on the face, are quite frequent and the formation of crusts is always present but these disappear in a few days with a complete and full recovery. Wiegell et al. showed that PDT with MAL was significantly less painful than with ALA but in 20 healthy patients.⁴⁵

In conclusion, PDT represents an effective therapy for thin and moderately thick AKs, particularly for

multiple lesions located on the face and scalp and superiority (in clinical results and cosmetic outcome) to cryotherapy, depending on the protocol. Efficacy is poorer for acral lesions. For very thick keratotic lesions, biopsies should be considered because, even if squamous cell carcinoma is limited to microinvasive involvement, the treatment outcome is poor.⁴⁶ It is well tolerated and noninvasive and there is no need for anesthesia.

Basal Cell Carcinoma

Comparison studies conducted in patients with basal cell carcinoma (BCC) of less than 2 mm depth have shown that PDT, but especially MAL-PDT, is more efficacious than the placebo and as efficacious as surgical excision.⁴⁷⁻⁴⁹ Other studies comparing PDT to cryosurgery for the treatment of BCC have shown at least equivalent efficacy.⁵⁰ In a recent multicenter, randomized study, comparing photodynamic therapy (topical MAL-PDT, a 3-hour incubation time, 75 J/cm² with noncoherent red light at 570-670 nm) with cryotherapy, complete clinical response rates after the 3-month follow-up were 97% for MAL-PDT and 95% for cryotherapy. After the 5-year follow-up, remission rates were almost identical with 75% for PDT and 74% for cryotherapy. Of the lesions initially cleared with MAL-PDT, 22% had recurred vs. 29% after cryotherapy, but cosmetic outcome was superior following PDT (87% vs. 49%).⁵¹

Soler et al.⁵² found no differences in cure rates (82% vs. 86%) comparing laser and a broadband light source when treating superficial BCCs with ALA-PDT, however, filtered broadband lamps or especially light-emitting diodes system offer practical advantages for clinical practice when treating multiple lesions, and are relatively inexpensive and compact. Recently, intense pulsed light (IPL) was evaluated for PDT, but there is a report of a decreased PDT effect compared to broadband light source.⁵³ In a prospective, comparative multicenter phase III study, superficial BCC treated with MAL and irradiated with noncoherent red light (570-670 nm, 75 J/cm²) was again compared to cryosurgery. The 3-year clearance after application of the two modalities was 78% and 81%, respectively.⁵⁰ Moreover, 93% clearance rates were reported when using two consecutive treatments (with a 1-week interval) of MAL-PDT with the same protocol (MAL 3 h, 75 J/cm², 570-670 nm).⁴⁹ MAL-PDT had some other important advantages over conventional therapy: repair occurred rapidly without scarring, there was no bleeding and the tolerability of the therapy was very good, especially for the treatment of multiple or broad-sized lesions, those recurring following surgery or radiotherapy or located in "surgically difficult" areas (face, especially the nose, around the ears, eyes and the genital and perineal area) although special preoperative handling is necessary. Although recurrence is difficult-to-treat, sBCC is high, PDT has shown good efficacy and is a viable alternative when surgery would be inappropriate for the patient or the physician wishes to maintain normal skin appearance.

However, there is apparently great variation in the response to photodynamic therapy of different morphologic types of BCC. PDT has the greatest activity against superficial BCC (Figures 65-2a and b), with topical ALA/MAL achieving complete clearance in some cases with a single treatment session, therefore two treatments 1 week

FIGURE 65-2 (A) BCC before PDT treatment. (B) Clinical result after 2 sessions of photodynamic therapy.

apart have been recommended in the most important guidelines.^{6-8,10-14} Lesional thickness in susceptible tumors must be less than 3 mm.

Nodular BCC, given its vertical growth and thickness, is less responsive to PDT and generally, surgical excision remains the treatment of choice. Early studies of PDT performed over a decade ago showed 3-month clearance rates for superficial BCC ranging from 55-79%, and rates of fewer than 70% for nodular BCC with ALA-PDT.⁵⁴ In a review of 12 early studies, the complete clearance rates of 826 sBCCs and 208 nBCCs with ALA-PDT were 87% and 53%, respectively.⁵⁵ A randomized double-blind controlled design comparing MAL-PDT to a placebo for nodular BCC treatment noted a 6-month clearance rate of 73% in the MAL group versus 21% in the placebo group.⁵⁶ A multi-center randomized trial of the effect of MAL on nodular BCC, compared MAL application for 3 hours occlusion prior to light exposure (570-670 nm, 75 J/cm², 50 to 200 mW/cm²) to surgical excision with a 5-mm margin. The 1-year clearance was noted to be 85% for MAL versus 98% for excision.⁵⁷

Debulking with curettage prior to PDT application was attempted to increase the cure rate of nodular BCC. Persistent BCC clearance was reported at 3 months with persistent resolution maintained at the 36-month follow-up. Treatments involved either a one-time application or a single cycle with two applications 7 days apart. The average clearance rate was 87% in superficial BCC and 53% in nodular BCC.⁵⁸

In an open-label, uncontrolled, prospective multi-center study, MAL treatment achieved 85% clearance of superficial BCC and 75% of nodular BCC at 3 months. At 24 months, the overall BCC clearance was 78% and a near 100% satisfaction with the cosmetic outcome.⁵⁹

Regarding long-term follow-up, a retrospective study examined lesions 35 months after treatment. The initial treatment protocol entailed application of MAL for 3 or 24 hours prior to light irradiation (570-670 nm, 50-200 J/cm², 100-180 mW/cm²) and, 3 years later, clearance was as high as 92% in selected cases.⁶⁰

BCC can have a more complex pathology and shape than AK. To overcome the hurdles involved with treatment of various morphologies of BCC, pretreatment regimens have been used to improve results with thicker tumors. Studies have also been published supporting the effectiveness of PDT for both superficial and nodular BCC, although it was noted that with nodular BCC, appropriate pretreatment preparation is required to enhance effectiveness, which includes removing the exophytic components for BCCs more than 2-3 mm in thickness, and a subsequent retreatment 7 days later.^{60,61}

Penetration enhancers, such as EDTA (ethylenediaminetetraacetic acid) and DMSO (dimethylsulfoxide), have also been suggested as treatment intensifiers and as intralosomal ALA administration but there are no comparative data that demonstrate increased efficacy.⁶²⁻⁶⁴

In a small prospective study, 3 weeks after debulking the tumor, 5-ALA was applied for 6 hours and then irradiated (630 nm, 120 J/cm², 100 mW/cm²), with results showing more than 90% clearance at 3 months.⁴⁸ Therapeutic use of PDT has also been assessed for morphologically complex BCC. In so-called "difficult to treat" BCC, a prospective multi-center noncomparative study found that 3 hours of MAL followed by light exposure (570-670 nm, 75 J/cm²) induced clearance for 2 years in 76% of lesions with "excellent" or "good" cosmetic outcome, rising to 94%. Truncal (88%) tumors responded better than those on the head (54%).^{65,55}

PDT may be a valuable adjuvant treatment for extensive BCC treated with Mohs' micrographic surgery and useful in the treatment of patients with nevoid basal cell carcinoma syndrome (NBCCS).^{66,67}

Pigmented BCC is yet another therapeutic challenge for PDT since the light irradiation associated with PDT does not achieve optimal light penetration into these tumors. Morpheeic BCCs should not be treated with PDT and Mohs' micrographic surgery is the gold standard.⁶⁸ PDT for BCC is generally well tolerated with transient and manageable pain and erythema in most patients.

Bowen's Disease

Bowen's disease (BD) is a form of intraepithelial SCC, and because of its superficial nature, has been one of the cutaneous malignancies for which PDT has been considered most promising. The literature suggests PDT may be a first-line treatment for SCC *in situ* that manifests as large and/or multiple lesions, is inoperable, or occurs in areas expected to heal poorly.⁶⁹ Conversely, for Bowen's disease with an invasive component, PDT may be used as an adjuvant therapy in combination with more definitive surgical treatment.⁷⁰ The therapeutic effects of topical PDT using 20% ALA or MAL have been assessed extensively in the treatment of BD with open (pilot and case series)⁷¹⁻⁸¹ and randomized comparison studies.^{77-79,82-84}

The ALA studies show initial cure rates of 88%, 94%, and 100%, the initial cure rate for MAL was 93%. At the 12-month follow-up, low rates of recurrences were seen with 15% for MAL compared to 21% for cryotherapy and 17% for 5-FU, and 0-12% for ALA compared to 10% for cryotherapy and 18% for 5-FU.^{84,85} ALA/MAL-PDT was found effective in BD, achieving good cosmesis; it had at least a similar efficacy to cryotherapy or 5-fluorouracil but with fewer adverse events. The side effects are mild-moderate, of short duration, and easily managed. A large randomized, controlled, multicenter study reported similar clearance response rates following MAL-PDT (86%), single freeze-thaw cryotherapy (82%) and a 1-month application of 5-FU (83%). Clearance rates after 2 years for MAL-PDT were 68% versus 69% with cryotherapy and 59% with fluorouracil (76%).⁸⁶

More recently, in a retrospective single-center study between 2001 and 2006, Doffoel-Hantz et al.⁸⁷ showed

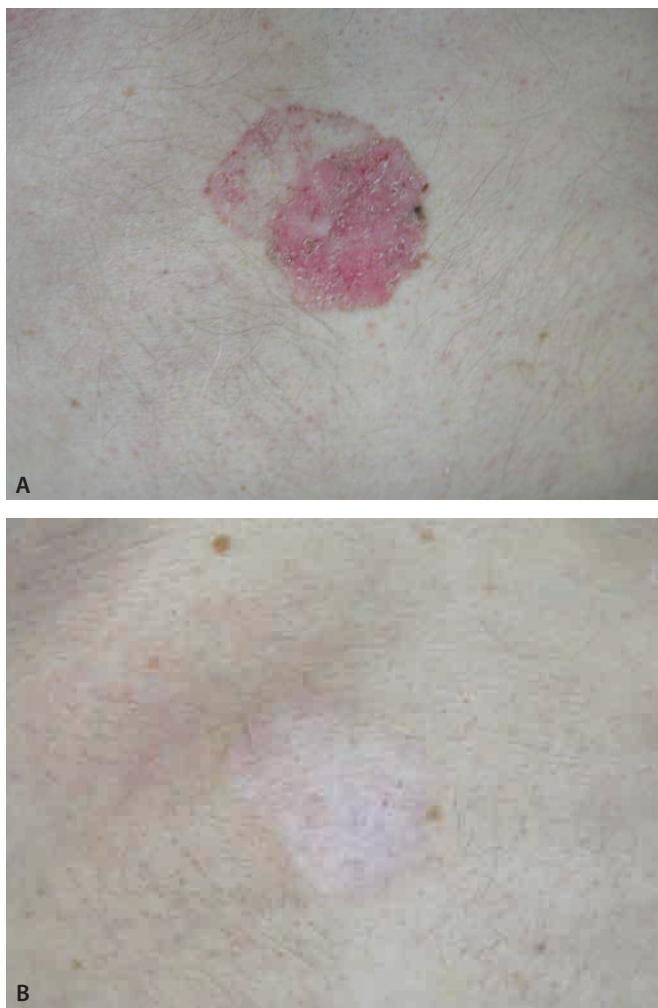

FIGURE 65-3 (A) BD before treatment. (B) Result after PDT.

in 22 patients with a total of 38 cases of BD, a complete remission in all patients at the 3-month follow-up, 100% remission rate at 6 months, 95% at 12 months, and 85% at 24 months, confirming the good efficacy of PDT in the treatment of BD in terms of both clinical remission and cosmetic results. A series of studies have shown PDT to be at least as or more effective than some other topical therapies for BD (Figures 65-3a,b).

Another multicenter randomized-controlled study comparing MAL-PDT to 5-FU and cryosurgery, found 12-month clearance rates of 74%, 65%, and 62%, respectively. The MAL treatment was thus found to be no less effective than the alternative choices.⁴⁶

Morton CA et al.⁷⁷ in an European multicenter randomized study using ALA with a 4-hour application and repeat treatment as required (630 nm, 100 J/cm², 50-90 mW/cm²) observed that there was an 82% clearance with PDT at 1 year compared to a 48% clearance in a group treated with 5-FU. This difference was statistically significant.

A prospective study using ALA with a 4-hour incubation time before light (630 nm, 100J/cm², 70 mW/cm²)

noted complete clearance of 80% of the lesions at 1 year and a suggested efficacy at least equal to that of cryosurgery.⁷⁸

The clearance rate in BD is 82-93% but long-term cure rates are highly variable, depending on different clinical thicknesses, the histologic depth of invasion, and the degree of cell atypia.⁴⁶

These results are comparable to those obtained by Britton and colleagues by using a pulsed dye laser (585 nm) instead of nonlaser light sources with ALA-PDT for the treatment of 17 patches of BD with an 82% complete clinical response.⁸⁸ Recently, a relapse rate of 17% after 64 months was reported, showing an acceptable long-term efficacy comparable with more established therapies.⁸⁹ In immunosuppressed transplant recipients, MAL-PDT was compared with 5-FU with a complete remission of 89% after PDT and 13% after 5-FU following the 6-month follow-up.⁹⁰

Topical PDT may offer advantages over existing modalities for lesions in poor healing sites such as the lower leg, and for penile, digital, and facial lesions where existing treatments have recognized limitations. Therefore, the removal of large BD, multiple lesions, or cancers in surgically "difficult" areas often causes functional loss or cosmetic disfigurements. Treatment is generally well tolerated and relevant adverse effects are not registered. Because of the appreciable nonresponse and recurrence rates, patients should be monitored closely during the first 2-3 years after PDT, which is when most lesion recurrences occur.⁹¹

Treatment of Other Cutaneous Malignancies

A recent report shows that MAL-PDT is equally effective in the treatment of Bowen's disease and microinvasive superficial squamous cell carcinoma SCC, whereas efficacy decreases for infiltrating SCC. Although ALA/MAL PDT has shown efficacy in some studies of superficial SCC, in view of its metastatic potential and high recurrence rates (up to 69%), caution is currently advised in the use of topical PDT to treat this tumor, and surgical excision is the gold standard.⁹²⁻⁹⁴

Pilot studies and cases report highlighted positive findings about the use of PDT in the treatment of early cutaneous T-cell lymphoma (CTCL), although no large-scale studies have been reported and the literature is mostly anecdotal. In the first reported treatment of CTCL, two plaque lesions were treated with 20% ALA cream followed by laser irradiation. PpIX production was demonstrated by real-time laser-induced fluorescence to have a fivefold increase in lymphoma cells over normal cells.⁹⁵ Subsequent studies investigated the possible reasons why CTCL cells could accumulate PpIX, finding that lower intracellular iron levels and competition for iron between ALA-induced heme production and cellular growth processes could be

responsible for selective accumulation and subsequent treatment effectiveness.⁹⁶ In the largest study to date, the Edstrom DW, et al. examined 10 patients with plaque and tumor-stage lesions of mycosis fungoïdes (MF), both from clinical and histologic and immunohistochemical points of view. The protocol was 6-hour occlusive medication with 20% ALA cream followed by red light irradiation of the lesions. After a single treatment, clinical remission was noted in 7 of 10 plaques, with a corresponding regression of infiltrate, lower proliferating cell levels, and a decrease in Ki-67 and CD71. The tumor lesions did not respond. The investigators concluded that there was a good clinical and histologic effect of PDT on local plaque CTCL.⁹⁷ In conclusion, PDT is shown to be useful in treating early CTCL.

Other cutaneous lymphomas, including cutaneous B-cell lymphoma (CBCL), have been treated successfully, but mainly when other treatment modalities have failed or if a particular patient cannot undergo more established therapies.⁹⁸

A retrospective study on extramammary Paget's disease (EMPD) using 5-ALA in repeat applications of 0-4 hours duration prior to light (500-790 nm, 200-400 J/cm², 18-150 mw/cm²) noted complete clearance of 31% of the treated lesions (16 cases) at 12 months. This study noted a possible relation between the likelihood of clearance and the diameter of the lesion; unfortunately, the results of this series were clouded by the inclusion of several cases that had failed prior therapy with alternate approaches.⁹⁹ For the frequent local recurrence and problems associated with extensive surgery, PDT treatment may be justified even if the results do not reach the levels obtained for BCCs, AKs, and BD.¹⁰⁰

Forman Taub,¹⁰¹ referred to a positive experience in the treatment of disseminated superficial actinic porokeratosis (DSAP), but multiple treatments seem to be necessary at the highest light dosages and longest incubations with some pretreatment of the lesions (5-fluorouracil, imiquimod, salicylic acid containing compounds, retinoids, or a combination thereof) to get consistent results. The same author, however, asserts that lesions will recur in 1 to 2 years, leading to the need for annual treatments. We are still in the field of anecdotal experience, thus it is hoped that more case reports and clinical trials will be reported in the future.

Tumor Prevention

The prevention of the incidence of neoplasms represents one of the most important clinical fields of interest in modern medicine and, regarding dermatology, PDT-based clinical action could play a great part in it. In fact, PDT chemoprevention with topical photosensitizing agents could offer a topical therapy for patients that would affect their lives for as long as they live. If PDT can be useful in photorejuvenation, in the rapid and effective treatment

of skin cancer and premalignant conditions, and definitely in the improvement of overall skin health, thus it must be a powerful means of preventing any degenerating skin condition. This could be PDT's most important feature, and continuing research is worthwhile. However, tumor prevention is important, especially for organ-transplant recipients (OTRs), and PDT has become an interesting treatment modality for dealing with NMSC among OTRs who exhibit an increased risk of developing NMSC because of their immune suppression.^{102,103}

Infectious Cutaneous Diseases

The use of PDT for treating infections started in the last few decades when the demonstrated antibiotic resistance required new antimicrobial strategies. In particular, *Staphylococcal* resistance to methicillin and closely related penicillins had been noted since the introduction of penicillase-stable β-lactam antibiotics like methicillin or cloxacillin. Inactivation of ubiquitous species of *Staphylococcus aureus* was studied using photosensitizers such as hematoporphyrin, phthalocyanine, Photofrin, and 5-ALA.

A novel porphyrin-based photosensitizer, XF73, showed high efficacy at killing methicillin-resistant *Staphylococcus aureus* (MRSA) without damage to keratinocytes or eukaryotic cells. PDT with this photosensitizer could serve to prevent MRSA infection in hospitals as well as for in burns or other open wounds.¹⁰⁴ An in vivo animal model of *Staphylococcus aureus*-infected mouse bone successfully treated with PDT, seems to suggest the future role of this technique as a good alternative treatment for osteomyelitis.¹⁰⁵

Mice with a severe combined immunodeficiency developed mucocutaneous candidiasis that was treated successfully with methylene blue and 664 nm diode laser in a dose-dependent fashion. This led the investigators to conclude that this particular PDT modality could be a possible treatment option in humans suffering from Candidiasis.¹⁰⁶ In a recent paper, an interdigital tinea pedis treated with PDT (29% ALA in Eucerin cream and 75 J/cm² red light) was completely resolved, but four of the nine patients had a recurrence of the disease within 4 weeks of therapy.¹⁰⁷

The most relevant results are reported for the treatment of viral infections, especially for immunosuppressed patients. The new indications for PDT include many types of viral infections that are related to the human papilloma virus (HPV), such as verrucae, condylomata acuminata, and periungual warts and widespread distributed as epidermodysplasia verruciformis (EV). The diagnosis is often straightforward, but the treatment is difficult and lengthy. Simple and currently employed medical treatments such as keratolytic agents, curettage, glutaraldehyde, and invasive methods such as cryotherapy or electrosurgery and laser therapy have shown good therapeutic effect.

Still, some warts remain resistant, and immunosuppressed patients or those under immunosuppressive therapies especially need new treatment modalities. Some pilot studies have demonstrated that PDT might be an additional option in the treatment of cutaneous and mucosal HPV-infections alone or combined with conventional modalities to reduce recurrence rates. Warts or condylomata treated with PDT have demonstrated good results. Other viruses not related to HPV treated with PDT that have been reported include molluscum contagiosum and herpes simplex. PDT can be used successfully to inactivate pathogens from blood products before infusion.¹⁰⁸ Treatments of verrucae are often discouraging to both the patient and clinician: therapeutic options for these clinical lesions can be found in every textbook and in numerous papers. They usually focus on the physical destruction of the lesion and treatments include cryotherapy, curettage, excision, carbon dioxide laser ablation, pulsed dye laser therapy, liquid nitrogen, electrosurgery, and the application of a variety of topical acid preparations, but many other modalities have also been reported in the literature. However, some warts remain resistant to the therapies. PDT has been reported in the treatment of recalcitrant verrucous lesions and molluscum lesions over the past 10 years, with good results. However, many papers report that the oil-in-water emulsion containing the photosensitizer was enriched with additives such as 2% ethylenediaminetetraacetic acid and 2% dimethyl sulfoxide. Dosing the correct regimen of light energy exposure and choosing the right mixture of sensitizer, ALA-PDT may represent a useful modality for recalcitrant verrucae and molluscum.^{109,110}

Its emerging antiproliferative and antimicrobial effects may have other uses in medicine and those areas of research identified appear to be promising for some new applications that may become useful in the future in clinical practice. Especially PDT may have a place in treating leg ulcers and cutaneous infections, and it may also reduce requirements for systemic antibiotics in the management of leg ulcers, thereby lessening antibiotic resistance. In 1990, it was demonstrated that *Escherichia coli* could be killed if pretreated with methylene blue and exposed to light and *Helicobacter* infection was eradicated with methylene and toluidine blue. New photosensitizers have shown a high efficacy at killing methicillin-resistant *Staphylococcus aureus* (MRSA) without damage to keratinocytes.¹⁰⁴ The investigators have postulated a use for this therapy to prevent MRSA infections in hospital, as well as for burns or other open wounds especially in immunocompromised hosts. The interesting notice is that the varied organisms tested do not seem to have been capable of mounting a defense or developing resistant strains to PDT.¹¹¹

Photodynamic inactivation of microorganisms is based on the concept that the photosensitizer should be localized, preferably in the bacteria and not in the surrounding tissue or cells, and subsequently activated by low doses of visible

light of an appropriate wavelength to generate free radicals and singlet oxygen, as mentioned above, that are toxic to the target microorganisms.

In leg ulcers, an increase from 24% to 50% oxacillin resistance in *S. aureus* and from 9% to 24% ciprofloxacin resistance in *P. aeruginosa* has been demonstrated and in superficial wounds, an increase from 24% to 36% ciprofloxacin resistance in *P. aeruginosa*.¹¹² This data demonstrates the rapid increase of antibiotic-resistant bacterial pathogens because of the systemic use of antibiotics in dermatology and highlights the importance of searching for alternatives. Photodynamic therapy could be a very important antimicrobial alternative because of the availability of a broad spectrum of photosensitizers that have shown significant antibacterial activity against gram-positive and gram-negative bacteria, for its applicability against antibiotic-resistant bacteria, independent from their antibiotic resistance pattern, which is important for the repeated treatment of chronic and/or recurrent infections. It determines the lack of induction of resistance after multiple treatments and the lack of mutagenicity as well. Recently, Clayton et al.¹¹³ showed dramatic wound improvement using 5-aminolevulinic acid-PDT, with significantly less infection and negative swabs for MRSA in a woman with a chronic recalcitrant venous leg ulceration that had been unresponsive to conventional treatments and complicated by several episodes of cellulites with eventual methicillin-resistant *Staphylococcus aureus* colonization. PDT is being clinically studied for other dermatologic infections such as leishmaniasis. Cutaneous leishmaniasis (CL) represents one of the most serious skin diseases in many developing countries and standard treatment are often ineffective, expensive, or yield poor cosmetic outcome. Pentavalent antimonial drugs are the first-line therapeutic agents but many different treatments have been described for Old World cutaneous leishmaniasis (OWCL) and some clinical reports have shown promising results by using PDT. Gardilo et al.¹¹⁴ compared the efficacy of PDT (MAL and 75 J/cm² red light) to paromomycin sulfate in 10 lesions of CL obtaining complete response in all PDT treated lesions versus two paromomycin treated plaques. Ten months after the last treatment session, there were no clinical signs of recurrence and healing and cosmetic outcome was excellent. Asilian and Davami reported,¹¹⁵ in a placebo-controlled, randomized clinical trial, complete response in 93.5% of patients treated with PDT versus 41.2% and 13.3% treated respectively with paromomycin and placebo. At the same point (2 months after the end of treatment), 100%, 64.7% and 20% of the lesions had parasitologic cure in groups 1, 2 and 3 respectively. Therefore, data are still limited, PDT cannot at this point be recommended in routine clinical practice, and additional controlled trials need to be performed in order to develop a better evidence-based approach.¹¹⁶ The study of photodynamic therapy in this area over the next several years seems to be very bright.

Inflammatory/Immunologic Disorders

The rise in antibiotic-resistant strains, reduces the future usefulness of current mainstay therapies and the use of ALA-PDT in the treatment of moderate to severe inflammatory acne vulgaris, and has received a great deal of publicity recently as a novel therapy. Although acne vulgaris therapy has been studied, using different photosensitizers, incubation times, and various light sources, the most effective treatment regimen for ALA-PDT in acne, therefore has not been established. An open randomized-controlled study by Hongcharu et al.¹¹⁷ using a broadband light source (550–700 nm), and a 3 hour ALA drug incubation time, demonstrated significant clearance of the lesions after 4 weeks that persisted up to 10 weeks in patients who received a single treatment and up to 20 weeks in those who had received multiple treatments. Adverse effects consisted of an acneiform folliculitis, postinflammatory hyperpigmentation, superficial peeling and crusting. The efficacy of ALA-PDT and the possible mechanism of action in acne were confirmed and presented by Pollock, but using a diode laser.¹¹⁸ Similar results, but at one-third of the fluence and as a single treatment were reported previously for an intractable case of acne vulgaris; the treated area remained disease-free for 8 months.¹¹⁹ A second study by the same authors of 13 patients using a single treatment of polychromatic visible light source (600–700 nm), showed good improvement (61.8% at 3 months) and a 6-month follow-up period with a reduction in new acne vulgaris lesions and they favor this light source because it is cheaper, quicker, and provides more uniform illumination than laser light.¹²⁰ Goldman first reported a short-contact (1 h drug incubation) experience with ALA, using either an IPL or blue light source in the treatment of acne vulgaris and sebaceous gland hyperplasia with “relative” clearing in all of the subjects evaluated and no PDT effect.¹²¹ Similarly, Gold reported a 60% improvement in acne (compared to 43% reported with blue light alone; eight treatments over 4 weeks) for ten patients with moderate to severe inflammatory acne vulgaris, using short contact (30-min drug incubation). The use of an IPL device with ALA in 12 individuals utilizing short contact, full-face therapy, showing a clearance of 72% in those patients with moderate to severe inflammatory acne vulgaris, and no adverse effects. These results were reviewed recently by the same authors.¹²² A study of 14 patients utilizing an IPL device in split-face acne analyses showed that the IPL plus ALA worked better than the IPL alone in treating inflammatory acne vulgaris (87.7% vs. 68.8% on PDT vs. IPL).¹²³ Recently, the use of MAL and red light was reported in a group of patients with inflammatory acne vulgaris with a 68% reduction of acne vulgaris lesions versus no change in the placebo group. All of the patients complained of moderate to severe pain during the treatment, severe erythema from the treatment along with pustular eruptions (lasting 2/3 days), and epithelial exfoliation in most patients. The same authors

showed no significant differences between MAL and ALA after a 3h incubation time in the improvement of inflammatory counts and no change in noninflamed lesions.¹²⁴

An interesting paper reporting on 2-3 PDT-treatments (at 2-week intervals) in short therapy (90 min.) showed good clinical results for the inflammatory component of acne at the 12-week follow-up in 16 patients with moderate to severe acne, by using MAL but at a 4% concentration. All the patients reported a slight but tolerable sensation of heat during the illumination, followed by slight erythema (which disappeared within 48 hours in 14 patients, and within 5 days in the two patients with phototype II skin) and modest scaling that began approximately 3 days after the treatment.¹²⁵ As in the study by Wiegell and Wulf,¹²⁴ no difference was noted in the noninflammatory lesions at the 12-week follow-up, whereas the count of inflammatory lesions had decreased on average by 66% (range 56–81%). They conclude that the use of MAL reduced to a 4% concentration, together with the application of low doses of light (10-20 J/cm²), may be useful for controlling the side effects of PDT in acne and have the same efficacy as the higher concentration but with lower costs.¹²⁵

In conclusion, researchers have been studying the effects of ALA on active acne vulgaris, and the results have been very encouraging to many in the dermatologic community, but it is evident that much of the literature data does not provide a gold standard level of clinical evidence, supporting the use of PDT in acne and controlled studies on a larger number of patients are needed in order to optimize the PDT parameter for acne, and the most effective therapy capable of balancing good efficacy with reduced side-effects.¹²⁶

There is a fair amount of literature about PDT and psoriasis that deals, in part, with the results, and, in part, with whether PDT is a practical or useful alternative for treatment. Bissonnette and colleagues¹²⁷ administered oral ALA at different concentrations (5,10,15 mg/kg) to psoriatic patients, and evaluated protoporphyrin IX (PpIX) fluorescence in lesional and normal skin, as well as in the inflammatory cells, demonstrating a ten-fold increase in fluorescence in the psoriasis over the normal skin at 3 to 5 hours after administration of a single oral dose, with the best clinical improvement observed in a patient who received 10 mg/kg. The same authors demonstrated that systemic PDT induces apoptosis in the lesional T-lymphocytes in psoriatic plaques. Boehncke et al.¹²⁸ showed that both PDT with red light and psoralen plus ultraviolet A light (PUVA) therapy exhibit a similar inhibitory effect on IL-6, TNF-a, and IL-1 secretion in a dose-dependent manner in mono-nuclear cells in psoriatic patients.

Moreover, in everyday practice, it is almost impossible to administer ALA orally because of the concerns about ALA clearance, photoexposure, persistent fluorescence, and subsequent long-lasting photosensitization of the subject. Thus, clinical trials were instituted and showed good improvement of the psoriatic plaques by using topical

5-aminolaevulinic. Even if improvement of clinical psoriasis with PDT has been observed in most studies, after a very thorough review of the literature, the major limiting factor has been the side effects during irradiation of pain and burning sensations. Other disadvantages of PDT are its treatment cost and the partial clearance of lesions. In addition, koebnerization secondary to PDT-induced inflammation was observed.¹²⁹ This highlights the need for other photosensitizers with better tolerability profiles.¹³⁰ Recently, Salm et al. evaluated in a single-blind study, the use of topical 0.1% methylene blue (MB) hydrogel and 565 mW light emitting diode at 670 nm in patients with resistant plaque psoriasis. Sixteen patients experienced complete clearance of their treated lesions, their skin appeared normal in color, texture, and pliability with no complications indicating a lack of skin sensitivity. Histopathologic examinations showed nearly normal epidermis at the end of all sessions.¹³¹ The results are encouraging for the acceptance of MB as a photosensitizer for PDT, as well as a safe and effective method for the treatment of selected cases of resistant localized psoriasis.

Localized scleroderma that is resistant to PUVA seems to respond well to PDT. Cultured keratinocytes subjected to PDT appear to produce increased levels of IL-1, TNF, and matrix metalloproteinase-1 and -3: these could be responsible for the observed antisclerotic effect of PDT.¹³² Another study found a dosimetry range that reduces tissue contraction and collagen density without damage to the keratinocytes, which may prove helpful as an adjuvant treatment for keloids.¹³³

Some authors have tried to treat alopecia areata by means of PDT, also because observations of fluorescence microscopy have revealed diffuse uptake in the epidermis and sebaceous glands.¹³⁴ However, no fluorescence was seen in the hair follicles or the inflammatory infiltrate surrounding the epidermis, and no significant results were seen, showing that PDT is not a successful therapy for alopecia areata.

An interesting study in six vitiligo patients showed a perifollicular pigmentation after the first session and almost double the repigmentation was observed after second session. At the end of the therapy, partial repigmentation of the lesions was observed in four of the six patients.¹³⁵

Photorejuvenation

Aging is a complex and multifactor process that occurs in all individuals at a variable rate, influenced by genetic, environmental, and hormonal factors, which result in several functional and aesthetic changes in the skin. It is manifested clinically by fine and coarse wrinkling, roughness, dryness, laxity, shallowness, pigmentary mottling, teleangiectasias, and, in some cases, with preneoplastic and neoplastic changes. Recently, increased physician expertise, with a view to expanding PDT applications, has introduced

its use for improving visible signs of photoaging ("photodynamic photorejuvenation"). In the initial experiments, ALA-PDT with a blue light source showed high clinical scores for photorejuvenation.¹³⁶

By combining the photothermal effects of pulsed light with the photochemical effects of PDT, an enhanced cosmetic effect has been demonstrated. Ruiz Rodriguez et al.¹³⁷ found that ALA-PDT using IPL as a light source (two treatments at a 1-month interval) resulted in higher levels of qualitative improvement of signs of photoaging in the skin. Goldman et al.¹³⁸ reported similar results with ALA-PDT by using blue light as the light source but with a 1-hour preincubation. The use of shorter incubation times permits improved patient tolerance during treatment and, consequently, fewer adverse effects.¹³⁹ A comparative study with short-contact (30-60 min) ALA-PDT with IPL activation by comparing ALA-PDT-IPL with IPL alone in thirteen patients and 3 months after the final treatment, showed a higher improvement on the ALA-PDT-IPL-treated side than on the IPL-alone side with crow's feet appearance (55% vs. 28.5%), tactile skin roughness (55% vs. 29.5%), mottled hyperpigmentation (60.3% vs. 37.2%), erythema (84.6% vs. 53.8%) and AK clearance rate, the end stage of the skin ageing process, was 78% versus 53.6%.¹⁴⁰ Similar results, comparing IPL alone and ALA-PDT-IPL, were reported by Dover et al.¹⁴¹ that shows an improvement in hyperpigmentation of 65% for IPL alone versus 95% for ALA-PDT-IPL and an improvement in fine lines of 20% for IPL alone versus 55% for ALA-PDT-IPL. Similarly, ALA-PDT alone was found to result in greater improvement in photorejuvenation than pulsed dye laser (PDL) alone.¹⁴²

More recently, an improvement in mottled hyperpigmentation, fine lines, roughness and shallowness of the skin was observed by using MAL cream under occlusion for 3 hours before exposure to 37 J/cm² of red light (2 treatments with a 1-month interval), but deep wrinkles, telangiectasias, facial erythema, and sebaceous gland hypertrophy did not change. The authors reported a novel mechanism for evaluating the effect of PDT on skin thickness using echographic analysis.¹⁴³ Similarly clinically obtained results could be evaluated by using optical coherence tomography (OCT), a noninvasive diagnostic method, which gives a histomorphology evaluation of the skin, while avoiding a biopsy and a histomorphology evaluation of the skin after 45 days from the last control.¹⁴⁴

These experiences show how the topical application of ALA/MAL acid followed by well-tolerated light sources (broadband and LED lamps or IPL), can be considered a new noninvasive procedure for the treatment, with minimal side effects, of photoaging skin, and bridges the world of medical and cosmetic dermatologic surgery.¹⁴⁵

Moreover, PDT could be combined in conjunction with other nonsurgical methods for skin rejuvenation, increasing our patients' satisfaction rate, and is relatively easy for any practicing dermatologist to adopt.¹⁴⁶

CONCLUSION

ALA/MAL PDT therapy shows great efficacy and high tolerability for the treatment of nonmelanoma skin cancer, especially in patients with large and multiple lesions, in poor-healing sites and patients immunosuppressed or with comorbidities. The advantages are linked to its selectivity for tumoral cells, its efficacy in treating field cancerization, and the capacity to preserve normal tissues that lead to very

excellent cosmetic results, thus offering a good therapeutic alternative to standard treatment options. In addition, PDT has been used widely and with great success for many off-label diseases and in cosmetic dermatology but further and larger prospective studies with long-term follow-up are required to verify its efficacy and safety in treating those conditions. In addition, possible advancements could be obtained, thanks to the future availability of new sensitizers and new treatment strategies.

What We Know

- The prevalence of AKs continues to rise throughout the world and the level of attention paid to it must be increased from a diagnostic and a preventive point of view.
- Treatment not only of the lesion but also of the “field cancerization” is part of an optimal strategy, aimed at resolving both the clinically obvious alterations, as well as those of the surrounding skin that probably is already the site of genetic alterations and of an initial, gradual replacement of normal cells.
- Among the therapeutic options available, it is advisable, when supported by the clinical situation of the lesions and the patient (numerous lesions and without serious hyperkeratotic phenomena), to favor those options whose objective is the treatment of both the lesion and the surrounding field.
- PDT is a treatment of choice for nonpigmented grade I to III actinic keratosis, especially for diffuse lesions, where it is important to treat the lesion and the cancerization field.
- PDT can be an effective noninvasive method to treat actinic cheilitis of the lower lip.
- PDT has demonstrated long-term efficacy in sBCC, offering excellent or good cosmetic outcomes and an advantage in the treatment of extensive, large, and multiple lesions.
- There is a variation in the response to PDT based on the morphology of the BCC and the thickness of the lesion.
- PDT has demonstrated efficacy in nBCC, offering excellent or good cosmetic outcomes; because of the appreciable recurrence rates, patients should be monitored closely.
- “Difficult to treat” sBCC and nBCC may benefit from pretreatment regimens including debulking and penetration enhancers.
- Given the superficial nature of SCC in situ (BD), PDT shows promise as a first-line treatment for multiple or large lesion SCC in situ, those that are inoperable or expected to heal poorly. It is particularly useful in immunosuppressed transplant recipients.
- For Bowen’s disease with an invasive component, PDT may be used as an adjuvant therapy in combination with surgical treatment.
- The ability of PDT to alter the course of other cutaneous malignancies, immunologic, inflammatory, and infective diseases is at an exploratory stage and clinicians need to combine resources and strengths to optimize PDT for these conditions.
- PDT can be considered a new noninvasive procedure for the treatment, with minimal side effects, of photoaging skin and is able to bridge the world of medical and cosmetic dermatologic surgery. PDT could be combined in conjunction with other nonsurgical methods for skin rejuvenation.
- Never forget that prevention is the best medicine.

Skin Substitutes

66

Tom Hodgkinson, M.Sc., B.Sc. (Hons), and
Ardesir Bayat, B.Sc. (Hons), M.B.B.S., M.R.C.S. (Eng, Edin), Ph.D.

INTRODUCTION

Skin has a number of diverse and complex functions including sensory perception, thermoregulation and fluid homeostasis¹. Importantly, it also represents the first physical and immunological protection the body has against both pathogenic attack and environmental stress. Chronic or acute damage to the protective barrier function of the skin leaves the body vulnerable to illness and even death. Additionally, extensive or prominent scarring due to poorly healed wounds can result in poor functionality and pain. Of equal importance is the emotional and psychological burden that cutaneous scarring can leave a patient with long after the physical wound has closed^{2,3}. Due to their nature and current treatment strategies the monetary and temporal consequences these wounds impose on the health industry is significant. For example, in the UK alone, treatment of the various forms of chronic ulcers is calculated to cost the NHS in excess of £1 billion a year⁴. Extensive thermal trauma is less common in economically developed countries, such as the UK, but remains of high importance due to the extremely painful nature of these injuries and continued high mortality rates.

Skin substitutes are now a common tool employed by surgeons and clinicians to modify the wound healing process, typically accelerate, in acute and chronic wounds. The main aim being to restore tissue integrity and improve the functional and/or aesthetic outcome of healing. The term ‘skin substitute’ encompasses a range of materials and formats. Substitutes can be categorized in terms of the origin of the scaffold material, such as biological or synthetic, whether they are cellular or acellular, and upon the origin of any cells or tissues used i.e. allogeneic, autologous or xenogeneic. These can then be further subdivided into epidermal, dermal and bilayer substitutes (Figure 66-1). As could be speculated from the number of categories involved, skin substitute design is diverse and continues to diversify as new technologies and techniques immerge and gain prominence.

The goal of skin substitutes is to recreate the anatomy, physiology, mechanical properties and aesthetic nature of the skin prior to damage. There are currently over 20 commercially produced skin substitute materials and numerous more in various stages of product development⁵. The use of these products has led to variable degrees

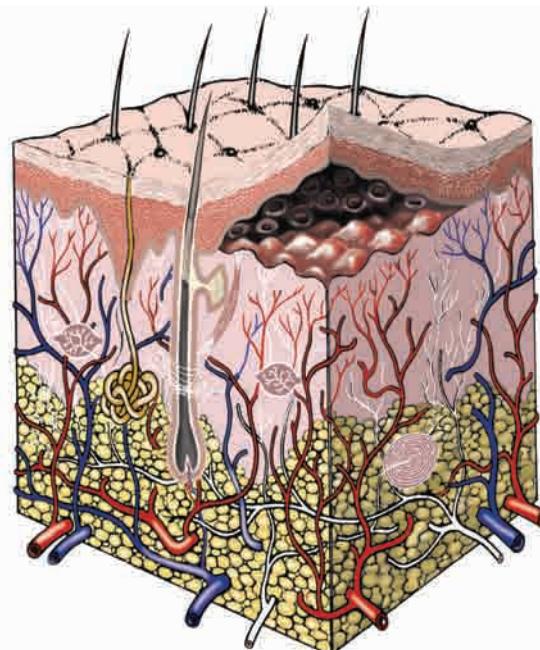

FIGURE 66-1 Structure of the skin with epidermis peeled away to illustrate the dermal papilla.

of improvement in the treatment of chronic and acute wounds.

In clinical studies into how skin substitutes modify the healing process a wide selection of experimental processes and outcomes have been used to assess success, including re-epithelialization, graft ‘take’, immuno-compatibility, mechanical properties and dermo-epidermal junction regeneration⁶. Selective presentation and analysis of these criteria often leave the reader with an incomplete picture of dermal and/or epidermal regeneration, exacerbated by divergent starting wound conditions and defect causes⁶. Often it is the qualitative morphological examination and characterization of the regenerated tissue, particularly dermis, which is crucially overlooked in favour of a quantitative assessment of wound closure, typically time.

Due to the above and the diversity of skin substitutes available there is a level of uncertainty over their effectiveness in comparison to standard wound management strategies in various applications. Evidence-based medicine categorizes the level of evidence available on the clinical efficacy of a treatment or product on the basis of the quality

TABLE 66-1—Levels of Evidence

LOE-1	Systematic review (SR) of Randomised clinical trials (RCTs) High quality RCT
LOE-2a	Low quality RCT SR of cohort studies
LOE-2b	Cohort study/Non-randomised controlled trial
LOE-3	SR of case control studies Case control study

of the research conducted. This allows a clear interpretation of available data which will ultimately aid in developing optimal clinical practice⁷ (Table 66-1). Rather than providing a comprehensive list of clinical studies, this article aims to use an evidence based approach to evaluate and highlight the important findings when using current skin substitutes on a range of cutaneous defects.

NORMAL SKIN STRUCTURE AND FUNCTION

Structurally, the skin can be divided roughly into two distinct layers; the stratified epidermis and dermis. These are separated by a specialized membrane structure termed the basement membrane. Below the dermis is a subcutaneous fatty layer called the panniculus adiposus. This is separated from the rest of the body either by a vestigial layer of striated muscle, the panniculus carnosus in a few anatomical locations or by fascia in the majority⁸ (Figure 66-1). The different structures of the epidermis and dermis reflect the different, but synergistic, roles of the layers.

The epidermis primarily acts as a barrier against environmental insult including UV radiation, air pollution, pathological microorganisms, and toxic chemicals. The squamous, layered 'bricks and mortar' structure of the epidermis reflects this. Its effectiveness largely depends on maintaining the integrity of the stratum corneum, the epidermis' outer most layer. Whilst the epidermis provides a physical barrier, the dermis provides the skin with mechanical strength, elasticity and some body heat insulation⁸. The mechanical properties of the dermis are achieved through high densities of collagen and elastin fibers, with collagen constituting around 77 % of the dry weight of the entire skin⁸. The dermis houses much of the cellular complexity of the skin and contains important structures such as hair follicles and sweat glands.

The epidermis itself is an avascular layer that is predominately composed of keratinocytes (~95 %) and

approximately 0.1-0.2 mm thick⁸. Over the majority of the body, epidermis can be further subdivided into four strata (inner-most first); stratum basale, stratum spinosum, stratum granulosum and stratum corneum. In palmoplantar epidermis a fifth transitional layer, the stratum lucidum, is seen between stratum granulosum and stratum corneum (Figure 66-2)⁸. These layers are generated by the cycling of keratinocytes undergoing gradual differentiation or maturation from the basal layer outwards towards the stratum corneum where they are eventually sloughed off (desquamated). In normal skin this entire process takes 52-75 days⁸. This continuous cycling of cells means that cells damaged by radiation, chemical or physical insult are cyclically removed, preventing the accumulation of damage that could result in disease, e.g. cancer.

Besides keratinocytes, the epidermis contains three other cell types, termed immigrant cells, that substitutes to date have failed to incorporate. These cells migrate into the skin early in development and have specialized roles in protection and sensory perception. Pigment (melanin) producing melanocytes migrate from a position adjacent to the spine during embryonic development⁹. They are found in the basal layer of the epidermis at a ratio of 1 melanocyte for every 35 keratinocytes¹⁰. Sensory Merkel cells are also found in this layer of the epidermis and are common in the glabrous palmoplantar skin and the lips. They are associated with the ends of sensory nerves and are responsible for our delicate sense of touch in the skin. Dendritic Langerhans cells are found in the stratum spinosum and are the first defense against pathogenic bacteria and viruses that attack the skin⁸. Epidermal substitutes rely on repopulation of the replaced skin by these native cells as the graft becomes integrated into the host tissue.

The basement membrane, a specialized structure situated at the dermal-epidermal junction, is a crucial component in the creation of a clinically successful skin substitute^{11,12}. Functionally, the basement membrane anchors the epithelium to the loose connective tissue of the underlying dermis, serves as a partial barrier against the exchange of cells and large molecules between the dermis and epidermis⁸, provides an mechanically scaffold that facilitates tissue repair^{6,13,14} and promotes the differentiation of endothelial precursors¹⁵. The membrane is comprised of the basal lamina, predominately a collagen type IV mesh with proteoglycan and glycoproteins attached, and the lamina reticularis. The lamina reticularis, mainly composed of fibronectin, is attached to the basal laminar through collagen type VII and fibrillin fibrils. Maintaining the connection between the two layers is achieved through adhesion molecules, such as integrins, expressed by the basal keratinocytes and papillary fibroblasts. The expression of specific sets of these molecules can be used to identify cells from this region in a mixed population. The lamina reticularis also contains elastic components which mainly consist of bundled fibrillin microfibrils. These extend into the dermis and entangle with elastin fibrils. These elastic molecules

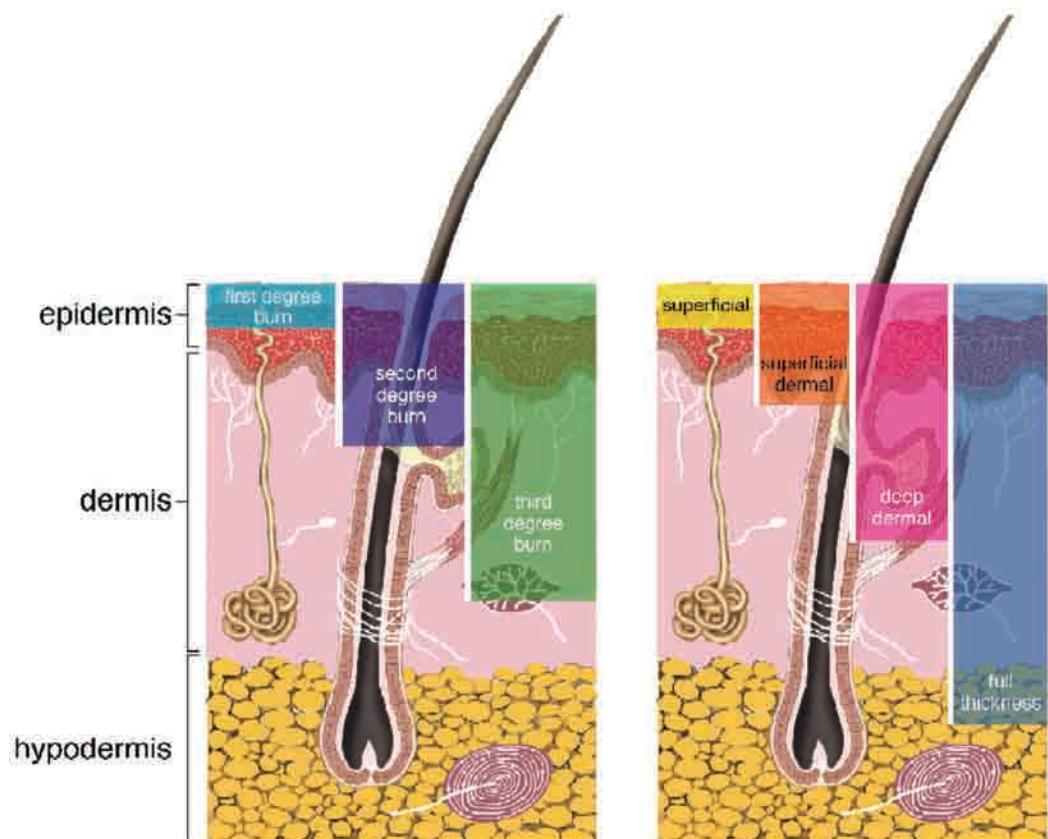

FIGURE 66-2 Classification of cutaneous wound based on depth of wound.

allow the skin to return to its original shape after stretching or contracting and importantly considerably enhance the load bearing ability of the skin⁸. The establishment of a strong epidermal-dermal junction is particularly challenging in skin injuries crossing into the dermis, thereby destroying the native basement membrane necessitating reconstruction.

Mechanical failure of the dermo-epidermal junction in wounds that incorporate engineered material is common^{6,16-21}. Any skin defect is exposed to mechanical forces that may in this case put strain on the attachment of graft to wound bed. These forces can take the form of exogenous normal and shear forces as a result of clinical handling, and shrinkage stresses e.g. due to graft contraction or dehydration^{6,22}. Various hypotheses have been postulated as to why failure at the basement membrane region is observed, particularly when using cultured epithelial autografts including lack of rete ridge formation^{6,18,23-25} and lack of a mechanically sufficient bond between sub-epidermal collagen and anchoring fibrils in the basement membrane^{19,26} (LOE-5). The latter of which is widely accepted as the responsible model⁶.

The main cellular component of the dermis is the fibroblast. These cells produce and secrete large amounts of extracellular matrix (ECM) components, mitogenic and modulatory cytokines, growth factors, and paracrine and autocrine signaling molecules²⁷. The dermis also includes mast cells and, monocytes and macrophages (histiocytes). The dermal cells are supported by a matrix that is mainly

composed of the fibrillar collagens I, III and V. These are organized spatially by the non-fibrillar collagens VI, IX and XIV²⁸. Proteoglycans and glycoproteins are also essential components while elastin provides the matrix with a degree of elasticity and flexibility.

The dermis can itself be subdivided into the papillary (uppermost) and reticular dermis. The uppermost portion of the papillary dermis undulates with the epidermis forming projections of dermis into the epidermis (papillae) and of epidermis into the dermis (Rete ridges). The reticular dermis is the thicker of the two dermal strata and contains structures such as the hair follicle root, sebaceous glands, blood vessels and sweat glands. It is composed of dense irregular connective tissue.

CUTANEOUS WOUND HEALING

Following cutaneous injury, the tissue repair events of the wound healing process have been basically separated into three overlapping stages: inflammation, tissue formation and tissue remodeling^{28,29} (Figure 66-2). Hemostasis, the first stage, is achieved through the formation of a fibrin-rich clot via platelet aggregation and blood coagulation (Figure 66-3). Platelet aggregation relies on their adherence to matricellular proteins exposed in the wound and produced by platelet activated fibroblasts through α IIb β 3 integrin³⁰. Activated platelets release α -granules and growth factors that stimulate fibroblasts to produce ECM components and construct a provisional matrix³¹. The coagulation of

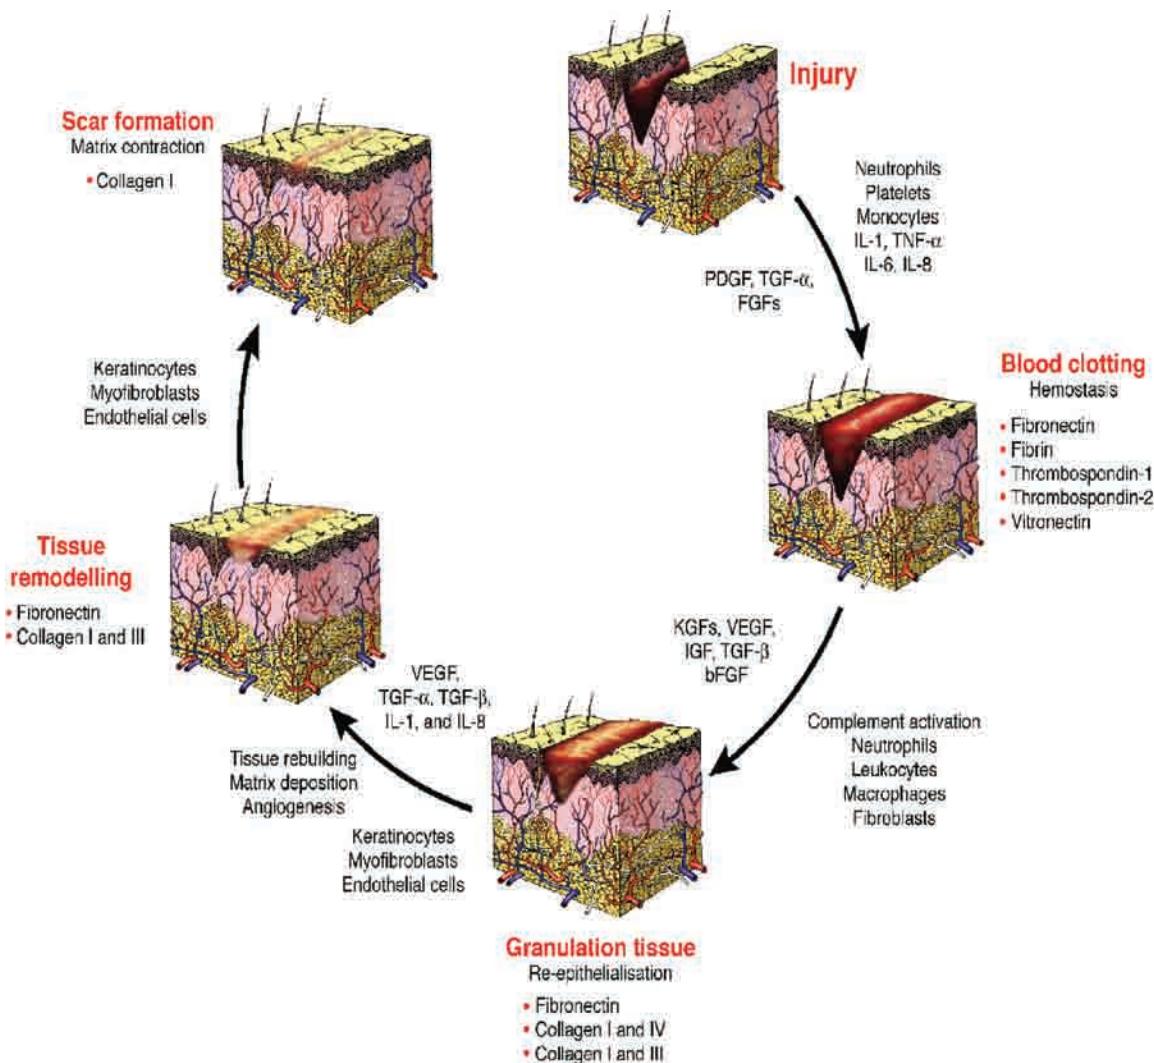

FIGURE 66-3 Wound healing stages with corresponding growth factors and cytokines.

the blood in this way also activates complement pathways, recruiting inflammatory leukocytes to the wound site^{32,33}. Infiltrating neutrophils destroy foreign particles and bacteria through the release of enzymes and reactive oxygen species³³. Monocytes mature into either inflammatory or reparative macrophages and express TGF- α , TGF- β , platelet derived growth factor (PDGF) and insulin-like growth factor-1 (IGF-1)^{33,34}. These growth factors are important for initiation of tissue formation. Prior to the addition of a skin graft or skin substitute the blood clot and provisional matrix is removed through surgical debridement. This step removes non-viable tissue from the wound and any physical barriers to cell migration that exist. This step also helps to clean the wound and prevents infection post-grafting.

The cells of the skin graft initially obtain nourishment through a process called plasmatic imbibition, where the graft takes up plasma. New blood vessels begin growing into the graft within 36 hours (capillary inosculcation) and link up with existing vasculature in the graft, effectively 'plugging' the graft into the host circulatory system³⁵.

Cells of the graft secrete matrix proteins and remodeling enzymes, such as matrix metalloproteases that reorganize the ECM, connecting the graft to the surrounding skin. Re-epithelialisation of the wound edge rapidly occurs through the migration and proliferation of activated keratinocytes originating from both graft and surrounding host tissue. The remodeling of the matricellular proteins in the wound bed begins after approximately four weeks and can continue for years after injury. The maximum collagen deposition occurs three weeks into the healing process²⁸. Following this, a dynamic equilibrium of collagen remodeling is maintained³³. The wound never attains the strength of uninjured skin and reaches its maximum strength (80 %) in twelve weeks.

In the skin, repair and regeneration can be viewed as exclusive processes in response to a wound stimulus⁶. Regeneration is recreation of tissue which is equivalent to the uninjured tissue, whereas the reparative wound closure process, outlined above, results in morphologically different, mechanically and functionally deficient tissue (scar tissue). Following full thickness skin injury collagen

fibers are orientated in parallel bundles rather than in the basket weave arrangement of uninjured skin³⁶. In post fetal skin only wounds involving the epidermis are capable of regenerative healing. Authors have proposed several theories as to why adult tissue fails to regenerate including increased contractile myofibroblasts^{37,38}, decreasing levels of hyaluronan³⁹⁻⁴¹ and lack of blastema formation due to interference from scar tissue⁴².

ASSESSING AND TREATING CUTANEOUS INJURY

In order to apply the correct treatment to a defect it is important to assess the depth of the damage, critically it is this feature that determines the quality and appearance of the resulting scar²⁸. Cutaneous wounds can be classified into four categories based on this (Figure 66-2). Epidermal injuries, characterized by erythema and minor pain, do not require surgical intervention and heal rapidly through the epidermal regeneration process. Partial thickness injuries involve the epidermis and only the most superficial layers of the dermis (previously 1st degree). These wounds are characterized by epidermal blistering and severe pain. In these wounds re-epithelialization occurs from the wound margin through the migration and proliferation of activated keratinocytes. These originate from either the remaining portions of hair follicles and sweat glands in the partially injured dermis or from the basal epidermal layer of surrounding viable tissue. Intermediate thickness injuries involve damage to the epidermis and varying depths of dermis and can be described as 'shallow' or 'deep dermal' (2nd degree) and heal in a similar way to partial thickness injuries where the extent of dermal destruction largely determines the wound healing time. These injuries often result in prominent scarring due to the extent fibroblast necrosis and matrix destruction. Full thickness injuries involve damage to the epithelium and the entire dermis can extend into the subcutaneous adipose tissue (3rd degree). These injuries are highly susceptible to infection due to the break down of desiccated tissue. Full thickness injuries are characterized by complete loss of epithelial regenerative structures in the dermis and as such heal solely by contraction with epithelialization from the edge of the wound. As such, wounds with this depth of damage as small as 4 cm in diameter will not heal effectively without surgical intervention⁴³. In addition to depth and surface area, another critical factor in the restoration of normal function and appearance of injured skin is wound closure time. The incidence of extensive, pronounced hypertrophic scars increases in proportion with the length of time to wound closure. This was demonstrated in a pediatric burn study where wounds that took longer than three weeks to heal resulted in higher proportions of hypertrophic scarring⁴⁴.

The current 'gold standard' treatment for wounds too extensive or deep to heal satisfactorily on their own

is split-thickness autografts⁴⁵. This technique involves the harvest of epidermis and superficial dermis from an undamaged site on the patient's body and grafting into the wound site. Although undoubtedly a success in terms of decreasing mortality rates amongst heavily burned patients⁴⁶ they are rarely used in the treatment of chronic injury due, in part, to the potential for creating another chronic injury at the graft harvest site. A further concern for clinicians is the scarcity of donor sites and the problems of creating permanent scars through over-harvest of graft tissue in patients with large areas of skin loss. Any graft site has the potential to become a very painful wound itself and many go on to form a minor scar with altered pigmentation when healed²⁸. Allografts and xenografts may be used to provide coverage but there are issues such as graft rejection and disease transmission as well as cultural and ethical considerations, surrounding their use⁴⁷.

NECESSITY AND PRINCIPLES OF SKIN TISSUE ENGINEERING

The development of skin substitutes arose from a clinical need to replace or vastly improve results from these current limited approaches. In the conventional treatment of acute injuries, efforts have been made to expand the area that a split thickness skin graft can cover through meshing, however this technique is problematic. Meshing involves the uniform perforation of a skin graft, allowing stretching over larger wound areas. This practice is a success in terms of decreasing mortality rates among the severely burned⁴⁸, but functional and aesthetic outcomes are poor and not comparable to split thickness autografts⁴⁸. This poor performance can be attributed to added contraction of the graft due to lack of dermis in the graft interstices⁴⁸. In addition to this contraction, epithelialization across the interstices is also slow, often resulting in a reptile-like scaly appearance to the skin. Conventional chronic wound treatments such as repeated debridement, saline-moistened gauze and pressure-relieving orthotics often fail to heal many chronic wounds. It is this group of unresponsive wounds that skin substitutes could have the biggest impact upon in reducing ongoing treatment and increasing patient quality of life.

The search for the ideal skin substitute has led to the development of numerous types of products. For these, as with all tissue engineered products, to be successful there are three main considerations that must be taken into account;

- i) Safety – Any cell culture material carries the risk of infection when implanted. Xenogeneic and allogeneic material must be carefully screened prior to use.
- ii) Clinical efficacy – It is also essential that a substitute can be demonstrated to effectively heal wounds and to not be rejected by the immune system.
- iii) Ease of use – A substitute must be easy to use in order to achieve widespread use⁴⁵.

One additional consideration that could be added to this list is cost effectiveness. A low cost to high benefit ratio is a must for a product to achieve truly widespread use. Indeed, one of the main problems with current tissue engineered skin is the high cost for little, if any, added patient benefit over other less costly alternatives.

The subsequent review of current skin substitutes is organized into categories based upon the layer of skin they are designed to regenerate. Where clinical evidence is available, an evidence based approach is used to appraise substitute healing. In some cases little clinical evidence is available and as such critical review of these products is difficult. In these cases, as informed a comment as possible is made by the authors in relation to the effectiveness of the substitute design.

EPIDERMAL SUBSTITUTES (TABLE 66-2)

Modern tissue engineered epidermal substitutes have developed from work which established that suspensions of epithelial cells could be isolated from the skin by trypsinization^{6,49,50}. Subsequently, problems with keratinocyte *in vitro* expansion were overcome by Rheinwald and Green who demonstrated *in vitro* expansion of keratinocytes, achieving an expansion factor of over 10,000 within three to four weeks culture⁵¹. From this cultured epithelial autografts (CEAs), composed of a confluent sheet of culture expanded keratinocytes obtained from a small sample of the patient's own skin were developed. Cultured epithelial autografts can be considered the earliest example of tissue engineered epidermis^{6,18}. The development of a moderately high level of epidermal maturity *in vitro* has been achieved with few difficulties⁵¹⁻⁵³.

Amongst the first clinical application of this technique was by O'Connor and co-workers in 1981 (LOE-5) to treat major burn injuries⁵⁴. In this preliminary case the authors reported that the future use of CEAs was feasible but that infection resulting in graft loss was likely to be a problem⁵⁴. Since then, CEAs have most widely been used in the treatment of major burns⁵⁵ with reported results varying from 'potentially lifesaving'^{56,57} to 'no demonstrable effect on outcome of extensively burned patients'⁵⁸. CEAs are commercially available as Epicel™, EPIBASE™ and Epidex™. Epicel™ and EPIBASE™ contain keratinocytes from the interfollicular skin on a petrolatum gauze backing. Epidex™ contains keratinocytes extracted from the outer root sheath of the hair follicle on a silicone membrane.

There exists little level 1 evidence investigating CEA use in the treatment of major burns. However, in a comprehensive review Wood and co-workers classify the limited level of evidence of studies investigating CEA use⁵⁵. The majority of identified reports were case studies (LOE-5) or case series (LOE-4) with highly variable results making the effectiveness of CEA application difficult to assess⁵⁵. Wood and co-workers do however identify seven main issues with CEA use that are consistently raised by clinicians⁵⁵.

These are 1) time taken to culture cells for clinical use 2) preparation and provision of an appropriate wound bed 3) vulnerability to infection 4) difficulty in assessing take 5) long-term fragility 6) cost of treatment and 7) quality of outcome. Some of these problems, such as vulnerability to infection, quality of outcome and long-term fragility are common amongst all current skin substitutes and tissue engineered products as a whole.

Initially, one of the main problems encountered when using autologous CEAs was the culture period of five weeks required to expand cell samples⁵⁴. Through optimization of the process this culture time was reduced to three weeks in the early 1990's⁵⁹. This delay remains detrimental to the successful treatment of patients, especially in burns patients where a stop-gap alternative is required while the substitute is constructed⁵⁵. This culture time also decreases the proportion of viable cells within lower epidermal portions of CEA sheets due to insufficient nutrient diffusion²⁸. As it is these basal cells that are the attachment site for the graft, it is essential that these cells are viable if the graft is to 'take' to the wound. Achieving the correct timing to enhance success is difficult, enough cells to partially stratify and to make handling easier is desirable but too many cells isolates basal cells from the nutrient medium, resulting in non-viable cells in the dividing, attachment cell layer. Additionally, partial stratification of CEAs *in vitro* has been investigated but has been reported to be fragile, with grafted substitutes prone to blistering owing to poor basement membrane formation⁵⁵. These issues are probable reasons behind reported unpredictable clinical outcomes with CEA use²⁸.

In an effort to reduce both culture time and improve total cell viability, some researchers endeavored to devise systems to deliver sub-confluent autologous cells to the healing wound. This resulted in the development of two main techniques, the culturing/attachment of cells *in vitro* to a carrier membrane (e.g. Laserskin™ and Myskin™), or the creation of a cell suspension which is then delivered as a spray (CellSpray™).

Of these two methods, keratinocyte suspension spray is perhaps the most intriguing due to the exceptional ease and speed of application this method could confer. The first reported clinical use of this delivery method was reported by Hunyadi and co-workers⁶⁰. In this study burn wounds and chronic leg ulcers were healed completely with the application of non-cultured keratinocyte suspensions with fibrin matrix⁶⁰. CellSpray™, a commercially available non-cultured keratinocyte suspension kit, was developed in 1994 in Australia by Fiona Wood⁶¹. In a small case series Zweifel and co-workers report the use of cell spray alone and in conjunction with split thickness autologous grafts to treat deep dermal to full thickness burns⁶². Used alone, CellSpray™ was reported to show promising results in terms of accelerated wound closure and scar quality⁶². When used in conjunction with split thickness grafts it was reported that full thickness wound healing would have

TABLE 66-2—Epidermal Substitutes

Product	Description	Application	Clinical Efficacy	LOE	Strength of Recommendation	Refs
Epicel™ and Epidex™	Confluent autologous keratinocytes from skin on petrolatum gauze backing Confluent autologous keratinocytes from hair follicles outer root sheath on silicone membrane	FTB, PTB, DU, VU	-Variable outcomes dependent on wound bed preparation and culture time. -Technically difficult to apply. -Long culture time prior to use.	2a, 2a, 2a, 1, 2b, 2a	B2	55–57, 167–169
Laserskin™ (vivoderm™)	Subconfluent autologous keratinocytes seeded on esterified laser-perforated hyaluronic acid matrix	FTB, PTB, DU, VU, Tattoo removal	-Heals diabetic foot ulcers and tattoo removal wounds more effectively than conventional treatment in low evidence studies.	4, 4, 4, 1, 4	B2	65–67, 69, 170
Myskin™	Subconfluent autologous keratinocytes seeded on specially treated silicone sheet	PTB, DU, VU	-Requires further clinical trials. -Healed diabetic ulcers that were unresponsive to conventional treatment with 6–17 applications (LOE-4). -Shows potential for treatment of burns	2b, 4, 4	C	70, 171, 71
CellSpray™	Preconfluent autologous keratinocytes delivered into a suspension for spray	PTB, DU, VU	-Accelerates wound closure most effectively in conjunction with split thickness autografts. -Possibility of fragile epidermis due to poorly formed BM	4, 4, 2a	C	61, 172, 173
Suprathel	Acellular co-polymer based on DL-Lactide (70%) but also containing trimethylenecarbonate and ε-caprolactone.	PTB/W, PTD	-Excellent flexibility and adherence to wound bed maintained throughout healing process. -Removal by polymer degradation leaves tissue intact. - Superior pain relief to conventional dressings.	2a, 2b, 2b, 3	B2	81–83, 85
Cryoskin™	Cryopreserved (viable cells) confluent allogenic keratinocytes delivered on a gel-like proprietary chemical surface	Pending Approval	-Treat burn injuries with no adverse immune reaction observed. -Similar results reported with fresh and cryopreserved keratinocytes. -Low cost alternative to other skin substitutes.	4	C	174

Strength of recommendations, (A) There is excellent evidence to support the use of the substitute. (B1) There is good evidence to support the use of the substitute. (B2) There is moderate evidence to support the use of the substitute. (C) There is poor evidence to support the use of the substitute. (D) There is fair evidence to support the rejection of the use of the substitute. (E) There is good evidence to support the rejection of the use of the substitute.

DU, Diabetic Ulcer; VU, Venous Ulcer; FTB/W, Full thickness burn/wound; PTB/W, Partial thickness burn/wound.

been substantially longer without CellSpray™ application⁶². The ease of use of this technique and the reduction in time the patient must spend in prone position were also positives commented upon by the authors⁶². Similar results are reported in a retrospective review of patients treated with CellSpray™ between 1992 and 2002 in Western Australia⁶¹. In comparison to patients receiving CEA sheets CellSpray™ patients stayed in hospital less time and showed less infection⁶¹. The author also comments that in her clinical experience, scar quality is improved in terms of color and contour with the use of CEA suspension⁶¹, although this opinion could be said to not be completely objective. Although easy to apply, authors have raised concerns when using CellSpray™ that healing rate may be inhibited by the need to form the stratified epidermis from unorganized cells at different stages along the terminal keratinocyte differentiation pathway⁶¹. In a similar way to CEAs, the epidermis that is formed may be fragile and vulnerable to mechanical stress due to a poorly formed basement membrane^{63,64}.

Naturally occurring extra cellular molecules in the epidermis often require modification before they are suitable for supporting keratinocyte growth and transport due to poor mechanical properties. One example, Laserskin™, utilizes a three-dimensional heavily cross-linked hyaluronan-based matrix which is perforated by laser and contains pre-confluent autologous keratinocytes⁶⁵⁻⁶⁷. Hyaluronan is a glucosaminoglycan (GAG) found ubiquitously in ECM throughout the body and known to be involved in cell proliferation, migration and angiogenesis⁶⁸. Initial success has been observed with this material in a pilot study involving 14 patients with diabetic foot ulcers that resisted conventional treatment for at least six months⁶⁷. Laserskin™ application resulted in 11 of the 14 wounds closing within a mean time period of 41 ± 18 days⁶⁷. In another study investigating Laserskin™ use in patients that have undergone tattoo removal, the substitute was seen to be advantageous as a single application for a 2-week period was sufficient during healing⁶⁹.

Myskin™ makes use of a treated silicone sheet to transfer subconfluent autologous keratinocytes to the wound bed. The potential of Myskin™ to be a successful tool in the treatment of chronic diabetic neuropathic ulcers has been demonstrated in a series of clinical trials. The ulcers in the trials had previously been unresponsive to conventional therapy. But Following 6 to 17 applications of Myskin™, complete healing was achieved in 67 % of ulcers, whilst a reduction in size was observed in one of those remaining. In this case, only one of the ulcers failed to respond after 24 applications of Myskin™⁷⁰. No recurrences in the healed ulcers were observed after six months follow up. Myskin™ has also demonstrated potential in the treatment of acute burn injuries where application of the substitute healed two injuries on two patients successfully⁷¹.

Whilst the transfer of sub-confluent autologous cells is advantageous in terms of time to treatment in order for a similar number of cells to be delivered larger initial

samples are needed. In addition to this, there is a consistent problem with graft fragility due to a lack of epidermal stratification and poor basement membrane assembly and organisation. It would appear that for these delivery methods to achieve their potential a way to enhance the grafted cells characteristics must be employed. This could be through the incorporation of growth factors or cytokines into carrier matrices or suspension media, or alternatively through genetic modification of cells. Future developments and current advances will be discussed in greater detail later within this review.

An alternative to transferring sub-confluent keratinocytes is to utilize the structure of formed epidermis by transferring fresh or cryopreserved split-thickness donor skin. Although not strictly tissue engineered skin this source of graft skin is worthy of note. Recently, techniques have been developed for the large scale production of high quality cryopreserved epithelium⁷²⁻⁷⁴. In a comparative study, cryopreserved keratinocytes were demonstrated to treat wounds faster and more efficiently than conventional hydrocolloid dressings⁷⁵. Additionally, comparable results between fresh and cryopreserved keratinocytes have been reported, suggesting that cryopreservation and storage does not damage the wound-healing potential of the cells⁷⁵. Cryoskin™ (previously CryoCeal™) consists of several layers of keratinocytes on an inert nylon gauze, obtained from heart-beating multi-organ donors and stored in cryopreservation medium⁷⁶. The use of Cryoskin™ in combination with meshed autologous grafts for the treatment of burn injuries was investigated in a trial involving 117 patients⁷⁷. The study reported that no adverse immune reaction to the allogeneic material was observed⁷⁷. The use of cryopreserved keratinocytes in the treatment of chronic leg ulcers has been shown to decrease the time to complete wound closure in several independent studies^{76,78-80}. Authors additionally mention that the use of cryopreserved keratinocytes has the advantage of being simple and safe to use whilst decreasing patient discomfort for a lower cost than other skin substitutes^{76,79}.

Of note is the recent development of the acellular epidermal substitute Suprathel. Although the synthetic scaffold may be considered a wound dressing it has shown promise in treating partial thickness burn injuries and split thickness skin graft donor sites^{81,82}. The substitute is composed of a copolymer which is >70% DL-lactide but also contains trimethylene carbonate and e-caprolactone and is designed to mimic the properties of natural ECM. The production of Suprathel from monomer polymerization by a melt procedure, dissolution in organic solvents, phase inversion and freeze drying results in a highly porous (80 %) membrane, with pore sizes ranging from 2-50 µm⁸². The material itself has several interesting properties that make it ideal as an epidermal substitute. Firstly, it has high elasticity and flexibility at body temperature, allowing the substitute to closely fit to the wound bed. Secondly, it is permeable to water preventing the build up

of fluid. Thirdly, it has been found to be transparent when applied to the wound, allowing visual inspection. Perhaps most innovative is the process of detachment from the healed wound through polymer molecular weight decrease, leaving the fully epithelialized tissue intact.⁸²

Suprathel was approved as a CE class III medical device in 2004 based on the results of a bicentric, randomized, non-blinded clinical study⁸³. In this study, Suprathel was compared intra-individually with paraffin guaze and Omiderm for use in the treatment of split thickness donor sites and partial thickness burns respectively. For the first indication, a major concern is the reduction in pain following treatment. Using the Visual Pain Analog Scale (VAS) the average cumulative pain score for 10 days following application was 9 for Suprathel and 21.7 for paraffin⁸³. The authors report that due to the high significance of the results the study was discontinued after 20 patients⁸³. In comparison with Omiderm for the treatment of partial thickness burns using the VAS scale 19 patients reported higher pain scores for Omiderm, three reported the same levels of pain for both dressings and two reported higher pain for Suprathel treated areas. No significant difference in healing time was reported between Omiderm and Suprathel treated wounds⁸³. Although a significantly better VAS score was reported for Suprathel, the non-blind nature of this trial could have affected the results⁸³. Omiderm has cheaper material costs than Suprathel, however, further studies should be conducted to confirm the significant pain reduction in wounds treated with Suprathel. Additionally, Suprathel is reported to maintain plasticity throughout the healing process, whereas Omiderm has been shown to form a crust when in contact with wound exudates⁸⁴. Suprathel should then be considered for areas that require added flexibility, such as the hands, this is supported by the experiences of Uhlig and co-workers in a single centre study involving 109 patients⁸⁵. In such cases, the added cost of this material may be considered to be worthwhile.

DERMAL SUBSTITUTES (TABLE 66-3)

The dermis provides the mechanical strength to the skin and structural support to the epidermal barrier. Many of the problems encountered upon application of epidermal substitute – e.g. contraction, fragility, poor take – can be exacerbated by the absence of a suitable dermal layer⁸⁶. One study reported that only 15 % of cases resulted in successful ‘take’ of grafts on unprepared chronic granulation tissue²¹. Since a speedy wound closure is of the high importance, it is desirable to construct a functional, well vascularized dermis as quickly as possible. This dermis provides not only mechanical support to the overlying epidermis but also to supply the avascular epidermis with nutrients. To accomplish this both acellular scaffolds (constructed to allow rapid host cell invasion from the surrounding viable tissue) and cellular scaffolds (replacing damaged or dead tissue directly with viable cells) have been devised.

The vast majority of these porous matrix materials are designed to imitate natural extra cellular matrix (ECM). When transplanted into the patient this matrix is intended to allow rapid cell proliferation and migration, rather than the cells first having to construct their own matrix. A good scaffold material should be strong but flexible, degrade at a rate that is equal to construction of replacement matrix by cells, contain adequate numbers of cell attachment sites and allow rapid cell migration and proliferation.

In designing a scaffold for engineering dermis, emulating the properties of natural matrix may be beneficial. However, the goal of a dermal substitute is accelerated neotissuegenesis, through a process that need not exactly follow that of development or the normal wound healing program. Therefore it may not be necessary or optimal for a successful skin substitute to mimic natural matrix exactly. Rather the manipulation of natural or artificial materials to construct optimal scaffold features could be advantageous. Many products utilize processed natural dermal matrices from various xenogeneic and allogeneic sources. The idea is that a decellularised matrix should retain the properties and matrix bound bioactive molecules present in the natural dermis. This should create a favourable environment for rapid cell migration and proliferation within the substitute. However, mature matrix tissue like this once processed with harsh de-cellularisation techniques to reduce immunogenicity often does not possess the fragile highly interconnected macro- or micro-pore structures needed to allow quick and uniform cell population. Furthermore, useful growth factors bound to the matrix are likely to be denatured or lost during washing. Conversely, mild procedures often fail to completely remove cell fragments, leading to immune reaction. Other substitutes utilize re-organized biomaterials from various sources with collagen the most common choice, perhaps due to its strength, availability and natural prevalence. Alternatively synthetic materials are common either as an additional component to aid stability to the biological component or as the main scaffold material themselves.

At least five of the currently available commercial dermal substitutes are constructed, in part, from xenogeneic material. More specifically these xenogeneic components consist of dermal matrix proteins from bovine and porcine sources. These proteins bear high structural similarity to their human equivalents, providing a cheaper and more easily extracted alternative to their human equivalent. Further to this, their structural homology means that cell adhesion sites and motifs are conserved or closely resemble those seen in human dermal matrix. Due to graft rejection and disease transmission issues xenogeneic substitutes do not contain xenogeneic cellular material.

Decellularized porcine small intestinal submucosa is one material that has been employed in the development of the commercially available substitutes OaSis™ and FortaFlex™. FortaFlex™ is intended to provide a template that can be remodeled by invading cells but has been the

TABLE 66-3—Dermal Substitutes

Product	Description	Application	Clinical Efficacy	LOE	Strength of Recommendation	Refs
Dermagraft™	Cryopreserved (viable cells) allogeneic fibroblast-derived dermal matrix	DU, VU, FTB/W, PTB/W,	-Take rate is inferior in patients treated in conjunction with autograft (LOE-4). -DFU treated with more Dermagraft applied more often heal quicker. -Performance variable – linked to ratio of viable fibroblasts after cryopreservation.	3, 1, 4, 3, 4, 1	B2	122–124, 47, 125, 175
Transcyte™	Similar to Dermagraft, but with a silicone membrane as temporary epidermal barrier	FTW/B, PTW/B,	-More effective than conventional treatment. -Reepithelialization quicker when using TransCyte over Biobrane in burn injuries (LOE-5)	3, 4, 3, 1	B2	47, 130, 132, 176
Alloderm™	Acellular (lyophilized) allogeneic dermis	FTW/B, PTW/B	-Results dependent on technical ability of clinician applying substitute. -Allows use of ultra-thin thickness autograft	3, 4, 4, 4	C	118–120, 177
Oasis™	Acellular porcine small intestine submucosa	FTW/B, PTW/B, VU, DU	-Reported to treat venous/arterial ulcers more effectively than Hyaloskin (LOE-4) -Accelerated healing of graft donor sites and decreased patient pain.	4, 2a, 2a, 3, 4, 4	B2	88–93
EZ-Derm™	Aldehyde crosslinked porcine dermal collagen	FTW/B, PTW/B	-Good short term capability (3 days) in the treatment of burns. -Meshed substitute leaves imprint and should not be used for facial burns.	4, 5, 4, 5	C	94, 96–98
ICX-PRO™	Active allogeneic human fibroblasts in a fibrin-based gel matrix	DU, VU, FTB/W	-Currently in Phase II clinical trials.	5	C	140
Biobrane™	Porcine collagen chemically bound to silicone/nylon membrane	FTW/B, PTB/W	-Widely utilized for the treatment of superficial and partial thickness burns, in particular those involving joints, large surface area and hands. -Has been reported to leave imprint when meshed.	3, 4, 5, 4, 5, 4, 5, 5, 5, 5, 5, 4, 4,	B2	95, 100, 102–113
Integra™	Acellular temporary silicone epidermal substitute over dermal scaffold made of bovine collagen and chondroitin-6-sulphate	FTB/W, PTB/W	-Most widely utilized dermal replacement for extensively burned patients. Also found application in chronic wounds. -Prone to infection and requires slow two stage procedure and autograft. -Good aesthetic and functional outcomes when used properly.	4, 4, 5, 5, 5, 5, 5	B1	28, 178– 180, 134, 137–139
Matriderm™	Acellular fibroblasts made with bovine collagen types I, III, V and elastin	FTB/W, PTB/W	-Effective take with one step procedure. -Effective particularly on hand burns, where elasticity of matrix is benefit.	3, 4, 4, 5, 5	B2	114–117, 181
ICX-SKN™	Allogeneic fibroblasts set in a natural human collagen matrix	Phase II trial pending	-Evidence that ICX-SKN is safe for human use.	5	C	141

DU, Diabetic Ulcer; VU, Venous Ulcer; FTB/W, Full thickness burn/wound; PTB/W, Partial thickness burn/wound.

subject of few clinical trials⁸⁷. Likewise, although the OaSis™ substitute was approved by the FDA in 2000 for use in the treatment of chronic ulcers and burns only a small number of articles have been published into the clinical efficacy of the substitute⁸⁸⁻⁹³. Within these studies, OaSis™ has been mainly utilized for the treatment of chronic ulcers, where it has shown some success.

In a randomized clinical trial for the treatment of venous leg ulcers weekly application of OaSis™ led to healing in 55 % of patients⁹². Similar healing potential was reported by a small multicenter trial comparing OaSis™ and Regranex Gel in the treatment diabetic ulcers⁸⁹. Although this trial was too small to prove statistical significance, the healing of OaSis™ treated wounds was as at least as effective as Regranex Gel after 12 weeks treatment⁸⁹. OaSis™ has also been reported to be superior to another substitute, Hyaloskin™, in the treatment of mixed arterial/venous ulcers⁹⁰. In this study, OaSis™ also was reported to be advantageous in terms of pain relief, patient comfort and time (for dressing changes)⁹⁰. In another application, OaSis™ was investigated as a dressing for split-thickness graft donor sites in 131 patients. Accelerated healing was observed with all but two of the wounds healing in one to three weeks and patients reporting decreased pain, that the authors attribute to nerve-end coverage by the matrix⁹¹. Larger double-blinded randomised clinical trials are needed to prove that the use of this xenogeneic material is an effective alternative treatment.

Instead of utilizing intact matrices several other substitutes employ reconstituted xenogeneic matricellular proteins in some form. These have found more widespread clinical application, with the most prominent of these being EZ-Derm™, Biobrane™ and Matriderm™. EZ-Derm™ is composed of an aldehyde-crosslinked porcine dermal collagen. Aldehyde-treatment in this way decreases the antigenicity of the substitute whilst enhancing its' structural integrity⁹⁴. Biobrane™ is porcine collagen which has been chemically bound to a silicone/nylon membrane first developed by Woodruff in 1979⁹⁵. Matriderm™ is a scaffold composed of bovine collagens types I, III and V, along with elastin.

The efficacy of the similar, porcine collagen based substitutes, EZ-DERM™ and Biobrane™ was compared in a retrospective review of 52 burns patients⁹⁴. The two substitutes both decreased exudative protein loss, protected underlying vessels and nerves (decreasing pain) and promoted the maturation of granulation tissue for autografting to similar level⁹⁴. The authors noted that Biobrane™ adhered to the wound bed with greater success and was more suited to longer term grafting (up to 10 days) in comparison to the shorter term capability of EZ-DERM™ (3 days), which does not incorporate into the wound and must be removed⁹⁴.

The use of these porcine collagen scaffolds has been linked to mesh imprinting of healed wounds if left on the wound for extended periods. For example, meshed EZ-DERM™ in the treatment of facial burns has reportedly

led to scarring⁹⁶. Similarly, the use of Biobrane™ has also led to scarring corresponding to the pores in the substitute⁹⁷. However, authors have since reported unmeshed EZ-DERM™ substitutes do not leave an imprint on healing even if left on the wound for up to 20 days⁹⁸.

The efficacy of Biobrane against more conventional dressings has also been investigated in a randomized prospective study comparing Biobrane and Duoderm hydrocolloid dressing for the treatment of intermediate burns in pediatric patients. Biobrane was found to show no therapeutic advantage despite significantly higher treatment costs⁹⁹. Having said this, a small randomized trial involving second degree pediatric burns showed that Biobrane performed significantly better than topical 1% silver sulfadiazine. The authors report that Biobrane reduces hospital stay, pain, the amount of pain relief medication needed and wound healing time significantly over the conventional treatment¹⁰⁰. These and other studies are good examples of how in some cases although skin substitutes are superior to topical treatments, their performance may not be significantly better than simpler, cheaper dressings¹⁰¹.

Despite reports of imprinting and comparable performance to cheaper alternatives, Biobrane™ remains a widely utilized substitute in treatment of superficial and moderate depth partial thickness burns^{100,102-105}. In particular it has found a niche in the treatment of burns with a large surface area¹⁰⁶, involving joints¹⁰⁷ and the hands^{108,109} due to the flexibility it confers to the healed wound. For these applications, it has again been shown to be effective in the reduction of pain and healing time in comparison to conventional treatment¹¹⁰⁻¹¹³.

Matriderm™, which utilizes bovine collagens coated with α -elastin hydrolysate, was developed as a one-stage alternative to other two-stage substitutes for application in the treatment of burns. In a one-stage process an epidermal layer, either epidermal substitute or graft, is directly applied onto the dermal replacement or graft. This one-stage approach is facilitated by the thinness of Matriderm™ and the diffusion of nutrients through it. A one-stage process allows speedier coverage of the wound bed but has not been previously favored due to poor take on the low quality dermis (or lack thereof) of the grafted dermal scaffold¹¹⁴. However, it has been shown that even when using a one step process, the take of Matriderm™ is unaffected in clinical trials (overall take rate 97 %)^{114,115}. Matriderm™ has particularly shown promise in the treatment of burns to the hands and areas requiring flexibility^{114,116,117}. Restoring function after injury is of key importance in hand injuries for the restitution of a quality of life. The elastin present in the Matriderm™ matrix may provide the flexibility needed to return freedom of movement to the healed wounds¹¹⁴.

In parallel to the development of these xenogeneic substitutes, several similar substitutes have been constructed using allogenic material, and, allogeneic plus synthetic material. AlloDerm™ and Repliform™ are both

based on acellular allogeneic dermis, although AlloDerm™ is lyophilized whilst Repliform™ is not⁵. Cymetra™ also contains acellular human dermal matrix, obtained from cadaver skin and processed into micronized particles⁵.

In a comparative study, Wainwright investigated AlloDerm™ in combination with meshed autograft and meshed autograft alone, for the treatment of full thickness wounds in two patients¹¹⁸. Qualitative assessment of elasticity and cosmesis favoured AlloDerm™ autograft combination¹¹⁸. This small study was expanded on in a multicentre study involving 67 patients and ten centres¹¹⁹. The results from this study are difficult to interpret. The authors state that the failure of centres to follow the approved methodology for the use of AlloDerm™ resulted in poor results¹¹⁹. However, the authors do state that when using AlloDerm™ it is possible to use a thinner autograft, which is beneficial for the healing of donor sites¹¹⁹. Another study comparing AlloDerm™ in combination with a thin autograft and thicker autograft alone to treat burns to the hands and feet was reported by Lattari and co-workers¹²⁰. Wounds were assessed for cosmetic appearance and functionality, with AlloDerm™ wounds and autograft-only wounds highly similar to each other as assessed by a blinded observer using the Vancouver Scar Scoring system¹²⁰.

Two of the most widely studied dermal substitutes, Dermagraft™ and TransCyt™, have similar compositions and contain a cellular component. They both include cryopreserved (viable) allogeneic fibroblasts grown in a polyglactin 910 or polyglycolic acid bioabsorbable mesh. This material allows the fibroblasts to deposit extra cellular proteins and negates the use of exogenous collagens¹²¹.

Dermagraft™ has been investigated for use in the treatment of both acute and chronic injuries. In a clinical trial involving 17 full thickness burns patients Dermagraft™ in conjunction with a split thickness meshed autograft was compared to meshed autograft alone¹²². However, the findings of this study indicated that take rate was inferior in patients treated with both Dermagraft™ and an autograft, in contrast to other dermal substitutes¹²². This indicates that perhaps other materials should be considered for this indication rather than Dermagraft™.

However, Dermagraft™ has found application for the treatment of chronic diabetic foot ulcers. In a controlled trial involving 50 patients it was reported that wounds healed faster and more completely when a greater amount of Dermagraft™ was applied and when it was applied more frequently¹²³. This result was supported by a larger randomized, controlled series, involving 281 patients with diabetic foot ulcers¹²⁴. A total of 50.8 percent of the dermal replacement-treated group exhibited complete wound healing at 12 weeks compared to 31.7 % in the control group¹²⁴. However, Dermagraft™ use in for this application is not without issue, with the main problem being inter-graft variation in levels of cell viability. The performance of the substitute for healing chronic wounds has been shown to be dependent on the viability of the fibroblasts within

it¹²⁵. If viability is severely decreased, for example through the cryopreservation process during manufacture, then the substitute fails to heal effectively¹²⁵. This data does suggest that cytokine, growth factor and ECM secretion could be responsible for the healing properties observed, although this is not the way the product was initially designed to work^{125,126}.

TransCyt™ is designed as a temporary biosynthetic covering and is composed of a semi-permeable silicone membrane and neonatal fibroblasts cultured on a porcine collagen coated nylon mesh¹²⁷. It has been used as a temporary covering for wounds prior to autografting, or in wounds that do not require autograft^{47,127}. TransCyt™ has been shown to out perform conventional treatments (in conjunction with silver sulfadiazine and topical antibiotics)¹²⁷⁻¹³⁰. The use of TransCyt™ in these cases resulted in a more rapid healing time, lower amounts of infection¹³⁰, better wound closure and scar severity and less dressing changes^{128,129}. The authors of these studies report improved wound management including decreased pain and length of stay¹³¹. In a larger study (n = 110), burns patients who treated with dermabrasion and TransCyt™ were 6 % less likely to require autograft¹³². In another randomized comparative trial 33 burns patients (58 wounds) were treated with Silvazine (silver sulphadiazine cream with 0.2 % chlorhexidine), Biobrane™ or TransCyt™. Mean reepithelialization time when using TransCyt was shorter (7.5 days) compared to either Biobrane™ or Silvazine (9.5 days and 11.2 days respectively) ($p < 0.001$). Wounds treated with either of the skin substitutes tested in this study required significantly fewer autografts than those treated conventionally (24 % vs. 17 % (Biobrane™) and 5 % (TransCyt™)). However, the authors neglect to describe the randomization process or how the assessment of epithelialization was made, possibly compromising the results.

Integra™ is amongst the most widely used synthetic dermal substitutes and was first described by Yannas and Burke in 1980¹³³. It is composed of bovine type I collagen and shark chondroitin-6-sulfate with a temporary silicone membrane to restore epidermal barrier function. Integra™ is normally applied to the freshly excised wound bed where the collagen component integrates over a three to four month period²⁸. The collagen component of the Integra™ is designed with a pore size (20-120 μm) that promotes autologous cell migration whilst maintaining enough surface area for cell attachment¹³⁴. Once the dermal component is fully integrated (15-20 days) the silicone epidermal portion is removed and a ultra-thin split autograft is applied²⁸. Integra™ has shown success in the treatment of full thickness thermal and non-thermal trauma and chronic ulcers. This material has several advantageous characteristics including long shelf life, straightforward handling, positive aesthetic and functional outcomes and low incidences of contraction and pronounced scarring^{48,135}.

Having said this, the use of Integra™ has a number of negatives including a steep learning curve for clinicians,

closely associated with graft success. Additionally, it is essential when using Integra™ to thoroughly surgically debride the wound bed for the substitute to "take". A further limitation of this substitute design is the need for a second surgical procedure and the eventual use of an autograft, albeit a super thin one. Aside from these technical limitations, there are two additional main problems with Integra™. The first of these is the long re-vascularisation period (10-15 days) required for the neo-dermis and the second is the high reported incidence of infection, although this does appear to decrease with clinical experience¹³⁶.

Efforts have been made to incorporate Integra™ into a single stage graft procedure. A single case study reports the successful combination of Integra™ with a CEA sheet, with little success¹³⁷. An alternative approach that has been investigated is the pre-seeding of Integra™ with either cultured autologous keratinocytes prior to grafting¹³⁸ or freshly isolated cell suspension¹³⁹. Initially this technique seemed promising with successful animal studies showing epithelial coverage after ten days¹³⁸. In a clinical trial an epidermal layer was produced after 3 weeks but quickly deteriorated suggesting that the cells were unable to maintain the required epidermal cell turnover²⁸. Seeding Integra™ with epidermal stem cells could be a possible way to prevent this deterioration.

The limited success of these older skin substitutes has driven the development of the second generation of engineered skin. ICX-PRO™ and ICX-SKN™, both developed by Intercytes, are such substitutes. They, and others, have been designed to build upon the valuable lessons learnt from the likes of Dermagraft™, Apligraf™ and TransCyte™¹⁴⁰. As such they are intended to be the most cost effective and easiest to use substitute available to date. One area in which ICX-PRO™ has succeeded is to decrease its assembly time and has a much shorter manufacturing cycle than other substitutes, taking 1 day to manufacture¹⁴⁰. It is delivered in an easy to use package and can be stored for 21 days in a refrigerator¹⁴⁰. ICX-PRO™ is currently involved in phase III clinical trials¹⁴⁰.

The focus of the ICX-SKN™ substitute has been to generate a collagenous matrix stable enough to withstand the harsh environment of the wound bed¹⁴⁰. It contains neonatal foreskin-derived dermal fibroblasts seeded into autosynthesised collagen and other human plasma proteins, including fibrin and fibronectin¹⁴¹. Effectively this reconstructs the wound bed environment *in vitro*. This process of collagen autosynthesis rather than degradation and reassembly collagen leads to a more robust structure and slower degradation once implanted¹⁴¹. A small clinical trial demonstrated the safety of this substitute and showed re-epithelialization of the wounds¹⁴¹. The exact mechanism of action of ICX-SKN™ in this trial is not known and requires further investigation.

BILAYER SUBSTITUTES (TABLE 66-4)

Bilayer substitutes can be considered the most advanced class of skin substitutes in terms of structural mimicry of

natural skin as they contain both epidermal and dermal layers. Unfortunately this complexity also means that they are the most expensive substitutes on the market and as such must exhibit a significant clinical advantage over their less advanced counterparts; the dermal and epidermal substitutes, to justify utilization. Most bilayer substitutes incorporate an allogeneic cellular component that allows the product to be produced with less delay.

Some products do incorporate autologous cells, PermaDerm™ is one such product and is similar in design to Integra™. Although recently sold to Lonza in 2007 there are currently no clinical trials involving PermaDerm™. Orcel™ and Apligraf™ (Graftskin) are also based on a similar model to each other. Apligraf™ is constructed of human fibroblasts seeded onto a bovine type I collagen scaffold. This fibroblast/collagen mixture then undergoes fibrillogenesis and forms a gel. The collagen fibers condense, mediated by the fibroblasts, resulting in a dense lattice¹²⁶. Keratinocytes are then seeded onto the lattice and allowed to differentiate and form a stratified epidermis with a functional stratum corneum¹²⁶. The cells used in the substitute can be allogeneic, autologous or a combination of the two¹²⁷. Upon application this composition gives Apligraf™ a similar appearance and handling characteristics to that of native skin¹⁴². As with other substitutes containing metabolically active viable cells these products have a shelf-life of just five days at room temperature¹²⁷.

Apligraf™ was originally designed as an organotypic skin substitute but its allogeneic cell component has been reported to be completely removed by one to two months after implantation, although no acute immune rejection is observed^{143,144}. Despite this, the substitute has been shown to exert some healing potential, in effect acting as a biologically active temporary dressing. Apligraf™ achieves this through the delivery of cytokines (Interferon α, Interferon β, Interleukins 1, 6 and 8), growth factors (e.g. platelet-derived growth factor (PDGF) and extra cellular matrix components to the wound bed^{145,146}.

The short life span of allogeneic cellular material in Apligraf™ means that they are unsuitable for the treatment of full thickness wounds, as definitive wound closure cannot be reached. In an effort to increase life span of the substitute autologous cells have been incorporated, either by split thickness skin grafts along side allogeneic cells or as cellular replacements for allogeneic material.

A combination of allogeneic fibroblasts and autologous keratinocytes was investigated in a preliminary clinical trial on six patients with burns or non-healing donor sites¹⁴⁷. Results from this trial were variable with percentage take rates ranging from 0 to 100 %. A positive point was that the technique allowed a 15-20 fold expansion of donor skin in just 4-7 days¹⁴⁷ but negatives associated with autologous cell use apply¹⁴⁸.

In a multicenter, randomized, controlled trial in burn patients, wounds were treated with Apligraf™ in combination with meshed autografts. The wounds treated in this

TABLE 66-4—Bilayer Skin Substitute

Product	Description	Application	Clinical Efficacy	LOE	Strength of Recommendation	Refs
OrCel™	Allogeneic keratinocytes seeded over dermal scaffolds (bovine collagen sponge) containing allogeneic fibroblasts	PTB/W	-Useful tool for quick regeneration of graft donor sites for re-use. -Fragile, quickly deteriorates in wound environment. -Healed burn sites more rapidly than Biobrane-L™.	4, 5	C	182–183
Apligraf™	Human fibroblasts seeded over bovine collagen scaffold. Keratinocytes seeded onto mature matrix.	VU, DU	-Variable take rates reported. -Effective as temporary covering over meshed autografts. -Contraction and deterioration in wound a reported problem. -Found to be more effective than conventional treatment for diabetic ulcers.	5, 4, 5, 4, 4, 5, 4, 2a	C	127, 148, 149, 147, 143, 150, 105, 152
TissueTech™ autograft system	Combination of Hyalograft 3D™ and Laserskin™	FTB/W, PTB/W, VU, DU	-Heal ulcers resistant to conventional treatment. -Similar performance to Dermagraft™ and Apligraf™ -Provide a cost-benefit gain over time in comparison to conventional treatment.	5, 3, 5, 4, 2a, 4, 4, 5	C	66, 156, 154, 153, 156, 184–185
StrataGraft	Second generation substitute providing dermis and fully stratified epidermis composed of viable NIKS cells.	FTB/W, PTB/W	-Comparable performance to cadaver skin graft. -Skin appears healthier and is more adherent to graft when used compared to cadaver skin. -Availability, uniformity and low infection risk benefits.	1	B2	159

DU, Diabetic Ulcer; VU, Venous Ulcer; FTB/W, Full thickness burn/wound; PTB/W, Partial thickness burn/wound.

way healed statistically better than the control (mesh graft alone) at all time points from week one to 24¹⁴⁸. This interesting result warrants further investigation of Apligraf™ for this application. In a case series the effectiveness of Apligraf™ for treating wounds caused by the surgical removal of skin cancers or keratoacanthomas was investigated¹⁴⁹. Apligraf™ application resulted in contraction of wounds by 10–15 %, slightly more than that seen with full thickness grafts¹⁴⁹. This initial clinical experience was extended into a multi-centre trial involving 107 patients in 10 centres¹⁴³. During this larger trial graft persistence was reported as 73 % at 1 week, 53 % at 1 month and 31 % at 1 year^{126,143}. Infection rate was reported at a relatively high 10.5 %¹⁴³.

Currently, Apligraf™ is only licensed for the treatment of venous and diabetic foot ulcers where its application has demonstrated significant advantage over conventional treatment. A comparative trial between Apligraf™ and multilayered compression therapy for this application, involving 233 patients and 15 centres was conducted by Sabolinski and co-workers¹⁵⁰. At six months post-grafting 61 % of Apligraf™ treated wounds were completely healed as apposed to 44 % treated conventionally¹⁵⁰. Apligraf™ treated wounds also exhibited a more rapid median time to complete wound closure of 57 days as apposed to

181 days for conventionally treated wounds^{150,151}. Similar healing potential was reported by Veves and co-workers in the treatment of 208 diabetic ulcers, where 56 % and 38 % of ulcers healed in 12 weeks with Apligraf™ and conventional treatment respectively¹⁵². Despite this, it is still debatable whether the clinical benefits observed in chronic ulcer treatment are large enough to justify widespread use of Apligraf™. At £17 per centimeter squared Apligraf™ is expensive in relation to less developed dermal substitutes, which may be able to deliver similar results.

TissueTech™ autograft system is a combination of the dermal substitute Hyalograft 3D™ and the epidermal substitute Laserskin™. The TissueTech™ system cannot be classified of a true bilayer substitute due to the separate components and the two stage application process. It offers a completely engineered treatment option but could become complicated when used in clinical practice.

In preliminary studies TissueTech™ has proven to be particularly useful for treating ulcers that have resisted healing through conventional techniques^{66,153}. Initial reports in an observational study in the treatment of diabetic foot ulcers of a healing rate of 91 % with a mean healing time of 72.7 ± 48.2 days¹⁵⁴ were supported by a randomized controlled clinical trial where 65 % healing was

observed¹⁵⁵. In an additional, large retrospective clinical review, the TissueTech™ system was assessed for treatment of chronic lower extremity wounds¹⁵⁶. This review featured data on 975 patients (1156 wounds) and concluded that the substitute is a 'safe and effective treatment for chronic wounds, which could even provide a cost-benefit gain over time'¹⁵⁶. In a LOE-1, detailed, retrospective review of the use of TissueTech™ for treating diabetic foot ulcers comprising 401 wounds in 346 patients from 60 centres¹⁵⁷. In this review the authors state that the performance of TissueTech™ reported is similar to that reported by randomized, controlled clinical trials involving established substitutes Dermagraft™¹²⁴ and Apligraf™¹⁵². In terms of healing rates, the authors state that TissueTech™ performs significantly higher than current conventional treatment studies¹⁵⁸.

The Orcell™ construct is composed of a bovine collagen type I sponge seeded with allogeneic neonatal fibroblasts. This sponge is coated with a collagen gel on the upper exterior, serving as a platform for neonatal allogeneic keratinocytes to form a confluent sheet. In a similar way to Apligraf™ due to this product's allogeneic cell component which does not survive in the long term it is thought to exert its effect through the release of cytokines and growth factors.

StrataGraft is a second generation skin substitute providing a dermis and fully stratified epidermis composed of keratinocytes from a genetically stable, pathogen-free, long lived progenitor cell line (Neonatal Immortalized KeratinocyteS, NIKS)¹⁵⁹. The epidermal barrier function of this substitute is reported to be comparable to that of uninjured skin¹⁵⁹. A comparative study between Stratagraft and cadaver allograft in patients undergoing sequential skin reconstruction procedures prior to autograft placement

was the basis of an FDA Investigational New Drug application¹⁵⁹. In a phase I/II multicentre, non-blind, randomized, safety, dose escalation trial 15 patients wound sites received 50 % Stratagraft and 50 % cadaver allograft treatment¹⁵⁹. The total body surface area treated with Stratagraft was increased from 0.5 %, to 1 %, to 1.5 % during the course of the trial. Following wound bed preparation with either treatment, subsequent autograft take and occurrence of infection was measured. The performance of Stratagraft and cadaver skin was not statistically different in terms of autograft 'take' or occurrence of infection¹⁵⁹. However, the Stratagraft treated wounds were deemed to be more adherent and pink in colour than cadaver skin treated wounds¹⁵⁹. This study demonstrates that this viable cell scaffold performs as well as the current standard of care and has obvious advantages such as availability and mass production whilst not disintegrating in the wound bed like first generation scaffolds^{159,160}.

DISCUSSION

Skin substitutes have faced a number of problems in becoming widespread useful clinical tools, including, perhaps most importantly, their high cost and relative underperformance. In addition to this, once in the harsh environment of the wound bed substitutes have often failed to behave as originally intended in the clinical setting. For example, Apligraf™ and OrCell™ break down in the wound and only contribute to healing by secondary intent, rather than as living skin equivalents¹⁴⁰. These almost universal problems can be attributed to nature of substitute design. At the outset of skin engineering researchers designed substitutes (Figure 66-4) that seemingly blindly copied

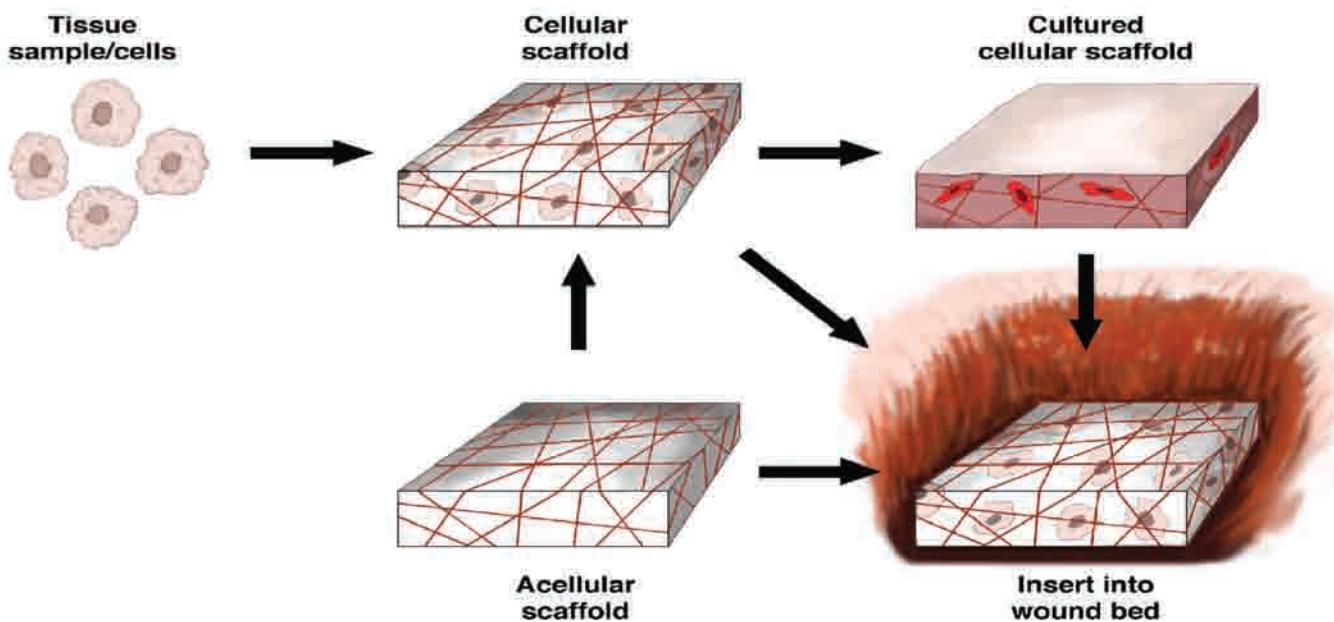

FIGURE 66-4 Simplified diagram comparing different skin engineering strategies.

natural end-point matrix structures or selected healing processes, but disregarding others, rather than designing on the basis of a detailed understanding of what was required. An interesting analogy, made by Kemp in 2006, is that of early aeroplane designers copying the shape of birds wings without really understanding the reason for their shape¹⁴⁰. Quite recently, it was recognized that focusing on the developmental processes that form the natural dermis, ECM and epidermis holds the key to engineer truly effective substitutes with the capacity to regenerate injured skin rather than repair it. An isolated recent example of an attempt to achieve this is the substitute ICX-SKN™. In ICX-SKN™ a collagen matrix is synthesized by fibroblasts seeded into the provided provisional matrix. The authors propose that this results in collagen with a stronger structure than remodeled collagen, similar in structure to that of uninjured collagen¹⁴⁰. This configuration should help to reduce scarring and increase the strength of the wounded area of skin once healed.

The poor cost to benefit ratio of current substitutes is also indicated by the fact that the most utilized substitutes are arguably not the most scientifically advanced. For example, Integra™, perhaps the most widely used substitute is technology that was developed in the early 1980's⁵⁴. On one hand, the reasons for this widespread use are that it is a storable product with a proven track record. On the other hand, the relative cheapness of Integra™ compared to a more advanced cellular product, which is not guaranteed to give superior results, make it the more attractive choice. For a future advanced substitute to become widely used it must produce a therapeutic benefit that justifies the extra cost of its use.

The development of more complex and effective skin substitutes hinges on an increased knowledge of detailed information on the mechanisms of wound healing. Further awareness of the key molecules, and the spatial and temporal action of these during the wound healing process, should sculpt the design of future substitutes. One way to exploit such knowledge would be to engineer cells seeded into the scaffolds to over express certain growth factors and/or cytokines to accelerate the healing process. For the treatment of chronic ulcers, for example, fibroblasts that have been engineered to over express vascular endothelial growth factor (VEGF) or platelet-derived growth factor (PDGF) could be beneficial through promotion of angiogenesis. An alternative method, which is the subject of intensive research, is the construction of bioactive scaffolds. These scaffolds are constructed from, or contain, growth factors and other molecules involved in wound healing. The theory again is to provide the healing wound with molecules that will speed up neotissuegenesis or margin cell migration. One of the main problems with this method is controlling the release of the bioactive molecules. This can be achieved through the designing the scaffold material to control the *in vivo* degradation rate, thus controlling the

release of the bioactive molecules from the scaffold. Growth factors could also be attached to the matrix, as found in the natural tissue. Alternatively the release of bioactive molecules has been controlled by their absorption into gel beads (often alginate) or containment in microspheres¹⁶¹. These are inserted into the scaffold and the bioactive molecule released as the beads or microspheres degrade.

Scarless healing is the ultimate goal in the development and use of skin substitutes. The key to achieving this seems to lie in the study of the embryonic healing process and in the ability of an embryo in the 1st trimester, when experimentally wounded, to heal the injury without the formation of a scar¹⁶². Although this well documented phenomenon has been known for a considerable time, it is still to be determined how embryos achieve this. The challenge facing tissue engineers is to selectively reactivate this ability. Currently it appears that hyaluronan, the immature immune system and the JNK cascade, which is important in the migration of the skin cells in embryonic development and in wounding, are involved in the process¹⁶². Substitutes designed to deliver the crucial identified factors could induce the ability for scar-less regeneration in the cells of post-natal skin.

Another area of interest that is relatively unexplored is the use of designer polymers to shape the biochemical and mechanical properties of scaffolds. Through this technique it may be possible for researchers to closely control physical factors such as degradation rate, tensile strength and flexibility. Additionally, attachment sites like the RGD attachment site could be incorporated into the structure of the polymers within the scaffold. This would allow placement of certain growth factors or selective attachment sites at specific points within the matrix. For example, incorporating VEGF into the dermal portion of the scaffold could encourage vascularization of the substitute, whilst incorporating epidermal growth factor (EGF) into the epidermal region of the scaffold could help to achieve rapid re-epithelialization. With the development of wound healing knowledge, the molecules and attachment sites involved could be fine tuned to optimize the efficiency of the substitute.

Although demonstrated in many cases to be a life saving surgical tool, skin substitutes remain to produce fully functional skin following implantation. The construction of a substitute that can do more than restore the barrier function of the epidermis and limited mechanical integrity to the dermis still represents a considerable challenge. This area has been overlooked as trivial in comparison to the often vital need to close an open wound. However, without the various appendages of the skin, like the pilosebaceous unit and the apocrine sweat glands, substitutes often represent little more than a biological dressing manipulating host cells through the release of cytokines and growth factors. One suggested way to increase the cellular complexity of substitutes is through the use of stem cells, with interest particularly in the identified populations

that reside within the hair follicle¹⁶³. The epidermal stem cells of the bulge region have been shown to be capable of differentiation into not only the cells of the hair follicle but also into inter-follicular keratinocytes¹⁶⁴. Indeed, it is well established that following epidermal injury the bulge cells help to achieve re-epithelialization following migration to the wound bed¹⁶⁵. Similarly a population of nestin expressing stem cells from the outer root sheath of the hair follicle have been shown to differentiate into functional blood vessels and neural cells¹⁶⁶. The successful exploitation of such populations in the future could be beneficial to the creation of a truly biomimetic skin substitute.

The use of viable autologous cells is preferable when creating a cellular skin substitute. However, the problems associated with using autologous cells are difficult to bypass. These include; culture and manufacture time, storage and transport, and cost. These problems must be addressed in addition to the research aims for an effective substitute to become widely utilised. The Intercytex products (inc. ICX-PRO™ and ICX-SKN™) have been designed with these problems in mind. The manufacturing process of these substitutes has several 'Stop' points inserted into it, at which product development can stop, products can be stockpiled and the process re-started when needed¹⁴⁰. The insertion of these points has reduced manufacture time to one week¹⁴⁰. This model could be applied to other substitutes and improved upon further. Lengthier storage times and easier transport of viable tissues is an area that also needs improving.

All skin substitutes suffer from a lack of level 1 evidence into their efficacy, with randomization a key issue. Small or poorly designed studies giving contradictory results make wider interpretation and comparisons difficult to make. This problem is exacerbated by the different conditions in trials, including different wound starting states and even types and by the natural complexity, inter-patient variability of the healing wound and surgeon experience or skill. The available evidence does suggest that skin substitutes are useful tools especially in acute life threatening wounds where rapid closure is required and in chronic treatment resistant ulcers.

CONCLUSION

Tissue engineered skin substitutes in their various forms have aided the treatment of cutaneous injury and benefited patients since the 1980s. Although possibly the most developed of engineered tissues, engineered skin still has considerable room for improvement. The creation of a substitute that can act as truly mimetic skin tissue should not be considered unattainable. It is anticipated that research into the wound healing process, embryonic development, stem cell differentiation and biomaterial design will combine synergistically in the future to enhance skin substitute design.

Thalidomide

67

Jyoti P. Mundi, M.D., and Delphine J. Lee, M.D., Ph.D.

Thalidomide, or alpha-phthalimido glutarimide, is a racemic glutamic acid derivative synthesized in Germany in 1956 by Kunz, Keller, and Muckter. The compound was introduced to the public, under the names of, “Distaval,” and, “Contergan,” as a nonbarbiturate sedative hypnotic with antiemetic properties and with minimal relative toxicity based on the observation that individuals exposed to accidental or intentional overdose recovered uneventfully. In 1960, Somers¹ described the sedative-hypnotic effects of thalidomide in animal models without the deleterious effects on the cardiac, respiratory, or autonomic nervous system previously observed with barbiturates. Reports of individuals surviving consumption of 1400 mg of thalidomide supported its marketing as a safe drug². In 1960, an open label clinical trial of thalidomide was performed to assess its efficacy as an antiemetic at the Women’s Hospital of Sydney, Australia; however, the trial was terminated in 1961 when Dr. McBride of the Women’s Hospital noted three cases of congenital absence of the radius in three neonates exposed to thalidomide in utero. Overall, 50% of pregnancies spontaneously aborted, and resulted in congenital malformations, particularly phocomelia (congenital partial limb deficits). Consistent with these observations, limb deformities were noted in offspring of New Zealand rabbits fed thalidomide during their 8th to 16th days of pregnancy. Lastly, Dr. Lenz of Hamburg, a pediatrician, documented over 4000 cases of abnormal limb growth to further strengthen the association between thalidomide exposure between the 30th and 40th days of pregnancy and fetal malformations. By the time thalidomide was taken off the market in 1961, over 5000 deformed infants were born in European countries because of its administration.³

This devastating chapter in medical history also marks the birth of the field of Pharmacoepidemiology. Physicians such as Dr. Williams³ quickly made the realization that if, “prompt reporting of the appearance of congenital malformations, with careful records by physicians of the medications given, had been made, the extent of the thalidomide disaster in Europe could have been enormously reduced.” He went on to further set the stage for the field by adding, “this public health procedure of constant surveillance of the incidence of disease must be, in the last analysis, the final protection against a similar great disaster.”

PHARMACOLOGY

Thalidomide is a white, tasteless, crystalline powder. It has a melting point of 271 degrees and is chemically related to bemegride (a-ethyl-a-methylglutarimide) and to glutethimide (8-ethyl-8-phenyl-glutarimide). The substance is further characterized by being sparingly soluble in water, methanol, ethanol, acetone, and glacial acetic acid, but readily soluble in dioxane, dimethyl formamide, and chloroform and insoluble in ether of benzene¹.

Structurally, thalidomide is a glutamic acid derivative with a single chiral center and a racemic mixture of two active enantiomers, S(–) and R(+), that undergo rapid interconversion at physiologic pH. It is a two-ring system with an asymmetric carbon atom link. The left-sided phthalimide ring is responsible for the drug’s anti-inflammatory and immunomodulatory effects, and the right-sided glutarimide ring is hypothesized to be responsible for the drug’s sedative properties. Thalidomide has high oral bioavailability, although absorption is slow and time to maximum plasma concentration of 1-2 mg/L is 3-4 hours after a single oral dose of 200 mg. Thalidomide has a half-life of 5-6 hours. Upon ingestion, it is enzymatically cleaved into more than 12 different metabolites that are quickly eliminated in the urine.⁴

In efforts to find a less toxic derivative, CC-5013, also known as Lenalidomide, and CC-4047, also known as Actimid, 4-amino-glutarimide derivatives of thalidomide were designed by adding an amino group to the fourth carbon of the phthaloyl ring of the parent compound. Both compounds are racemic mixtures of S(–) and R(+) enantiomers. Like thalidomide, they have high oral bioavailability and are renally excreted. The half-life of CC-5013 and CC-4047 are 3 and 7 hours, respectively. They lack significant dose limiting neurologic and sedative toxicities that are associated with thalidomide and have heightened immunomodulatory activity relative to thalidomide. Furthermore, CC-5013 possesses direct antitumor activity and has been noted to be nonteratogenic when tested in rabbits.⁵

MECHANISMS OF ACTION

The mechanisms of action of thalidomide and its derivatives are not entirely clear. Thalidomide and its derivatives

have been shown to have several anti-inflammatory and immunomodulatory properties, as well as, antiangiogenic effects, which are important for their role in inhibition of tumorigenesis.

Inhibition of Neutrophil Chemotaxis

The differential regulation of expression of adhesion molecules by thalidomide alters leukocyte migration and rolling. *In vitro* studies of the effects of thalidomide on polymorphonuclear cells demonstrate a dose-dependent inhibition of neutrophil chemotaxis⁶⁻⁷. Nogueira et al⁸ revealed that, although thalidomide does not alter the expression of adhesion molecules on resting endothelial cells, it inhibits the induction of adhesion molecules on the surface of endothelial cells by endotoxin and inflammatory cytokines including tumor necrosis factor-alpha (TNF- α) and IL-1. Thalidomide is capable of changing the density of TNF- α induced ICAM-1, V-CAM, and E-selectin antigens⁹ as well as IL-1 β and IFN- γ -induced E-selectin¹⁰. Studies have depicted that the drug dose dependently inhibits lipopolysaccharide (LPS)-stimulated and TNF- α -induced leukocyte chemotaxis¹¹. Thalidomide may reduce inflammation in erythema nodosum leprosum by altering neutrophil chemotaxis, while in multiple myeloma and myelodysplastic syndrome thalidomide modifies the tumor microenvironment.

Inhibition of TNF- α Production

TNF- α is an important regulator of other proinflammatory cytokines and leukocyte adhesion molecules. Sarno et al¹² observed elevated TNF- α and IL-1 in serum from leprosy patients suffering from acute inflammatory reactional episodes-erythema nodosum leprosum (ENL). Her study suggested that TNF- α may be a potential target for thalidomide as decreased serum levels of TNF- α were observed in patients given thalidomide and thalidomide was noted to be a highly efficacious drug for the treatment of ENL. These observations prompted further examination of the role of thalidomide on cytokine production. In 1991, thalidomide was shown to partially inhibit LPS-induced TNF- α production by human blood monocytes at comparable therapeutic serum concentrations in successfully treated ENL patients.¹³ Additional studies investigating the role of TNF- α in mediating the clinical manifestations of leprosy, demonstrated a decrease in TNF- α release with concomitant clinical response in those treated with thalidomide.¹⁴ Thalidomide has been shown to accelerate the degradation of TNF- α mRNA transcripts in LPS-stimulated monocytes, which in turn influences the total amount of TNF- α protein released in response to LPS.¹⁵ Cytokine mRNA inhibition has been correlated to resolution of the inflammatory response *in situ*.¹⁶ Thalidomide has also been shown to act on the downstream signaling events of

NF- κ B, a key transcription factor that mediates the effects of various proinflammatory cytokines, such as TNF- α as well as IL-1 β .¹⁷⁻¹⁸ Although there is evidence for TNF- α and its downstream pathways as a target for thalidomide, there are some conflicting reports to suggest otherwise. Thalidomide likely mediates its clinical efficacy by several mechanisms. Inhibition of TNF- α may be a more prominent effect when macrophage production of this cytokine is high; however, in other settings, thalidomide's ability to costimulate T cells to produce cytokines, including TNF- α , may outweigh this inhibitory effect, as has been noted in patients with toxic epidermal necrolysis, sarcoidosis, and scleroderma.¹⁹⁻²³

Modulation of the T cell Response Systems

Thalidomide has been shown to regulate T helper (Th) cell differentiation *in vitro*, promoting Th2 versus Th1-type cytokines, which may suppress TNF- α .²⁴ Thalidomide has a dose-dependent inhibitory effect on mononuclear cell production of the T helper 1 (Th1) cytokines, or IFN- γ , and IL-12.²⁴⁻²⁵ The effect of thalidomide on cytokine production varies according to the nature of the stimulus and the cell type being stimulated. Whereas thalidomide inhibits LPS-induced monocyte IL-12 production, it stimulates the production of IL-12 in T-cell dependent systems. IL-12 has been shown to enhance natural killer cell and T cell activity causing, "immune stimulation."²⁰ Importantly, this increase in natural killer cell cytotoxic activity induced by thalidomide has been shown to augment lysis of human multiple myeloma cell lines, providing a mechanism of action for thalidomide in the treatment of multiple myeloma.²⁶

Thalidomide may also stimulate CD8 T cells.²⁷ CD8 + T cells are vital components of the immune response to foreign antigens. The activation and proliferation of these cells require costimulation of the T-cell receptor by a second signal, usually provided through interaction between surface markers on antigen-presenting cells and their ligands on T-cells. Thalidomide augments the CD8 T-cell response in the absence of a second costimulatory signal.²⁸ Additionally, thalidomide has been found to decrease the T helper to T suppressor cell ratio, boosting regulatory T cell function, another potential immunomodulatory mechanism for the drug.²⁹

Inhibition of Angiogenesis

Thalidomide's potential, as an antineoplastic agent was not fully realized until D'Amato demonstrated the drug's antiangiogenic activity. In 1994, D'Amato³⁰ demonstrated the ability of thalidomide to inhibit neovascularization in rabbits. Thalidomide metabolites have also been shown to inhibit angiogenesis induced by basic fibroblast growth factor (bFGF) and vascular endothelial growth factor

(VEGF) in a rabbit cornea micropocket assay and mouse corneas.³¹ Although this may be partially caused by thalidomide's anti-TNF properties, as TNF- α has been shown to positively influence vessel formation,³² thalidomide has been shown to also independently affect angiogenesis.³¹

Hypnotic Properties

Thalidomide's right-sided glutarimide ring is thought to be responsible for the drug's sedative effects.³³ It is hypothesized that the mechanism involves activation of a sleep center in the forebrain.³⁴ It should be noted that unlike other sedative agents such as barbiturates, ingestion of even extremely high doses of thalidomide has not resulted in fatal outcomes².

FDA-APPROVED USES OF THALIDOMIDE

Erythema Nodosum Leprosum (ENL)

Leprosy, also known as Hansen's disease, is a chronic progressive granulomatous infection of the skin and peripheral nerves caused by *Mycobacterium leprae*, a fastidious, gram positive, intracellular, acid-fast bacillus. Although leprosy is endemic to Asia, Africa, and South America, in 2006, 137 new cases of Hansen's disease were reported in the United States to the National Hansen's Disease Registry, with 63% occurring in California, Florida, Louisiana, Massachusetts, New York, and Texas. Clinical features are determined by the immunologic response to the organism and vary along a spectrum between tuberculoid and lepromatous leprosy. Tuberculoid leprosy is limited to well-defined skin patches and nerve trunks because of a cell-mediated response to the organism. Lepromatous leprosy is characterized by more widespread infiltration of the skin and nerves by the mycobacterium caused by T-cell unresponsiveness, hypothesized to be the result of immune deviation of cytokine production from a Th-1 type to a Th-2 type pattern, deletion of T cells reactive to the organism, and the presence of suppressor T-cell activity. Affected patients have high titers of antibodies to antigens specific to *M. leprae*.

Upon initiation of treatment, the disease can be complicated by the development of immunologically mediated, "reactional states," including type 1 leprosy reactions, also known as reversal reactions, and type 2 reaction, also known as erythema nodosum leprosum (ENL). Type 1 reactions are characterized by painful inflammation of affected areas caused by spontaneous increases in T-cell reactivity to *M. leprae* and the resultant cytokine response. Type 2 reaction, or ENL, occurs only in borderline-lepromatous and lepromatous leprosy states, and is characterized by a systemic inflammatory response syndrome, the development of erythematous skin nodules, and other regions of focal inflammation caused by complement-mediated reactions to extravascular immune complex

deposits. Histologic findings include infiltration of the dermis and subcutaneous tissues with lymphocytes, macrophages, and neutrophils sometimes accompanied by a leukocytoclastic vasculitis.³⁵

In 1965, Israeli dermatologist Jacob Sheskin used thalidomide to treat insomnia in a patient with ENL and unexpectedly discovered that lesions cleared within 48 hours of drug administration.³⁶ Thalidomide, as noted previously, functions as an immune system modulator, although its main mechanism in the treatment of ENL remains unclear. Disease symptomatology has been associated with elevated levels of TNF- α with clinical and pathologic resolution upon treatment with thalidomide and concomitant reduction in levels of TNF- α .³⁷ *In vitro* studies demonstrate profoundly diminished TNF- α production from peripheral blood monocytes in response to *M. leprae* and associated clinical symptom resolution with administration of thalidomide¹⁴. However, the significance of TNF- α in the pathophysiology of ENL is unclear as increases in TNF- α have been observed in patients treated with thalidomide.²⁰ Thalidomide has also been shown to down-regulate expression of adhesion molecules such as ICAM-1 on epidermal keratinocytes and reduce dermal infiltration of neutrophils in ENL, contributing to reduction in the dermal inflammatory response.³⁷

Controlled and open label trials demonstrate the effectiveness of thalidomide for ENL. In a double-blind trial by the World Health Organization comparing thalidomide and acetylsalicylic acid³⁸, 73% of reactions treated with thalidomide resolved by day 8 of treatment versus resolution of 23% of reactions in the acetylsalicylic acid group over a similar time frame. In a worldwide survey, Sheskin reviewed the effects of thalidomide in 4522 patients with ENL and noted that 4479 or 99% of patients improved.³⁹ Thalidomide was recommended by the Fifth International Leprosy Congress in 1973 and the World Health Organization in 1994 as the preferred treatment for moderate to severe ENL in men and women of non-child-bearing potential. In 1998, the United States Food and Drug Administration (FDA) granted approval for the use of thalidomide for the treatment of ENL. Dose recommendations range from 100 mg to 400 mg daily. Observations suggest that discontinuation of treatment, whether it is abruptly or by taper is frequently complicated by disease recurrence, and further studies are needed to establish improved regimens.⁴⁰

Multiple Myeloma

Systematic reviews of clinical trials have highlighted the efficacy of thalidomide in patients with previously untreated⁴¹ or relapsed/refractory multiple myeloma⁴²⁻⁴³ and in May 2006, the FDA granted approval for the use of thalidomide in combination with dexamethasone in patients with newly diagnosed multiple myeloma. Multiple myeloma is a B cell malignancy characterized by accumulation of clonal malignant plasma cells in the bone marrow, suppression of

erythropoiesis and consequent anemia, destructive bony lesions, increased susceptibility to infections, hypercalcemia, and renal insufficiency caused by accumulation of light chains of the monoclonal myeloma immunoglobulin in renal tubules. It is the second most common hematologic malignancy. Per the National Cancer Institute's SEER Cancer Statistics Review, based on data from 2002-2006, the age-adjusted incidence rate of multiple myeloma is estimated at 5.6 per 100,000 men and women, with an overall 5-year survival rate of 37.1%.

Recognition of thalidomide's teratogenic properties instigated studies of its effects in patients with cancer. The drug's potential as an antineoplastic agent became more apparent upon D'Amato's demonstration of its antiangiogenic activity. Prominent bone marrow vascularization is known to be positively correlated with increased myeloma activity. Additionally, levels of cytokines that promote angiogenesis, including beta fibroblastic growth factor (bFGF) and vascular endothelial growth factor (VEGF) are elevated in affected patients. This prompted Singhal et al⁴⁴ to test the role of thalidomide as a single agent in 84 patients with relapsed and refractory multiple myeloma. The response was defined as a decline in the level of serum or urine paraprotein of at least 25% on two occasions at least 6 weeks apart. A response rate of 32% was observed, including two complete remissions, triggering further interest in the study of thalidomide in multiple myeloma.

Further studies also confirm that increased bone marrow angiogenesis in multiple myeloma is caused by increased expression of bFGF and VEGF.⁴⁵ Patients responding to thalidomide do have a significant decrease in marrow microvascular density, although microvessel density does not necessarily predict clinical response to thalidomide.⁴⁶

Tumor and microenvironment interactions are critical in the pathophysiology of multiple myeloma.⁴⁷ Adhesion of multiple myeloma cells to bone marrow stromal cells via adhesion molecules⁴⁸ mediate proliferation of the malignant clone via stimulation of intracellular signaling pathways and subsequent release of paracrine and autocrine cytokines⁴⁹ and growth factors,⁵⁰ including VEGF. Production of osteoclastogenic cytokines uncouples the regulatory mechanisms for bone formation and bone resorption and results in the clinical sequelae of the malignancy. In addition, certain cytokines, such as IL-6, function as growth stimuli for the malignant clone, via activation of the NF-κB anti-apoptotic signaling cascade, fostering a vicious cycle of bone resorption and tumor growth.⁵¹ Bone marrow stromal cells and plasma cells isolated from multiple myeloma patients have also been shown to express TNF-α.⁵² In 2001, Hideshima et al. demonstrated that TNF-α directly stimulates IL-6 production in bone marrow stromal cells and up-regulates expression of adhesion molecules on myeloma and bone marrow stromal cells, thereby augmenting tumor microenvironment interactions and promoting tumor growth.⁵³ Additionally,

certain cytokines such as IFN-γ inhibit IL-6-dependent proliferation of myeloma cells.⁵⁴ Therefore, thalidomide's anti-inflammatory and immunomodulatory activities, including its anti-TNF activity and costimulation of CD8 T cells with resultant IFN-γ production and specific anti-tumor T cell cytotoxicity, likely all contribute to promote disease stasis or reduction in affected patients.

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal hematopoietic stem cell disorders characterized by ineffective hematopoiesis and pancytopenias, with affected patients having an increased risk of disease transformation into acute myeloid leukemia (AML). One of the more common chromosomal abnormalities associated with MDS is deletion of chromosome 5. Patients with a 5q deletion have a distinct hematologic profile, including macrocytic anemia, normal to increased platelet count, mild leukopenia, hypolobulated megakaryocytes in the bone marrow and medullary blast count of <5%. Those with an isolated 5q deletion have a better prognosis than patients with multiple chromosomal abnormalities.

The immunomodulatory activities of thalidomide and its derivatives including T-cell costimulation, augmentation of natural killer cell cytotoxicity, suppression of hematopoietic inhibitory cytokines, inhibition of angiogenesis and endothelial cell adhesion and migration in the tumor microenvironment, as well as direct proapoptotic effects of the thalidomide derivative, lenalidomide, to deletion 5q clones all contribute to the antitumor response seen with administration of these medications. In phase II clinical trials with thalidomide, although a hematopoietic response has been noted, patients have required prolonged drug treatment and toxicity-related discontinuation is prominent.

An international phase II trial of lenalidomide (MDS-003) at a dose of 10 mg daily in 148 patients with 5q- MDS, resulted in transfusion independence in 67% of the subjects studied, and an additional 9% had a 50% or greater decrease in the number of transfusion required while being treated. Approximately 45% of the subjects studied demonstrated a complete cytogenetic response.⁵⁵

In December of 2005, lenalidomide was approved by the U.S. Food and Drug Administration for the treatment of patients with low-risk to intermediate risk MDS with deletion 5q, with or without additional chromosomal abnormalities at a dose of 10 mg daily. Patients with more complex cytogenetics are eligible for treatment, only if they have no more than one cytopenia and a medullary blast count of less than 5%.

Nonplasma Cell Malignancies

The role of thalidomide in the treatment of solid tumors is currently under investigation and is thoroughly detailed

in a review by Kumar et al.⁵⁶ The drug has shown variable promise. In patients with malignant melanoma, breast cancer, or high-grade brain gliomas, thalidomide alone has not been shown to be efficacious; however, its role when combined with other chemotherapeutic agents is yet to be more clearly delineated. Thalidomide has shown more promise when used in patients with renal cell carcinoma, Kaposi's sarcoma, prostate cancer, in combination with irinotecan in patients with metastatic colorectal cancer, unresectable hepatocellular carcinoma, malignant mesothelioma, small cell lung carcinoma, and metastatic neuroendocrine tumors. However, more data is needed for any statements supporting the use of thalidomide in the treatment of any of these malignancies.

ADDITIONAL USES OF THALIDOMIDE AND THALIDOMIDE DERIVATIVES

Thalidomide has been introduced for treatment of a variety of disease states associated with immune system dysfunction. Serious adverse effects including teratogenicity and irreversible peripheral neuropathy have precluded FDA approval as well as restricted its use to recalcitrant conditions only.

Aphthous Stomatitis

Aphthous ulcers are self-limited shallow, painful lesions caused by destruction of poorly keratinized surfaces of the oral mucosa. Although the initiating factor is unclear, immunologic dysfunction has been hypothesized to play a role. Studies have demonstrated enhanced neutrophil chemotaxis, increased TNF-alpha production, and a decreased CD4 to CD8 ratio in affected patients.⁵⁷ Thalidomide was first applied towards treatment of aphthous ulcers in 1979 when six males with recurrent and necrotic mucocutaneous refractory aphthae were given 100 mg of thalidomide daily. The ulcers healed in 7-10 days with occasional recurrences after the medication was discontinued.⁵⁸

Several studies thereafter, have demonstrated the efficacy of thalidomide in the treatment of this condition. In an open label clinical trial with 40 patients treated with 100 to 300 mg of thalidomide daily for 3 months, 34% were cured and the rest showed a marked clinical improvement.⁵⁹ In a multicentered, randomized, crossover study of 100 mg of thalidomide daily versus placebo in 73 patients, 32 patients treated with thalidomide experienced complete remission in the treatment group compared to six patients in the placebo group.⁶⁰ In an open label trial comparing thalidomide to other immunomodulatory agents including dapsone, colchicine, and pentoxifylline, thalidomide was noted to be the most efficacious and most tolerable.⁶¹ Further studies evaluating the efficacy of lower doses of thalidomide will be important.

Thalidomide also appears to be highly effective in the treatment of HIV-associated aphthous ulcerations.

In a double blind, randomized, placebo-controlled study, patients received a four-week course of either 200 mg of thalidomide or placebo orally once per day. Fifty-five percent of the thalidomide group had complete healing of their aphthous ulcers after 4 weeks versus 7% in the placebo group. Patients in the thalidomide group also experienced improvement in quality of life measures such as discomfort with oral intake.⁶² However, in this study, patients in the thalidomide group had an increase in their viral load and although additional studies have not detected significant increases in viral loads or changes in CD4 T cell counts,⁶³⁻⁶⁴ thalidomide should be used cautiously in patients with HIV. Additionally, thalidomide in low intermittent maintenance doses does not successfully treat recurrence of HIV-associated ulcers in patients who had previously responded to the drug.⁶⁵

HIV-Associated Wasting

HIV-associated weight loss often manifests itself in patients with advanced disease. It occurs secondary to decreased appetite and decreased caloric intake, malabsorption, and chronic diarrhea, frequently caused by microsporidial infections, cytokine effects, and endocrine dysfunction and has a high morbidity and associated mortality if not adequately treated.⁶⁶ In a double-blind, placebo-controlled trial, thalidomide was randomized at 100 mg/day or 200 mg/day versus placebo for 8 weeks. Patients in the two thalidomide groups were noted to have significant increase in their weight, half of which was noted to be fat-free mass.⁶⁴ Thalidomide has also been shown to be effective in treatment of microsporidiosis-associated diarrhea.⁶⁷ Although thalidomide carries significant dose-limiting toxicities, it has been shown to be beneficial in the treatment of HIV-associated wasting.

Behçet's Syndrome

Behçet's syndrome is a chronic, relapsing, multisystem disease of unclear etiology characterized by a triad of aphthous stomatitis, genital ulcerations, and uveitis. Immune complex-mediated vascular damage and immune dysregulation has been implicated in the pathogenesis of the disease although the exact mechanism of action is unclear.⁶⁸ Thalidomide use in Behçet's syndrome was first reported in 1982. Patients with symptoms refractory to other immunomodulatory medications were given 400 mg/day of thalidomide for 5 days, followed by 100 mg twice a day for 15 to 60 days. The majority of patients had resolution of orogenital lesions.⁶⁹

Several studies thereafter, sought to demonstrate the efficacy of thalidomide in patients with Behçet's disease. A randomized, double-blind, placebo-controlled trial depicted a complete mucocutaneous response in two out of 32 patients treated with 100 mg/day of thalidomide, in five out of 31 patients treated with 300 mg/day

of thalidomide, and in 0 out of 32 patients who received placebo.⁷⁰ Oral manifestations improved after 4 weeks of treatment and genital ulcers improved after 8 weeks of treatment. Thalidomide treatment significantly increased development of erythema nodosum skin lesions during the first 8 weeks of the trial, but with continued treatment, the frequency in the treatment and placebo groups was similar. Discontinuation of treatment resulted in relapse of mucocutaneous lesions. Somnolence, neuropathy, and constipation were noted to be the most frequent limiting toxicities, however, lower doses of thalidomide have been observed to be effective and have fewer side effects.⁷¹ Additionally, case reports describe the successful use of thalidomide for the relief of other systemic manifestations of Behçet's disease, including arthritis, pyoderma gangrenosum, neuro-Behçet's, and colitis.⁷² Further studies are necessary to establish the disease-modifying power of thalidomide in Behçet's syndrome.

Graft-Versus-Host Disease

Graft versus host disease has a significant impact on morbidity and mortality after an allogeneic stem cell transplant. Although thalidomide does not appear to be of benefit in acute GVHD, it has been shown to be of some benefit in refractory chronic GVHD in conjunction with other immunosuppressive agents at doses of 600-1200 mg per day.⁷³ A randomized trial, however, demonstrated significant toxicity, particularly neurologic side effects, at the doses that have been used to ameliorate disease symptoms.⁷⁴ Moreover, thalidomide does not add benefit when incorporated into the initial therapy for chronic GVHD. Thalidomide is therefore, reserved for salvage therapy for refractory chronic GVHD.⁷⁵

Jessner-Kanof Lymphocytic Infiltration of the Skin

This benign chronic disorder is characterized by smooth, erythematous, and asymptomatic papules, or plaques secondary to T cell infiltration. Thalidomide was first used to treat this entity in an open label trial in 1983.⁷⁶ In a prospective, multicenter, double-blind, crossover study in 1995, a statistically significant response was noted in patients treated with thalidomide at 100 mg/day over 2 months.⁷⁷

Uremic Pruritus

Inflammation appears to be an important contributor to pruritus in patients with end stage renal disease.⁷⁸ Based on the observation that thalidomide alleviated pruritus in a dialysis patient with leprosy, investigators conducted a randomized, double-blind, crossover trial evaluating the efficacy of thalidomide for pruritus associated with uremia.

Twenty-nine patients with refractory uremic pruritus were treated with thalidomide at 100 mg/day for one week versus placebo. Over 60% of patients experienced an 80% reduction in symptoms.⁷⁹

Cutaneous Lupus Erythematosus

Thalidomide is indicated in patients with refractory severe cutaneous manifestations of lupus. In 1983, thalidomide was studied in 60 patients with chronic discoid lupus erythematosus, refractory to topical steroids and antimalarials. Initially, patients were prescribed 400 mg/day of the medication, but this was reduced to 50-100 mg/day and 90% of patients experienced complete or significant disease regression in a two-week period. Although treatment discontinuation led to disease recurrence in a majority of patients, a clinical response was obtained with repeat courses of thalidomide.⁸⁰ Lower starting doses of thalidomide (50-200 mg/day) and maintenance doses of 25 mg/day have been shown to be efficacious⁸¹, although a high incidence of neurotoxicity has been reported even with low-dose therapy.⁸² Further studies also support the initial findings of relapse after discontinuation of therapy.

Prurigo Nodularis

Prurigo nodularis is a chronic inflammatory dermatosis of unclear etiology characterized by pruritic, symmetric, papulonodular lesions on the extensor surfaces of extremities. Although initial reports demonstrate efficacy at doses of 200 mg/day,⁸³⁻⁸⁴ case reports of success with lower doses of thalidomide (100 mg/day starting dose for 1 month, and thereafter, 50 mg and 100 mg/day on alternate days) are published.⁸⁵ Additionally, an excellent response and minimal side effects were seen in an open trial combining thalidomide as initial therapy, followed by narrow-band UVB radiation.⁸⁶ In addition, of note, an uncontrolled case series found thalidomide to be effective for the treatment of prurigo nodularis in patients with HIV, in whom prurigo nodularis tends to be refractory to other forms of treatment.⁸⁷

Actinic Prurigo

Actinic prurigo is a photodermatosis that occurs mostly in Mestizo, or mixed Native American and European women and is characterized clinically by macules, papules, crusts, hyperpigmentation, and lichenification. Skin lesions are thought to develop because of increased TNF-alpha production in response to UV light in genetically predisposed individuals. The clinical response seen with thalidomide has been correlated with a reduction in serum TNF-alpha levels and modulation of IFN-gamma and CD3 positive T cells.⁸⁸ Thalidomide was first used to treat actinic

prurigo in 1973.⁸⁹ Observational studies since then have confirmed the drug's efficacy in treatment of this disease. Case reports describe success with low doses of thalidomide⁹⁰ and have demonstrated its safe use for long-term disease suppression at these doses⁹¹.

Adult Langerhans' Cell Histiocytosis

This rare disorder is characterized by abnormal proliferation and dissemination of histiocytes, cells that are almost identical in physical and functional properties to normal dendritic cells of the immune system. The disease is thought to result from an inappropriate immune response to antigens or an appropriate response to abnormal signals from other immune cells, as lesions have aggregates of other immunologically active cells, decreased numbers of suppressor T lymphocytes, and increased levels of inflammatory cytokines including TNF- α .⁹² Thalidomide was first used to treat histiocytic lesions in 1987 at doses of 50 mg/day, followed by 50 mg every other day for disease suppression.⁹³ In 1992, a 29-year-old female was treated with thalidomide at doses of 100 mg/day for 3 months for histiocytic infiltration of the parotid gland; however, in this case, no improvement was noted in the cutaneous manifestations of the disease and treatment had to be discontinued because of development of neuropathy.⁹⁴ Further reports document remission of cutaneous manifestations, with recurrence after discontinuation of thalidomide therapy, but with subsequent remission after reintroduction of treatment.⁹⁵ Case reports also describe the efficacy of thalidomide for treatment of mucocutaneous as well as hypothalamic disease manifestations, including diabetes insipidus.⁹⁶⁻⁹⁸ In a phase II clinical trial⁹⁹, thalidomide was noted to be effective in patients considered low risk, or those with bone, skin, pituitary, or neurologic spread; however, it did not elicit a significant response in patients with involvement of the spleen, liver, lung, or bone marrow.

Sarcoidosis

Sarcoidosis is a granulomatous multisystem disorder of unknown etiology. Granulomas form because of an immunologic response to an unknown antigenic trigger in genetically predisposed individuals. T cell activation and associated macrophage activation with subsequent release of cytokines such as TNF- α lead to granuloma formation.¹⁰⁰ Thalidomide was first used to treat two patients with steroid refractory cutaneous sarcoidosis and two patients with cutaneous and pulmonary involvement in 1983.¹⁰¹ Since then, several case reports have been published that demonstrate the efficacy of low-dose thalidomide (50-400 mg/day) in treatment of cutaneous lesions.¹⁰² Thalidomide has also reportedly been successfully implemented in the treatment of pulmonary¹⁰²⁻¹⁰³ and neurologic¹⁰⁴⁻¹⁰⁵ manifestations of sarcoidosis.

Erythema Multiforme

Erythema multiforme is a hypersensitivity reaction in response to infectious or chemical agents that clinically appears as a symmetrically distributed polymorphous eruption consisting of macules, papules, and target lesions, with minimal mucosal involvement. IFN- γ -induced inflammatory cascades as well as TNF- α expression in response to specific antigenic triggers are responsible for disease pathogenesis. There are several anecdotal reports of persistent¹⁰⁶⁻¹⁰⁷ and recurrent¹⁰⁸⁻¹⁰⁹ erythema multiforme successfully treated with thalidomide. A retrospective study of 26 patients with chronic erythema multiforme refractory to typical agents including acyclovir and prednisone, demonstrates a reduction in disease duration and disease remission in patients treated with 100 mg of thalidomide daily.¹¹⁰

Lichen Planus and Lichen Planopilaris

Lichen planus of the skin is a pruritic, papular, polygonal, and violaceous eruption often covered with lacy appearing white striae (i.e., Wickham's striae). It typically afflicts the wrists and the ankles, although it can affect any part of the body including the genitals, scalp, and nails. Follicular lichen planus is also known as lichen planopilaris. Mucosal lichen planus may present as painless white streaks in a lacy pattern, painful ulcerations, or as erosive lesions on the tongue, lips, buccal, or genital mucosa.

Histopathologic findings of T lymphocyte-mediated epidermal damage suggest that the disease is secondary to a cell-mediated response to an unknown antigenic trigger. Lichen planus has been associated with other autoimmune diseases and infectious agents such as hepatitis.

The efficacy of thalidomide in treating lichen planus and lichen planopilaris is controversial and no controlled trials are reported. Case reports demonstrate the efficacy of thalidomide in treatment of erosive lichen planus at doses ranging from 25 mg to 300 mg daily, however, treatment-limited toxicities led to eventual discontinuation of the drug.¹¹¹⁻¹¹⁴ In a 6 month open label trial, six patients with lichen planopilaris were treated initially with 100 mg/day of thalidomide for 1 month and then 200 mg/day thereafter depending on the initial response. The results depicted no clinical benefit of thalidomide in treatment of lichen planopilaris.¹¹⁵

ADVERSE EFFECTS

Teratogenicity

The most serious adverse property of thalidomide is its teratogenicity. Teratogenic effects have been observed after a single dose of 200 mg on the fortieth day of pregnancy. There are several proposed mechanisms for this. Thalidomide may block transmission of a signal from the mesonephros

that is necessary for normal limb development.¹¹⁶ The drug's antiangiogenic properties likely also play a role. Additionally, thalidomide causes free radical-mediated damage to DNA and other cellular macro-molecules.¹¹⁷

In efforts to prevent teratogenic events, the drug is marketed via the S.T.E.P.S. (System for Thalidomide Education and Prescribing Safety) program. Women of childbearing potential must undergo a pregnancy test prior to starting therapy and every 2 to 4 weeks during treatment. Women of childbearing potential must use two contraceptive modes starting 4 weeks prior to treatment onset, and must continue this for 1 month following the last dose of the drug, or remain abstinent over this same time course. Breastfeeding over this period is contraindicated. Males must abstain from sexual activity or use a condom. Patients and prescribers must sign an informed consent form prior to initiating treatment and complete questionnaires over the course of treatment in efforts to reiterate the drug's teratogenic potential.

Neurotoxicity

Thalidomide's neurotoxic effects have been well characterized and are significant dose limiting toxicities of the medication. Painful paresthesias of the hands and feet and proximal muscle weakness became apparent as clinically significant, possibly irreversible, effects of thalidomide therapy in the 1960s. Although duration of treatment has been purported to affect the severity of symptoms, other studies contradict this finding, although the size of the dose itself does appear to be a factor, with higher doses causing disability earlier in the course of therapy. Nerve conduction studies are suggestive of an axonal neuropathy and sural nerve biopsies demonstrate patterns of Wallerian degeneration and selective loss of large diameter fibers.¹¹⁸ In a study of 22 patients suffering from thalidomide neuropathy who were followed out 4 to 6 years after stopping drug therapy, 50% of patients continued to suffer without improvement in symptomatology, and those who improved experienced a very slow recovery.¹¹⁹ Peripheral neuropathy has been shown to be the most common cause for discontinuation of therapy.¹²⁰

Pretreatment electrophysiologic testing of sensory nerve action potential amplitudes and repeat testing after each 10-gram increment in the total dose of thalidomide or on a biannual basis has been suggested. A fall from the baseline score of greater than 40% should prompt reduction or discontinuation of thalidomide therapy as sensory loss may be severe and permanent.¹²¹

Venous Thromboembolic Events (VTE)

Although this is a less frequent side effect of treatment, several reports have presented a statistically significant association between the use of thalidomide and

thalidomide derivatives and the development of VTEs, particularly in patients with an underlying procoagulant state such as a malignancy. Generation of apoptotic cells, endothelial damage, and production of IL-2 and IFN- γ from thalidomide therapy foster a thrombogenic environment. A recent meta-analysis evaluated the risk of VTEs in 3,322 multiple myeloma patients receiving treatment and found that thalidomide increased the risk of thromboembolic events by 2.6 times, dexamethasone increased the risk by 2.8 times, and thalidomide/dexamethasone combination treatment increased the risk by eight times. Prophylactic doses of low-molecular-weight heparin or warfarin titrated to achieve a therapeutic international normalized ratio (INR) significantly reduced the risk of VTEs in this patient population.¹²²

Other Adverse Effects

The most common side effect associated with thalidomide treatment is somnolence, however, this may resolve after 2 to 4 weeks of treatment. Other side effects include constipation, depression, headache, nausea, weight gain, edema, transient papular or vesicular rashes, and subclinical hypothyroidism.¹²³

What We Know

- Thalidomide is a racemic glutamic acid derivative with anti-inflammatory, anti-angiogenic, immunomodulatory, and hypno-sedative properties.
- Lenalidomide and Actimid are less toxic 4-amino-glutarimide derivatives of thalidomide.
- Thalidomide is FDA approved for the treatment of erythema nodosum leprosum (ENL), multiple myeloma, in combination with dexamethasone, and low to intermediate risk myelodysplastic syndrome with deletion 5q.
- The use of thalidomide for non-plasma cell malignancies is currently under investigation.
- Thalidomide has been used for the treatment of a variety of disease states associated with immune system dysfunction that are refractory to other immunomodulating therapies.
- Thalidomide is a teratogen. In utero exposure results in congenital malformations, particularly phocomelia, or partial limb deficits. Patients and prescribers must be enrolled in the S.T.E.P.S. program.
- Serious adverse effects include irreversible neuropathy and venous thromboembolic events.

Percutaneous Hormone Transfer

Balvinder Rehal, M.D., and Howard I. Maibach, M.D.

INTRODUCTION

Transdermal hormone application is becoming an increasingly popular form of therapy, given the percutaneous route allows for the use of fewer hormones and avoids the potential side-effects associated with first pass metabolism. However, topically applying hormones may result in skin-to-skin transfer of the bioactive chemical from the patient to an unintended subject, like the patient's partner or family member. There have been documented cases of skin-to-skin transfer of testosterone creams from a father, the patient, to his son causing precocious puberty.¹⁻⁶ Given the potential harm from topical hormone use, investigation of percutaneous hormone transfer is needed.

METHODS

We conducted a systematic search in Scopus using keywords "estrogen" and "skin transfer." A second search was con-

ducted in Scopus using keywords "testosterone" and "skin transfer." The search was limited to articles published in the English language up until February 2, 2010.

RESULTS

Four articles studied skin-to-skin transfer of estrogen. Three of the four involved the transfer of estrogen *in vivo* from healthy women to naive recipients. One article was excluded because it studied absorption of estrogen *in vitro*⁷. The details of the three articles are in Table 68-1.

Schumacher studied the skin-to-skin transfer of estradiol from 20 postmenopausal women to 20 healthy men. They used an estradiol metered-dose transdermal spray (Evamist) to apply the hormone on the women's skin. The women had their inner forearms sprayed and 1 hour after application, they held their forearms tightly against the inner forearm of the untreated men with no rubbing

TABLE 68-1—Estrogen

	Schumacher	Wester	Taylor
Subjects	20 postmenopausal women	6 postmenopausal women	14 postmenopausal women
Naïve transfer recipients	20 healthy men	6 healthy men and women	14 male partners

Comments	Sig transfer did not occur	Transfer occurred	Sig transfer occurred

or movement for 5 minutes. Blood samples were collected from the men at specified timed intervals after contact and compared to precontact blood samples. Estradiol levels were determined by calculating the area under the concentration-time curve (AUC) from time 0-24 hours. From precontact to postcontact, the AUC increased from 550.9 pg·hr/mL to 572.2 pg·hr/mL. However, the 90% CI of the ratios of AUC was 1.00 to 1.07, which was within the prespecified equivalence range of 0.8-1.25. Therefore, the conclusion was made that significant transfer of estradiol via skin-to-skin contact did not occur.

Wester examined skin transfer of estradiol via a gel formulation (oestrogel) was determined between six postmenopausal women and six healthy recipients, both men and women. A single dose of ¹⁴C labeled estradiol was applied to the inner forearm of postmenopausal women and after 1 hour of air drying the women rubbed their forearms against the naive recipients. After contact, urine samples were collected from the recipients at timed intervals. The amount of estradiol on the skin of the recipients was calculated as a percentage of the original dose applied to the women subjects, with the thought that the amount remaining on the skin equaled the amount that was transferred. The results showed that 2.3% of the original dose was still on the skin of the recipients, and therefore the

conclusion was made that skin-to-skin transfer of topical estrogen can occur.

Taylor and Gutierrez studied 14 postmenopausal women who had a single dose of estradiol applied to their legs via an estradiol topical emulsion (estraserb). Two hours after application, on 2 consecutive days, their male partners vigorously rubbed their forearms against the application site on the women's legs. Blood samples were then collected from the men at timed intervals to determine estradiol serum levels. The results showed an increase of the average serum estradiol concentration (Cavg) from precontact to postcontact on day 2 by 25%. Although this increase was statistically significant, all levels were still under the upper limit of the normal range for men (<45 pg/mL).

For testosterone skin transfer, we found two articles involving skin-to-skin or skin-to-clothing transfer. The details of the testosterone articles are listed in Table 68-2. Mazer et al. studied the transfer of testosterone from a patch and a gel formulation to a t-shirt. The subjects were 28 hypogonadal men who had testosterone applied to their abdomen via one of two techniques: a patch (Androderm) or a gel (AndroGel). Their t-shirts were then analyzed on two occasions, 7 days apart, to determine the amount of testosterone that was transferred from their skin to their clothing. Results showed an average transfer of 54.9 µg

TABLE 68-2—Testosterone

	Mazer	Rolf	Rolf
Subjects	28 hypogonadal men	12 healthy men	14 healthy men
Recipient	t-shirt	Themselves	14 artificially hypogonadal men
Skin application			
Formulation	Androderm vs. AndroGel	2.5% gel	2.5% gel
Daily dose of testosterone	Androderm (5mg/d) AndroGel (5g)	0.4g	5g

Results	Amount of testosterone extracted from t-shirt (µg) Pre-contact= 1.20 Patch Post-contact (avg Day 7 and 14)= 54.9 Gel Post-contact (avg Day 7 and 14)= 7049.6	% of applied testosterone recovered = 3.1 +/- 1.8	Testosterone serum concentrations (nmol/l) Mean= 2.4
Comments	Sig transfer occurred from subjects to t-shirts, with gel > patch	Transfer occurred	No sig increase in serum testosterone levels occurred

from precontact to postcontact for the patch and 7049.6 µg for the gel. This correlated with a 58-fold increase over the amount extracted at baseline for the patch and 15,000-fold increase for the gel, clearly showing that transfer of testosterone from skin to clothing occurred.

Rolf et al. investigated two separate procedures: the transfer of testosterone interpersonally, from the left forearm to the right forearm of the same subject, and the transfer of testosterone from subject to recipient. The study used a newly developed 2.5% testosterone gel preparation to investigate the transfer of testosterone via skin contact. Results were given by the percentage of applied testosterone recovered at the recipient site. For interpersonal contact, results showed that 3.1% of the dose applied was recovered from the recipient site. For the second part of the study, involving healthy male subjects, there was no increase in serum testosterone levels in the recipients indicating significant transfer of testosterone did not occur.

DISCUSSION

The articles regarding estrogen transfer are difficult to compare because each used various estrogen formulations, at varying doses and had different exposure methods. Of the three articles, the Wester and Taylor papers showed that significant transfer of estrogen from subject to naïve recipient occurred. However, the Schumacher paper did not show significant transfer. Possible explanations for why transfer did not occur may involve the method of skin-to-skin contact used. Both the Wester and Taylor studies involved vigorous skin-to-skin contact, whereas the Schumacher study used no movement during skin-to-skin contact.

Examining testosterone transfer is also difficult because testosterone formulations come in the form of different salts. In addition to differing formulation, dosing and method of transfer, the baseline characteristics including baseline testosterone levels were different between the two studies. The Mazer paper showed that transfer of testosterone could occur from both a testosterone spray and gel formulation onto clothing, with gel transferring a greater amount. The Rolf article showed significant interpersonal transfer but no transfer between subject and recipient.

The skin contains a substantial amount of water and lipid, along with a smaller amount of protein. The stratum corneum specifically contains the following lipids: free sterols, free fatty acids, triglycerides, and sphingolipids. The lipid component of the skin is an important regulator of skin permeability, and is therefore an important factor when considering the skin transfer of chemicals. The solubility of estrogen and testosterone differ depending on the substance they are in. In water, estradiol is practically insoluble with a solubility of 1.51 mg/L. The solubility of testosterone in water at 20°C is 66 µg/mL. In future research, the study of skin-to-skin transfer of hormones should relate to the amount of water and lipid found in the skin.

Transdermal hormone delivery has the potential to offer safer and more effective drug therapy to patients. However, due to the possibility of skin-to-skin transfer of the bioactive chemical, careful and standardized evaluation of percutaneous hormone therapy is necessary. In the broad sense, the topic of skin transfer and permeability is important not only for drugs, but also for toxins that can be used in chemical warfare agents.

CONCLUSION

Skin transfer of hormones is an important and relevant topic that has not been studied extensively. Further investigation of percutaneous hormone transfer is needed to ensure safe usage of topical hormone applications.

What We Know

- Topical hormone transfer is difficult to study and compare because the formulation, dosing and exposure methods vary.
- Of the three estrogen studies, two showed significant transfer of estrogen between subject and naïve recipient.
- Of the two testosterone articles, one showed significant transfer of testosterone from subjects to their clothing.
- Transdermal hormone delivery has the potential to offer safer and more effective drug therapy to patients. However, due to the possibility of skin-to-skin transfer of the bioactive chemical, careful and standardized evaluation of percutaneous hormone therapy is necessary.

Cost Effectiveness Studies

Cost-Effectiveness of Psoriasis Treatments

69

Xinaida T. Lima, M.D., Patricia Ting, M.Sc., M.D., and Alexandra B. Kimball, M.D., M.P.H.

INTRODUCTION

Psoriasis is a common skin condition affecting 1-2% of the general population. It is associated with significant morbidity that is exacerbated by its chronic and cyclical nature. Psoriasis affects approximately 7 million people in the United States, with an estimated 17% of these patients affected by moderate to severe forms of psoriasis.¹ Furthermore, the annual incidence of concomitant psoriatic arthritis ranges from 1 to 420 (median 180) cases per 100,000² or 6 to 30% of patients.^{3,4} Annual direct health-care and indirect costs (lost work days) are estimated at greater than US \$1500 per person per year (or US \$11.25 billion per year).⁵

The number of therapeutic agents for psoriasis and psoriatic arthritis has increased substantially in the past 10 years and this has led to considerable changes in the standard of care for patients with psoriasis, especially for patients with moderate to severe chronic plaque form of the disease.

Over the past decade, biologically engineered agents from recombinant DNA (i.e., biologics) with specific targets in the immune pathway of psoriasis have emerged into the mainstream pharmaceutical market. These agents have the potential to offer a much improved quality of life in addition to the potential to improve psoriatic arthritis.⁶ While biologics, in general, tend to be as or more effective than traditional therapies for psoriasis, such as topical agents (e.g., corticosteroids, vitamin D analogues and retinoids), phototherapy, and conventional systemic agents (e.g., methotrexate, cyclosporine and oral retinoids), the cost burden of biologics is extremely high. In addition to the high costs of biologics, further costs of regular monitoring and follow-up also need to be included in any accounting.

For mild disease, topical calcipotriol, and its combination with topical steroids are the main recent additions to the armamentarium. Economic analyses of topical treatments have also been published and, in some cases, such as the combination of betamethasone and calcipotriol, treatment can be very expensive if the body surface area (BSA) affected is large.

Fortunately, a number of studies evaluating cost-effectiveness and cost-utility have increased in the past years, allowing comparison between treatment options. Given that head-to-head trials are very expensive and

require large sample sizes, they are rarely performed and, therefore cost-effectiveness analyses generally use multiple studies with similar outcomes and models based on several assumptions.

Several pre- and post-treatment outcome measures are commonly employed to determine the impact of psoriasis on physical and psychosocial function. According to the National Psoriasis Foundation (NPF), psoriasis severity in the context of BSA is defined as mild (BSA <3%), moderate (BSA 3-10%) and severe (BSA >10%).³ The Psoriasis Area and Severity Index (PASI) is a more specific and refined measure of BSA and severity; it is widely used in clinical trials for psoriasis. A PASI score ≥10% is a frequent entry criteria for moderate to severe psoriasis. Most clinical studies define a “responder” with a PASI 75 (75% improvement compared to baseline) and while a “nonresponder” would have less than PASI 50 (50% improvement compared to baseline). Although PASI 75 is an excellent clinical outcome,⁷ PASI scores are still unable to account for the full impact of physical symptoms or limitations (i.e., facial, genital, palmar, and plantar psoriasis, etc), psychosocial factors, and overall quality of life. Health-Related Quality of Life (HRQL) outcome measures account for physical, psychosocial, and occupational impact of various disease states. Examples of relevant indices are Dermatology Quality of Life Index (DLQI) and Dermatology Quality of Life Scales (DQOLS), which are capable of population-specific measurements. More specific indices for disease-specific states include Psoriasis Disability Index (PDI) and Psoriasis Disability Scale (PDS).

Another important outcome for psoriasis research is quality-adjusted life-years (QALYs). QALY not only measures the number of life-years saved but it combines it with the “quality” of those years. It is both a quantitative and qualitative measurement. Studies have demonstrated high correlation between cost/ life-years and cost/QALY.⁸ For psoriasis, a chronic disease with low-mortality but high morbidity, QALY is a more appropriate measure than life-years saved and cost-utility analysis is likely the more appropriate outcome measure. However, the major disadvantage of using QALY is the subjectivity and variability of the qualitative component.

As mentioned above, most of the cost-effectiveness and cost-utility analyses currently published are performed through economic modeling. One of the advantages of

**TABLE 69-1—Currency Exchange Rates
(November/ 2009)⁴⁹**

	USD
FIM 1 (Finnish Markka)	0.23

1 CHF (Swiss Franc)	0.99
1 CDN \$ (Canadian Dollar)	0.95

using models is that it allows head-to-head comparisons, even when there aren't previous clinical studies comparing two specific drugs.

METHODS

We searched the PubMed (U.S. National Library of Medicine), by using the Medical Subject Headings (MeSH) terms "psoriasis" and "cost-benefit analysis" or "cost-effectiveness". The abstracts were reviewed and among those, we selected the articles published in English that present a cost-effectiveness/utility analysis of psoriasis therapy. The currencies were all converted to US dollars (Table 69-1). We did not correct for inflation.

ECONOMIC EVALUATION MODELS

The information for cost-effectiveness analysis can be gathered directly from clinical trials, cohort studies, registries, and databases or through model building process. Economic models are a quantitative method organized to assess the value or utility of each option in the decision analysis process. Models have been increasingly used for cost-effectiveness analysis and they offer several advantages: they allow results from a shorter study to be extrapolated into longer time-horizons and clinical surrogates into final endpoints. Information from different studies can be included in the same model, allowing head-to-head comparisons between drugs that have not been compared in randomized-controlled trials (RCTs), for example. There are different decision-analytic models, such as Markov models, decision trees, and discrete event simulations. In all of them, some basic methodologic steps have to be taken. After defining the research question, a model structure has to be developed and into this structure, probabilities of each branch have to be assigned, as well as their utilities and costs. Besides the main structure (base-case result), different assumptions will be made to address uncertainty and test the robustness of the approach (sensitivity analysis)⁹.

Decision Trees

Decision trees are a simple tool that can be used in cost-effectiveness and decision analysis⁹. In these models, each

action leads to one or more consequences until final predetermined events occur at the end of the branching process. The events receive probabilities, based on the literature or expert knowledge, as well as utilities and costs. From each node (or branching point), different occurrences will have probabilities that add up to 100% of the probability of the previous occurrence. This type of model is very straightforward and easy to interpret and it is helpful to organize multiple phases of decisions. However, its simple design does not allow more complex courses, more similar to a real life situation to be evaluated.

Markov Model

A Markov model is a more refined and complex way of performing analytic modeling. It often is best applied to clinical situations with continuing risk, because it allows analysis of events that can recur over time as well as transient events. A Markov model is built by states, the Markov states. There are absorbing states (once patients reach this state, they cannot leave it), such as death. Temporary states are created for short-term events and patients usually do not return to them. At the end of the cycles, patients can change states. This model is built under the assumption that each patient is always in one of these states. Costs and utilities are assigned to each state. It is also taken into account the duration (number of cycles) that patients spend in non-death states. The analysis is performed within a limited time horizon^{9,10}.

In order to present the model, the most commonly used methods are cohort simulation and Monte Carlo simulation. In the first one, the model is performed on a hypothetical cohort of patients that transfer between states in each cycle. The analysis is then made on the number of patients in different states other than 'death' in each cycle. On the other hand, the Monte Carlo simulation includes a large number of individual patients that transfer randomly through the many states. Finally, the results for each patient in each cycle are summed, independently from their last state being an absorbing state or not. These two methods can lead to different results and, while the cohort simulation is straightforward, the Monte Carlo simulation imposes fewer limits to the model⁹.

Discrete Event Simulation

Discrete event simulation allows more flexible presentation of the data than the Markov model, at the cost of being more complex and time consuming. Events can happen at any time period after the previous event. The minimum time period has to be pre-specified, but the events can happen at different intervals. Each time an event occurs, the analysis is elicited. The results from the analysis that uses this method are similar to the results yielded by Markov model¹¹.

TOPICAL THERAPIES

Several studies have been reported that compare cost-effectiveness of topical treatments for mild to moderate psoriasis, especially with topical corticosteroids, calcipotriol and dithranol. These studies not only compare the performance of different drugs, but they also take into account the frequency and compliance of topical treatment that can be a challenge and reason for therapy failure for many patients. Costs of topical therapy are presented in Table 69-2 and vary widely based on generic versus branded status.

An economic analysis comparing topical tazarotene in the concentrations of 0.1 and 0.05%, topical corticosteroid (fluocinonide) and topical calcipotriol for the treatment of mild to moderate psoriasis used a decision-analytic tree from a meta-analysis carried out by the authors (Table 69-3). Success was defined as at least 50% improvement of psoriasis lesions in physician's assessment. Treatment failures led to treatment with secondary drug. Sensitivity analysis evaluated the impact of drug acquisition and medical-care costs, efficacy, and length of treatment in cost-effectiveness analysis. In this analysis, tazarotene 0.1% was found to be the most cost-effective treatment. The sensitivity analysis showed that for tazarotene 0.1% to lose the rank of most cost-effective topical therapy, its price and other associated costs would have to increase by 37% and 68%, respectively, and its efficacy decrease by 18%. It is unclear whether the prices used for the analysis are for branded or generic drugs.¹²

Calcipotriene was compared to different potency steroids in a retrospective analysis of a US claims database. Both total costs and medication costs per episode were calculated. The costs for calcipotriene (\$111/episode) were higher compared to the costs of ultra-high, high, mid, and

TABLE 69-3—Efficacy and Costs/Disease-Free Days (USD) of Topical Psoriasis Therapy¹²

	Success rates*	Relapse rates	Cost per disease-free day	Expected annual costs
Calcipotriol (4 week)	79.9%	41.4%	\$120.56	\$4219.65
Fluocinonide (4 weeks)	78.5%	44.9%	\$91.73	\$3394.08
Tazarotene 0.1% (12 weeks)	73.9%	37.4%	\$49.46	\$3412.96
Tazarotene 0.05% (12 weeks)	67.5%	35.1%	\$57.74	\$3464.61

*At least 50% improvement of psoriasis lesions.

low-potency corticosteroids (\$47 to \$75). However, when the total costs of therapy were taken into account, calcipotriene regimen costs were not significantly different from the costs of regimens using topical corticosteroids. The authors emphasize that costs per gram of topical drugs should not be used alone for comparison of psoriasis treatments.¹³

Ashcroft et al. compared calcipotriol twice a day versus dithranol short-contact regimen once a day. The decision trees used short and long-term horizons of 12 weeks and up to a year, respectively. Efficacy data and relapse rates were collected from previous head-to-head RCTs. The long-term model assumed that treatment failures would lead to use of the comparator drug. Costs of dithranol were based on Dithrocream® 2%. The costs are converted to US dollars in Table 69-4. Patient's perception of improvement in psoriasis was used as the endpoint for effectiveness. Sensitivity analysis with different efficacy and cost estimates (using data from other studies) was performed. The authors concluded that short-contact dithranol was the most cost-effective first line therapy because of reduced costs for acquisition of drug and more long-lasting remission of disease after treatment.¹⁴

A retrospective analysis of a Canadian clinical study evaluated the effect of adding calcipotriol cream

TABLE 69-2—Comparative Costs of Topical Therapies for Psoriasis²²

Topical medications	Wholesale price (USD/gram)	Monthly cost [§] (USD)

[§]Versus dithranol.

TABLE 69-5—Cost-effectiveness Analysis of Different Vehicles¹⁶

Group	Efficacy (decrease in PASI in 2 weeks)	Amount of medication/ % BSA treated (g)	Costs/ % BSA treated (USD)
Clobetasol Foam	41%	7.43	\$8.18
Clobetasol Cream/Solution	35%	10.16	\$7.05

(Daivonex®/ Dovonex®) once a day to a twice-weekly UVB regimen versus UVB three times a week combined with emollients. The former had lower than the latter over a 20-week period, representing a 3% drop in costs. However, the results did not hold after a sensitivity analysis with changes in costs of UVB therapy. This may be a good alternative for patients that are not able to comply with three sessions a week.¹⁵

One single-blinded study aimed to compare efficacy and cost-effectiveness of the same active ingredient, but administered in different vehicles. Patients with mild to moderate psoriasis presenting with both skin and scalp lesions were randomized into either clobetasol propionate (Olux®) foam 0.05% (skin and scalp) versus generic clobetasol cream 0.05% (skin) and solution 0.05% (scalp). This study showed that the foam was more effective in terms of absolute improvement in PASI, but not significantly different in terms of percent change in baseline PASI. Subjects reported relative less time for the foam application. The costs to treat 1% BSA were similar in both groups (Table 69-5). This study was limited by short treatment duration and small sample size.¹⁶

There are a few studies that evaluated cost-effectiveness of the dual-action compound of calcipotriol and betamethasone dipropionate versus each ingredient alone or both drugs in separate morning and night applications.^{17–20} They were based on evaluation of data from European centers. The first one was performed in Scotland¹⁷ and the second in Germany.¹⁸ These studies confirmed the findings of a similar analysis that compared three combinations of calcipotriol/betamethasone available versus morning and evening use of the active ingredients separately. Use of the combination was shown to be more cost-effective.¹⁹

One study compared the use of an ointment containing betamethasone dipropionate and calcipotriol (combination therapy - Daivobet®), once a day for 4 weeks, followed by calcipotriol (Dovonex®), only also once a day for 4 weeks versus tacalcitol (Apsor®, Curatoderm®, Bonalfa® and Vellutan®), only once a day for 8 weeks. Efficacy and cost-effectiveness were analyzed over 8 weeks. This evaluation was based on a randomized, double-blind study that included 501 subjects from 4 European centers. Sensitivity analysis was performed with and without subjects that withdrew from the study and assuming partial and complete treatment duration. The combination

TABLE 69-6—Cost-effectiveness Analysis of Combination Therapy with Calcipotriol/Betamethasone Dipropionate Versus Tacalcitol²⁰

	Efficacy (PASI \geq 75)* at 8 weeks	Total direct costs for psoriasis (USD) [§]	Cost/ successfully treated patient (USD)
Calcipotriol/betamethasone dipropionate (4 weeks) + Calcipotriol (4 weeks)	44.6%	\$ 161.54	\$ 362.38
Tacalcitol (8 weeks)	23.8%	\$ 170.51	\$ 716.15

* Last observation carried forward.

§ Costs included study drug, alternative treatment for psoriasis and other skin disorders and adverse events costs.

therapy was found to be more effective and cost-effective than tacalcitol alone for the treatment of plaque psoriasis (Table 69-6).²⁰

In the Scottish cost-utility analysis, calcipotriol/betamethasone dipropionate (Dovobet® - Leo Pharma - UK) was compared to other commonly prescribed therapies in England, such as calcipotriol once or twice a day, betamethasone dipropionate daily, or concurrent calcipotriol (morning) and betamethasone dipropionate (evening). An indirect comparison of randomized clinical trials was performed, using a Markov model with 12 1-month cycles. Sensitivity analyses evaluated several different assumptions, including different costs, response to phototherapy, amount of the topicals used, baseline utility, topical prescribed and utility while on the wait list for phototherapy, duration of the waiting list, PASI \geq 75 per treatment option, magnitude of utility gain associated with response and nonresponse, relapse rate of the comparators, and use of other potent steroid. They concluded that treatment with the two-compound calcipotriol/betamethasone dipropionate would lead to annual savings of approximately \$230.00 per patient compared to calcipotriol QD (1st choice), followed by steroids (2nd choice); and \$454.00, compared to use of the constituents separately (calcipotriol applied morning and betamethasone evening) (Table 69-7). It is unclear whether the cost calculations were based on generic or branded drugs.¹⁷

In the German study, a Markov model was also developed to evaluate the cost-effectiveness of the two-compound calcipotriol/betamethasone dipropionate (Daivobet® - LEO Pharma GmbH, Germany), followed by calcipotriol (Daivonex®), compared to the two individual agents used separately (Daivonex® and Diprosone®) (similar to the scheme in the previous study), as well as a comparison with tacalcitol (Curatoderm®). The most cost-effective approach was the two-compound calcipotriol/betamethasone dipropionate once daily (Table 69-8). This result did not change after allowing for variability of 10% in the efficacy of the compound product or assuming

TABLE 69-7—Cost-effectiveness Analysis of Combination Therapy with Calcipotriol/Betamethasone Dipropionate Versus Calcipotriol and Betamethasone Separately¹⁷

Drug	Frequency	Efficacy (PASI \geq 75)*	Costs/ 4 weeks (USD)	Estimated annual cost	QALY gained

maximum compliance with the separate use of corticosteroid and calcipotriol.¹⁸

Topical therapies have also been compared to phototherapy in the treatment of moderate to severe psoriasis. An open-label, randomized study from the Netherlands compared short-contact dithranol, UVB phototherapy, and inpatient therapy with dithranol (Table 69-9). The duration of therapy was 12 weeks for UVB or short-contact dithranol and 8 weeks for inpatient therapy. Costs were calculated for the drug (it was not specified whether the generic or branded drug were used), physician and nurse's times, UVB unit, day-care unit, outpatient visits and inpatient costs. The authors concluded that short contact treatment is a cost-effective option for moderate to severe psoriasis when compared to inpatient treatment. However, UVB

phototherapy continues to be the first line therapy in these cases.²¹

A single-blinded study compared 15% LCD solution (Psorent[®]) versus 0.005% calcipotriol cream (Dovonex[®]) in the treatment of moderate psoriasis. Sixty subjects were randomized to one of the two treatment options for 12 weeks and were followed for 18 weeks total. Cost-effectiveness analyses were based on improvement of PASI and DLQI scores. Sensitivity analysis evaluated the impact of a different point of view having the patient as the payer with the respective prices of acquisition of OTC LCD solution and copayment for calcipotriol. LCD therapy proved to be more efficacious (higher improvement in PASI score) and less expensive than calcipotriol (Table 69-10). The effect of LCD solution was also more durable in the 6 weeks following therapy. Sensitivity analysis achieved similar conclusions.²²

TABLE 69-9—Cost-effectiveness Analysis of Dithranol Compared with UVB Phototherapy (Hartman)

	Success rates*	Costs/ treatment (USD)	Number of days of clearance
Short-contact dithranol	57%	2,465.27	160
UVB phototherapy	57%	1,889.89	136
Dithranol (inpatient therapy)	85%	11,576.72	211

* Decrease of at least 90% of BSA affected by psoriasis. UVB - ultraviolet B

PHOTOTHERAPY

A large noncontrolled study evaluating PUVA therapy was one of the first cost-effectiveness studies in psoriasis. It evaluated prospectively more than a thousand subjects. The number of days of hospitalization, concomitant therapies, and costs were evaluated during the year prior to PUVA and the year after the 10 months of phototherapy. Some patients remained on phototherapy during the subsequent year (continuers). PUVA not only improved psoriasis and

TABLE 69-10—Cost-effectiveness Analysis of Tar (LCD solution) Versus Calcipotriol²²

	Efficacy (% PASI improvement)	Cost of 1% improvement in PASI score	Efficacy (points of DLQI improvement)	Cost of 1 point improvement in DLQI score
Week 12				
LCD solution	58.2	\$0.92	5.1	\$10.50
Calcipotriol	36.5	\$35.42	3.5	\$360.04
Week 18				
LCD solution	52.5	\$1.01	6.9	\$7.70
Calcipotriol	22.2	\$58.11	2.8	\$450.05

LCD - Liquor Carbonis Detergents; DLQI - Dermatology Life Quality Index

What We Know: Topical Therapies

- Generic corticosteroids are relatively inexpensive options for topical treatment and have high short-term efficacy for mild to moderate psoriasis. They should be part of first-line therapy and could be applied alone or in combination with other topical or systemic therapies.
- Calcipotriol and Tar seem to be reasonable second-line options for mild psoriasis or could be combined with corticosteroids as first-line therapy for moderate disease. One study that compared these two drugs showed that tar (LCD solution) was more cost effective than calcipotriol.
- A few studies have shown that combination therapy of calcipotriol and corticosteroids works better than either active ingredient alone or their use in a morning and night regimen.
- Many factors have to be taken into account when prescribing topical treatments, such as vehicle used (e.g., foam is easier to be applied), cosmetic acceptability and convenience of application leading to better compliance.

TABLE 69-11—Overall Efficacy and Cost-effectiveness Analysis of PUVA²³

	Number of days of hospitalization (mean/year)	Cost of hospitalization per patient (USD)	Total costs of hospitalization + PUVA per patients (USD)
Pre-treatment year	5.1	\$1,550	\$1,550
Follow up year	1.2	\$360	\$970

decreased the need of concomitant therapy, it decreased the overall costs (Table 69-11).²³

Another uncontrolled clinical trial evaluated the impact of daily heliotherapy for 4 weeks in Spain for 46 Finnish patients. This evaluation compared the costs of therapy during the year prior to the heliotherapy course to the costs of heliotherapy and during the year afterwards. The average total direct costs decreased after the heliotherapy (Table 69-12). The cost reduction (22%) was not statistically significant though, because of large variability in

costs. Heliotherapy itself was expensive with estimated costs ranging from \$2309.24 to 4618.48. The authors point out that many patients in this study had mild disease and conclude that this therapy is effective and would be justified for patients with severe disease that require systemic drugs or hospitalization.²⁴

An economic analysis, using a decision tree built to reflect the AAD recommendations for rotational therapy for mild-to-moderate psoriasis, was performed to compare the impact of second-line therapy selections, particularly excimer laser. Costs for each therapy itself, office visits, and management of adverse events were included in the analysis. First-line therapy was topical corticosteroid plus calcipotriene. For nonresponders, second-line therapy included intralesional corticosteroid, excimer laser, PUVA, UVB phototherapy, tazarotene plus steroid and anthralin plus steroid. The estimated annual costs (US dollars - USD) per patient were \$2,340 in the model, including excimer laser and \$2,342 in the model excluding it. The conclusions

TABLE 69-12—Comparison of Costs Before and After Heliotherapy²⁴

	Costs/ time period (USD)
Pre-heliotherapy	\$1693.83/1 year
Heliotherapy in Spain	\$2837.83/4 wk
Post-heliotherapy	\$1316.27/1 year

TABLE 69-13—Comparison of Costs of Second-line Therapies for Psoriasis (USD)²⁵

Second line therapy	Cost of first line + one second-line therapy/ treatment free day	Cost of first line + one second-line therapy/ remission day	Estimated total annual costs	Cost/ treatment regimen
Intralesional corticosteroid	\$35.53	\$9.65	\$2,035	\$106.43
Excimer laser	\$41.61	\$10.73	\$2,335	\$909.36
UVB	\$56.56	\$13.10	\$2,653	\$1,412.64
PUVA	\$47.37	\$13.16	\$2,732	\$2,464.00
Anthralin + Corticosteroid	\$291.92	\$9.89	\$2,034	\$50.24
Tazarotene + Corsticosteroid	\$99.92	\$10.92	\$2,254	\$278.60

UVB - ultraviolet B; PUVA - psoralen combined with ultraviolet A

of this evaluation were that the 308-nm excimer laser was more cost-effective than other second-line options, such as UVB, PUVA, and topical therapies, in terms of the costs to attain a treatment-free day (Table 69-13). Adding the excimer laser to the rotational scheme resulted in improved clinical outcomes without adding costs.²⁵

A cost comparison between home ultraviolet B phototherapy versus systemic therapies for severe psoriasis has been performed using US data. The systemic drugs used in this payer perspective comparison were PUVA, methotrexate, acitretin, alefacept, efalizumab, and etanercept (efalizumab was not included in the results presented here, because it has been discontinued from the market). Doses are presented in Table 69-14. The time horizon used for this analysis was 30 years and, in addition to the head-to-head comparison of costs, a break-even analysis was performed to determine when the therapy with home UVB became more cost-effective than the other therapies.²⁶

The authors concluded that home UVB phototherapy had lower costs than the systemic therapies at 30 years horizon (Table 69-14). They also showed that, after a 2-year period, phototherapy had become the least expensive therapy for severe psoriasis. The initial costs of acquiring the home UVB phototherapy unit would be compensated by the very low costs in maintaining it and no requirement of follow-up tests.

The results from this analysis were straightforward and easy to interpret. However, the evaluation is limited to cost and does not include long-term effectiveness or safety issues. The authors acknowledge that no consistent data exists on efficacy of home UVB therapy. Sensitivity analyses were also not performed, so it was not tested whether different doses, for example, under different assumptions, would yield different results. The conclusions of this study would most likely not change, given such a striking difference in costs between the treatment options.

TABLE 69-14—Comparison of Home UVB Phototherapy with Systemic Therapy for Severe Psoriasis.²⁶

	Dose/Administration	Follow up tests	First year total costs (USD)	30-yr total costs
Home UVB	6 min EOD	None	2,345.04	7,085.27
PUVA	40 mg PO 30 sessions/yr	None	2,420.74	37,591.46
Methotrexate	15 mg PO/ week	CBC, LFTs (8x/year) + liver biopsy (every two years)	1,440.61	19,102.36
Acitretin	25 mg PO/day	Lipids and LFTs (4x/year)	4,900.43	75,112.69
Alefacept	15 mg IM 18 injections/yr	CD4 count (with each injection)	20,206.11	319,356.19
Etanercept	50 mg SC/week	PPD at initiation	16,596.60	257,683.89

UVB - ultraviolet B; EOD - every other day; PUVA - psoralen combined with ultraviolet A; PO - oral; SC - subcutaneous; CBC - complete blood count; LFTs - liver function tests; PPD - purified protein derivative

What We Know: Phototherapy

- The first cost-effectiveness studies in psoriasis evaluated phototherapy performance and showed that it reduced the days of hospitalization and consequently the costs of treatment.
- Phototherapy is not cost-effective for patients with mild disease that are responsive to topical therapies, but it is an excellent alternative for patients with moderate to severe disease as single or adjuvant therapy.
- The costs of the visits and the time devoted to the phototherapy sessions are the biggest disadvantages of this therapeutic approach.

SYSTEMIC THERAPY FOR PSORIASIS

A national survey estimated that 30% of patients with psoriasis require more than topical therapy.²⁷ For moderate to severe psoriasis, phototherapy, or systemic therapies (conventional and biologics) in monotherapy, or in combination with topical modalities are often used in clinical practice. Well-known conventional therapies (i.e., nonbiologics) include methotrexate (MTX), cyclosporine (CsA), and oral retinoids such as acitretin (Soriatane[®], Stiefel Laboratories Inc, Coral Gables, Florida). Biologics include alefacept (Amevive[®], Astellas Pharma US, Deerfield, Illinois), etanercept (Enbrel[®], Amgen, Thousand Oaks, California and Wyeth Pharmaceuticals Inc, Collegeville, Pennsylvania), infliximab (Remicade[®], Centocor Ortho Biotech, Malvern, Pennsylvania), adalimumab (Humira[®], Abbott Laboratories, Abbott Park, Illinois), ustekinumab (Stelara[®], Janssen-Ortho Inc, Toronto Ontario) and efalizumab (Raptiva[®], Genentech, South San Francisco, California). Efalizumab was withdrawn from the market in 2009 for its association with progressive multifocal leukoencephalopathy and will, therefore, not be further discussed.

The cost of systemic psoriasis therapies is highly variable (Table 69-15) with conventional therapies (approximately \$63.50 to \$750 per month USD) costing far less than biologics (approximately \$1100 to \$1800 per month USD).²⁸ However, laboratory monitoring of systemic therapies need to be included in cost calculations and change the relative costs somewhat (Table 69-16).

Nonbiologics

Methotrexate (MTX) has long been considered the “gold-standard” for moderate to severe psoriasis treatment over the past 40 years²⁹ and is one of the most commonly prescribed systemic treatments for psoriasis. A chemotherapy agent in higher doses, MTX, likely acts as an immunosuppressant in lower doses. Efficacy of MTX for psoriasis ranges from 43-82%.²⁸ MTX requires monthly laboratory work to monitor bone marrow and liver function as well as a surveillance liver biopsy to rule out cirrhosis for each cumulative dose of 1500 mg (i.e., approximately every 2 years of continuous therapy). MTX is available in tablet or an injectable liquid (for intramuscular IM, subcutaneous SC or intravenous IV administration). The liquid form is less expensive than the tablet (Table 69-17) and can also be taken orally.²⁸

Using a visual analog scale survey comparing visual clinical improvement in mild, moderate, and severe psoriasis patients on oral (tablet or liquid) MTX versus Goeckerman therapy, dermatology faculty (staff and residents), psoriasis patients, and a sample of people without psoriasis nor their treating physicians, Chen et al.³⁰ concluded that Goeckerman therapy was less cost-effective than liquid MTX in severe psoriasis patients over a 52-week extrapolated model. Sensitivity analysis assumed that the best case

with MTX was 82% clearance (for moderate to severe), 18% clearance (for mild) while the worst case with MTX was 43% clearance and 57% with no improvement, while the best case with Goeckerman therapy was 100% clearance and worst case was 90% clearance (for moderate to severe) and 100% clearance (for mild). These conclusions were challenged by Lim et al.³¹ by highlighting issues related to actual costs of physician visits on MTX, safety issues with patients extracting their own doses of liquid MTX from 25 mg/mL vials and typically short remission periods from MTX (2-3 months) versus Goeckerman (20-22 months).³²

Cyclosporin (CsA) was developed as an immunosuppressant agent used in transplant patients. CsA tends to be highly effective and rapid acting for PsO, but is associated with numerous adverse effects including hypertension, dyslipidemia, and nephrotoxicity; and therefore requires monthly serum creatinine and blood pressure monitoring. The US Food and Drug Administration (FDA) recommends that continuous CsA therapy should not exceed 1 year, while an international consensus statement on the use of CsA for psoriasis suggests limiting CsA to two years.³³

Hakkaart-van Roijen et al. in a multicenter, nonblinded international clinical trial ($n = 212$) conducted in parallel to the Psoriasis Intermittent Short Course Efficacy of Sandimmun Neoral[®] trial (PISCES)³⁴ compared the effects of tapered dosages versus abrupt discontinuation of CsA over a 1 year period for patients with chronic plaque-type psoriasis. These patients were treated with CsA until clearance (at least 90% BSA reduction in BSA) or up to 12 weeks, then either discontinued or tapered from therapy; retreatment was instituted for relapse (greater than 75% BSA). Outcome measures for systemic therapy free days (STFD) and cost-effectiveness ratio (ICER) found that a slow CsA taper was more cost-effective yielding an additional 32 days of STFD and reduction in cost per patient by \$US258 (ICER -8.1).³⁵

Ellis et al. used a computer decision analytic model with Markov processes of 1000 simulated patients with moderate ($n = 800$) and severe ($n = 200$) psoriasis not responsive to topical therapy. Patients were randomly assigned a treatment regime of either primarily MTX 10 to 20 mg/week or CsA 3 to 3.5 mg/kg/day with methotrexate 10 to 20 mg/week (CsA/MTX) in 1-year rotational cycles. Data was used to determine 10-year costs of therapy. Their analysis determined that MTX strategy cost \$33,000 USD over 10 years with approximately 2 years of clearance (i.e., \$4,100 per clear year), while CsA/MTX rotational strategy cost \$38,000 USD over 10 years with approximately 4 years of clearance (\$2,700 USD per clear year), thereby suggesting a greater cost-effectiveness of rotational therapy.³⁶

Oral retinoids such as isotretinoin and acitretin are also used in psoriasis. In particular, acitretin can be effective for erythrodermic and pustular psoriasis,³⁷ but less than one-third of plaque-type psoriasis are responsive. Oral retinoids are associated with many unpleasant adverse effects, namely xerosis, cheilitis, musculoskeletal symptoms, in addition to

TABLE 69-15—Approximate Costs Calculations Used for Systemic Psoriasis Therapy.^{28,50}

Medication (administration route)	Dosage (annual doses)	Per Unit Medication Cost USD ^{28,40}	Cost Calculations	Approximate Annual Cost USD
Nonbiologics

CXR = chest x-ray, PPD = purified protein derived tuberculin at treatment initiation. Methotrexate lab work = Complete blood count, liver enzymes (AST, ALT, alkaline phosphatase and bilirubin) and creatinine prior to therapy, then monthly thereafter. Cyclosporin lab work: complete blood count, complete metabolic panel, creatinine, lipid panel (total cholesterol, triglycerides, LDL and HDL), cyclosporine levels and blood pressure monthly. Acitretin lab work: Complete blood count, liver function (AST, ALT, alkaline phosphatase and bilirubin), lipid panel prior to therapy, then monthly for the first 3-6 months, then every 3 months thereafter.

Monthly costs of medication were determined by Pearce et al. (2004) from the average wholesale price (AWP) listed in the 2003 Drugs Topics Red Book* and www.drugstore.com internet pharmacy.

teratogenicity in women of childbearing age. Laboratory work is required for monitoring liver function and lipid profiles. Estimated annual cost of acitretin 25 mg daily is \$6000.²⁸

Biologics

Five FDA-approved biologic agents for the treatment of psoriasis etanercept (Enbrel[®]), infliximab (Remicade[®]),

alefacept (Amevive[®]), and adalimumab (Humira[®]) and ustekinumab (Stelara[®]) will be discussed.

PASI 75 Comparisons

Two systemic reviews expressed cost-effectiveness in the context of attaining PASI 75 (Tables 69-18 & 69-19). Greiner & Braathen (2009) evaluated cost-effectiveness of

TABLE 69-16—Costs Associated with Monitoring Laboratory Investigations^{26,36,40}

Investigation	CPT Code	Cost (USD)
Complete blood count and differential	85025	\$23(10-50)

PPD	86580	10 per test
R3 physician office visit	99213	53-75
Percutaneous liver biopsy	47000	\$750(300-1300)

Legend: IM = intramuscular; IV = intravenous; PO = oral; SC = subcutaneous
 CXR = chest x-ray, PPD = purified protein derived tuberculin at treatment initiation. Methotrexate lab work = Complete blood count, liver enzymes (AST, ALT, alkaline phosphatase and bilirubin) and creatinine prior to therapy, then monthly thereafter. Cyclosporin lab work: complete blood count, complete metabolic panel, creatinine, lipid panel (total cholesterol, triglycerides, LDL and HDL), cyclosporine levels and blood pressure monthly. Acitretin lab work: Complete blood count, liver function (AST, ALT, alkaline phosphatase and bilirubin), lipid panel prior to therapy, then monthly for the first 3-6 months, then every 3 months thereafter.

biologics used in Switzerland, adjusted to Swiss prices and tariffs in 2006. These authors determined ICER in patients achieving PASI 50, 75, or 90, at weeks 12 with responders (PASI >50) continuing to 24 weeks; analytic models were used to determine ICER at 36 weeks. Placebo-adjusted values for infliximab 5 mg/kg demonstrated the highest efficacy (i.e., 77.8% and 78.4% with PASI 75 at weeks 12

and 24 respectively), with the lowest ICER \$29,730 (from a 36-week extrapolated model), followed by adalimumab (i.e., 56.0% and 61.5% with PASI 75 at week 12 and 24 respectively, ICER \$29,160) and etanercept (i.e., 46.4% and 50.9% with PASI 75 at week 12 and 24 respectively, ICER \$35,286), while alefacept comparatively had the lowest efficacy (i.e., 16.0% and 20.0% with PASI 75 at week 12 and 24 weeks respectively), with the highest ICER \$48,606 (see Table 69-18).³⁸

Poulin et al., (2009) pooled data from randomized-controlled trials studying the use of biologics for chronic plaque psoriasis published through December 2008 (Table 69-19). Their analysis determined the number needed to treat and the estimated cost to achieve PASI 75, based on product monograph recommended doses for the first year of therapy. Annual treatment cost ranged from \$18,752 to 35,577 USD per patient. From their analysis, the most cost effective agent to achieve PASI 75 at 12 weeks and 1 year respectively was adalimumab (\$7,879, \$27,578), followed by ustekinumab (\$11,859, \$35,577) and infliximab (\$14,290, \$38,106). The least cost-effective was alefacept (\$67,150, \$135,020).³⁹

PASI 75 & DLQI Comparison

Nelson et al., (2008) performed a meta-analysis of pooled data from randomized-controlled trials from January 1, 2003 and January 1, 2007, to compare the cost-effectiveness of biologics to achieve a minimally important difference Dermatology Quality of Life Index (DLQI-MID) and PASI 75 over a 12-week treatment course (Table 69-20). Over the 12-week treatment period, the most cost-effective biologics in attaining DLQI-MID improvement were etanercept 25 mg weekly (\$2,250 USD) followed by infliximab 3 mg/kg (\$3,508), adalimumab 40 mg every other week (\$3,511).⁴⁰

TABLE 69-17—Comparison of Methotrexate (Oral and Liquid) Versus Goeckerman Therapy³⁰

DLQI: Dermatology Quality of Life Index; DLQI-MID: Dermatology Quality of Life Index minimally important improvement; PASI: Psoriasis Assessment Severity Index; PASI 75: 75% improvement from baseline; N/A: not applicable.

In comparison, the most cost-effective biologic agents to achieve PASI 75 in the most patients were infliximab 3 mg/kg (\$8,797 USD, 70.6%), followed by infliximab 5 mg/kg (\$10,422, 79.1%) and adalimumab 40 mg every other week (\$11,657, 53.3%). Estimated annual cost of infliximab administration (based on three infusions per year) ranges from \$6,559.12 (3 mg/kg/infusion) to \$8,547.16 (5 mg/kg/infusion) to \$16,499 (10 mg/kg/infusion). A cost-effectiveness meta-analysis comparing 3 mg/kg and 5 mg/kg versus placebo over a 12-week period reported mean DLQI improvement of 9.0 and 9.7 (versus 0.5 with placebo) with 70.6% and 79.1% achieving PASI 75 respectively. Cost per patient to reach PASI 75 was \$8,797 and \$10,422 respectively versus placebo.⁴⁰ The least cost-effective biologic to achieve DLQI-MID and PASI 75 was alefacept 15 mg IM weekly and over a 12-week period mean DLQI improvement of 4.9 (versus 2.7 with placebo), with 21% achieving PASI 75. Cost per patient on alefacept to reach PASI 75 is \$74,625.⁴⁰

PASI 75 & Quality Adjusted Life Years (QALY) Comparison

Sitzo et al., (2008) analyzed 22 randomized controlled trials conducted over a 12-16 week period comparing biologics (adalimumab, etanercept and infliximab) to nonbiologic systemic agents (MTX, CsA), and supportive care in patients with moderate to severe psoriasis using PASI 75 and quality-adjusted life years (QALY) with cost-effectiveness ratios based upon QALY (Table 69-21).⁴¹ Compared to supportive care (baseline), both MTX (ICER -\$49,045) and CsA (ICER -\$41,424) appeared to be most

cost-effective, but were noted to require monitoring for systemic toxicity. While infliximab had the highest incremental QALY (0.18) compared to supportive care, adalimumab was most cost-effective (ICER \$49,442 per QALY), followed in sequence by etanercept (ICER \$60,979 per QALY) and infliximab (ICER \$69,219 per QALY).⁴¹

QALY COMPARISON

Heinen-Kammerer et al., (2007) pooled data from three clinical trials to compare the cost-effectiveness of etanercept 25 mg twice weekly to nonsystemic therapy for moderate to severe plaque-type psoriasis using QALY gained extrapolated over 10-years (Table 69-22).⁴² In their model, patients were started on etanercept for 12 weeks. Responders (PASI \geq 75) were discontinued active treatment until PASI decreased by 50%. Partial responders (PASI <75) continued with treatment for another 12 weeks and those that did not reach PASI 75 were considered nonresponders. All nonresponders (from initial 12 week period) and partial responders that did not respond to a second 12-week course of etanercept did not receive further treatment. Estimated cost for medication and physician's fees for etanercept and basal therapy per 4-week cycle were \$2,577.15 and \$37.24 respectively. These authors reported that increased PsO severity is associated with decreased cost per QALY with increased PsO severity from \$68,341 (PASI & DLQI >10) to \$27,273 (PASI & DLQI >20). Furthermore, for the most severe (PASI and DLQI >20), the ICER decreased with increasing age: ICER \$27,047 (age >20), \$23,117 (age >40) and \$9,325 (age >60). Sensitivity analysis for PASI and DLQI >20 with basal treatment consisting of

TABLE 69-21—Comparison of Cost-effectiveness of Nonbiologic and Biologic Agents to Supportive Care Using QALY⁴¹

Medication	Dose	Cost versus supportive care (USD)	Mean QALY	PASI75 (%patients)	ICER per QALY versus supportive care (USD)	ICER per QALY versus biologics (USD)
Methotrexate	15-25 mg/week	-6,335	0.13	37	-49,045	N/A

Etanercept	>15	2,577.15	72,028	1.34	48,161
Basal therapy	(n=192)	37.24	61,662	1.13	4.66
Etanercept	>20	2,577.15	82,617	1.74	27,273
Basal therapy	(n=87)	37.24	72,656	1.37	4.66

*Cost includes medication and physician fees.

QALY = quality adjusted life years, PASI = psoriasis adjustment severity index; n = number of patients.

systemic therapies (cost \$180/cycle), and 30% reduction in hospitalization risk from etanercept therapy reported ICER values to be \$23,808 for basal therapy, \$24,525 for intermittent etanercept and \$36,109 for hospital stay. These authors concluded that intermittent etanercept 25 mg twice weekly is most cost-effective for severe (and moderate) psoriasis, particularly in older patients.⁴²

Woolacott (2006) in a systemic review of etanercept and efalizumab for the treatment of psoriasis performed several cost comparison analyses (Table 69-23). For any baseline DLQI treated with etanercept twice weekly compared to supportive therapy (without hospitalization), biologic therapy would not be cost-effective unless the cost-effectiveness threshold approaches ICER \$115,365 per QALY gained. Comparing patients with any baseline DLQI versus those with low fourth quartile DLQI only on supportive care (without hospitalization), the cost for treatment was \$109,931 (any DLQI) versus \$57,409 (fourth quartile DLQI) for etanercept 25 mg (intermittent), \$137,215 versus \$71,656 for etanercept 25 mg (continuous), and \$199,177 versus \$103,998 for etanercept 50 mg (intermittent).⁴³ The first scenario using only patients with baseline DLQI in the fourth quartile determined the threshold of cost-effectiveness would be ICER \$57,682,

thereby favoring supportive care (without hospitalization) below this threshold and biologics entering the sequence as intermittent etanercept 25 mg followed by continuous etanercept 25 mg above this threshold. The second scenario included any baseline DLQI where all nonresponsive patients would undergo a 21-day (adjusted \$409/day from NHS Reference Costs 2003 and National Tariff 2004) inpatient hospitalization per year; etanercept 25 mg (intermittent) entered in the treatment sequence with ICER \$49,442 followed by continuous etanercept 25 mg with ICER \$82,404. The third scenario accounted for patients in the fourth quartile DLQI and assumed nonresponsive patients undergoing a 21-day inpatient hospitalization; etanercept 25 mg (intermittent) entered the sequence with ICER \$32,961 followed by continuous etanercept 25 mg with ICER \$32,961. The fourth scenario included any baseline DLQI on several systemic therapies and supportive therapy with nonresponders requiring 21 days per year of inpatient hospitalization; biologics enter the treatment sequence with etanercept 25 mg (intermittent, ICER \$48,537), etanercept 25 mg (continuous, \$75,852), infliximab (\$85,284) etanercept 50 mg (intermittent, \$137,906) only after failure of methotrexate and cyclosporine.⁴³ When PASI scores from all treatments were compared, the most

TABLE 69-23—Cost-effectiveness of Systemic Therapies for Psoriasis Over 12-Weeks Using Quality-Adjusted Life Years in the United Kingdom (QALY)⁴³

Medication	Dosage	Incremental Cost (USD)	QALY improvement	Incremental Cost (USD)	ICER/QALY versus supportive care (USD)
Etanercept (intermittent)	25 mg 2x/wk for 12 weeks	5,628	0.116	5,628	48,537
Etanercept (continuous)	25 mg 2x/wk for 12 weeks	8,796	0.116	8,796	75,852
Etanercept (intermittent)	50 mg 2x/wk for 12 weeks	16,906	0.123	16,906	137,576
Infliximab	3-5 mg/wk × 3 doses in first 6 weeks, then every 8 weeks	11,401	0.134	11,401	85,284
Methotrexate	Weekly	-6,960	0.126	-6,960	dominates

Supportive care, hospitalization	N/A	-	-	-	-

QALY = quality adjusted life years. ICER - incremental cost-effectiveness ratio

TABLE 69-24—Cost-effectiveness of Licensed Regimes of Etanercept Over 12 Weeks (Extrapolated to 10 Years) for PASI and DLQI > 10 Psoriatic Patients Using Quality-Adjusted Life Years (QALY) in the United Kingdom⁴⁴

Medication	Dosage	Cost (USD/10 years)	Incremental Cost (USD/10yrs)	QALY improvement	ICER versus no systemic therapy (USD)
Etanercept	25 mg 2×/wk, then 25 mg (intermittent)	73,924	4,730	0.67	7,082
Etanercept	50 mg 2×/wk, then 25 mg (intermittent)	78,427	9,234	0.9	10,246
No systemic therapy	—	69,194	—	—	—

efficacious psoriasis treatment was infliximab, followed by methotrexate and cyclosporine, then etanercept 50 mg (twice weekly), then etanercept 25 mg (twice weekly).⁴³

Lloyd et al., (2009) used an economic model to determine the incremental cost per QALY gained for etanercept 50 mg twice weekly in chronic plaque-type psoriasis patients with DLQI and PASI ≥ 10 ($n=671$) who were not candidates for other forms of systemic therapy.⁴⁴ The study pool data from three randomized placebo-controlled studies using licensed etanercept treatment regimes for at least 12-week duration (Table 69-24). In their model, patients were started on either etanercept 25 mg or 50 mg twice weekly for 12 weeks. Responders (PASI ≥ 75) discontinued active treatment until response was lost. Partial responders (PASI < 75) continued with their respective treatment for another 12 weeks and those that did not reach PASI 75 did not receive further treatment. All patients that did not reach PASI 50 from the initial 12-week period were discontinued from the study. These authors found that incremental cost per QALY were \$7,082 and 10,246 for etanercept 25 mg and 50 mg biweekly, followed by intermittent 25 mg biweekly for relapses. Sensitivity analysis with etanercept 50 mg twice weekly compared to no systemic therapy found that incremental cost per QALY with PASI > 20 (\$8509) and

DLQI > 20 (\$7579) made this treatment regime a cost-effective option for severe psoriasis.⁴⁴

DISCUSSION

Cost-effectiveness analysis is a tool that can be used to evaluate the therapeutic and economic trade-offs for an intervention. In this era of cost containment, the efficacy, utility, safety, and cost of medications need to be assessed in an integrated way in order to prioritize how to choose therapies on a societal level. Unfortunately, even the most comprehensive models likely miss or are forced to omit some relevant details. Moreover, information gathered from cost-effectiveness analyses based on data from randomized-controlled trials may not reflect ‘real world’ settings, whereas other factors affect adherence, efficacy, and cost. External validation may be one way to solve this problem,⁴⁵ but to date, most evaluations are based on models, rather than prospective collection of cost data. Lastly, and perhaps most importantly, in an individual patient, risk factors, preferences, quality of life, economic productivity, and coping, may be relevant parts of therapeutic decision-making. These considerations can only be evaluated and addressed within the individual physician-patient construct.

What We Know: Systemic Therapies

- Conventional systemic agents for psoriasis include methotrexate, cyclosporin, and acitretin. Depending on the dosage, the annual costs of these agents are relatively low, ranging from approximately \$1,200 to 2,800 USD for methotrexate, \$5,800 to \$10,100 USD for cyclosporin and \$6,000 for acitretin.
- Biologic agents for chronic plaque psoriasis include infliximab, adalimumab, and etanercept (anti-tumor necrosis factor agents), alefacept (inhibitor of CD4 and CD8 T-cells), as well as ustekinumab (interleukin 12 and 23 antagonist). Furthermore, antitumor necrosis factor agents are also effective for psoriatic arthritis. Annual costs for these agents range from \$15,000 to \$38,000 USD.
- A cost-effective clinical approach to the management of chronic plaque psoriasis would start with a conventional systemic agent such as methotrexate or cyclosporin. Failure of a therapeutic trial or contraindications to these agents would be followed by management with biologic agents.
- Based on the available cost-effectiveness comparisons of biologic agents for chronic plaque psoriasis, it would be reasonable to start a patient on adalimumab 40 mg every other week or infliximab 5 mg/kg every 8 weeks or ustekinumab 45 mg every 12 weeks. Alefacept was the least cost-effective agent demonstrated in cost-effectiveness comparisons.
- Biologic agents, particularly antitumor necrosis factor-alpha agents (e.g., adalimumab, infliximab, and etanercept) should be considered in patients with psoriasis and concomitant psoriatic arthritis.

The majority of psoriasis patients have mild to moderate disease and can be potentially treated with topical therapy.⁴⁶ While there are some studies comparing specific therapies this area is problematic for analysis across studies because efficacy, the definition of success, and cost-effectiveness have not been measured uniformly. In general, while generic formulations of topical medications are substantially less expensive than the branded alternatives, some of the novel ingredients or better formulations of branded products performed similarly in some cost effectiveness analyses because of improved efficacy, adherence, or both. Of note, for patients with large body surface areas affected by psoriasis (<10%), systemic medications can be more cost-effective when compared to some of the more expensive branded medications.

For UV and systemic therapies, older studies of cost-effectiveness are somewhat non-uniform, but more recent studies have employed similar methodologies and scoring systems allowing for more comprehensive analyses across studies. In general, while biologic agents have the potential to achieve high PASI scores, the cost of the medication itself, is more expensive than topical or conventional systemic therapies. However, because of their substantial efficacy, the incremental cost of biologics per QALY generally fall within acceptable economic ranges. Additionally for some patients, there would be a gain in treating concomitant psoriatic arthritis: around 30% of moderate to severe psoriasis patients are also afflicted by psoriatic arthritis⁴, and the combination of the effects on both conditions should be considered when performing economic analysis in this population.⁴⁷

From the studies available for analysis, it appears that a rational clinical and cost-effective approach would be to start with UV or conventional systemic therapies (i.e., MTX, CsA or acitretin) where medically appropriate, and failing these medications, biologics should be considered. UV therapy can be very cost-effective, but is currently discouraged in the United States based on high copays set by private insurers, which ironically, may not be in their best interest. Based on cost-effectiveness studies available to date, biologics should be considered in the following sequence: adalimumab, infliximab or ustekinumab, then etanercept and finally alefacept. We were only able to locate one cost-effectiveness study on ustekinumab³⁹ as this is a relatively new addition to the biologic market. Furthermore, it is unclear if ustekinumab offers any benefit for psoriatic arthritis, unlike its predecessor anti tumor necrosis factor-alpha agents (i.e., infliximab, adalimumab, and etanercept).

Of note, many studies presented conflicts of interest. Some of them were funded by pharmaceutical companies that manufacture the drugs being analyzed or their employees were directly involved in the design and analysis process.

One additional problem in applying these economic analyses is that in clinical practice, multiple medications

are often used simultaneously to augment effectiveness or allow for treatment of specific body regions. On face, this approach may increase cost,⁴⁸ but if it allows decreased dosing of other more expensive medications such as a biologic or expensive systemic therapy, it may be more cost-effective.

Lastly, a clear limitation of current cost-effectiveness studies is a limited time horizon. Psoriasis is a chronic disease that lasts decades in some patients and most efficacy studies include only short-term data.

In summary, cost-effectiveness analyses are an important integrated way to inform therapeutic decision-making, but do depend on the assumptions that underlie their models. Progress in the treatment of psoriasis in the last decade has been remarkable and a careful understanding of the strengths and limitations of these models can lead to better approaches for our patients.

APPENDIX

Psoriasis Therapy

Traditional systemic therapy. *In the context of psoriasis includes methotrexate, cyclosporine, acitretin, and prednisone.*

Biologic agents (biologics). Pharmaceuticals derived from living organisms such as animals and humans that target specific pathways in the immune system.

Acitretin. A synthetic retinoid available in oral form used for the treatment of psoriasis. Extreme caution must be used in women of childbearing potential due to its teratogenic effects (Pregnancy category X). Used in oral form.

Coal tar. Distilled tar mixtures of polycyclic aromatic and heterocyclic hydrocarbons and phenols derived from bituminous coal used as a topical treatment for psoriasis.

Corticosteroid. A hormone produced by the adrenal glands. Synthetic forms such as prednisolone, prednisone, and dexamethasone have similar biologic and chemical properties. Available for oral, injectable, and intravenous administration.

Cyclosporin (CsA). An immunosuppressant agent with inhibitory activity on T-lymphocytes commonly used postallogenic organ transplantation. Other uses in medicine include psoriasis, atopic dermatitis and many autoimmune diseases.

Goeckerman therapy. A classic psoriasis treatment regime consisting of crude coal tar and UVB light therapy administered in a clinic or hospital-based setting. Modified Goeckerman therapy combines the classic regime with other topical and systemic psoriasis treatments.

Methotrexate (MTX). An antimetabolite that inhibits the metabolism of folic acid. It has a wide spectrum of uses in medicine, particularly in cancer chemotherapy and immunosuppression in autoimmune diseases. Available for oral or injectable administration.

Phototherapy. The use of ultraviolet (UV) light for the treatment of various dermatoses. Narrowband UVB (NBUVB) includes wavelengths of UV light from 311 to 313 nm and is considered more effective and safer for the treatment of psoriasis and other UVB responsive dermatoses.

Psoriasis Scoring Scales

National Psoriasis Foundation Score (NPF-PS). A measurement that accounts for induration (of two representative target sites), body surface area compared to baseline, physician and patient global assessment scale, and patient itch score on a scale of 0 to 5. Total score range: 0 to 30.

Psoriasis Area and Severity Index (PASI). A measurement of erythema, thickness and scale for psoriatic lesions (score: 0 to 4) on four body regions (head, upper and lower extremities and trunk) which provides an approximate estimate of body surface area involvement. Scores range: 0 to 72. For clinical studies and medical therapeutics the goal is at least a PASI 75 (i.e., 75% improvement with therapy). Total score range: 0 to 100.

Physician Global Assessment (PGA). A measurement of overall erythema, thickness and scaling and body surface involvement compared to baseline on a seven-point scale (severe, moderate to severe, moderate, mild to moderate, mild, almost clear, clear). Total score range: 0 to 7.

Dermatology Life Quality Index (DLQI). The most common quality of life measurement used for psoriasis that accounts for symptoms, activities, occupation/vocation, social relationships, etc.) on a scale of 0 to 3. Total score range: 0 to 30.

Quality of Life (QoL). A comprehensive assessment of all physical, psychosocial, occupational well being.

Quality-Adjusted Life Years (QALY). A measurement of disease burden that accounts for quality of life (morbidity) and survival years (mortality) for a medical intervention.

Cost Comparison Analysis

Cost-benefit analysis. A comparison of cost of intervention (or medication) to the cost of the effects of intervention expressed in the same monetary values. Final measurement is a net benefit or cost-benefit ratio. It does not account for quality of life measures.

Cost-effectiveness analysis. An expression of the final effect of intervention (not in monetary values) similar to cost-utility. A commonly used health-related measure is the Incremental cost-effectiveness ratio (ICER) between two different interventions determined by the additional cost per life year gained. Health policy makers may use ICER thresholds to determine if an intervention is considered cost-effective and to be funded. ICER thresholds are variable between countries; the United

States and United Kingdom has ICER set at <\$50,000 per QALY and <\$30,000 per QALY respectively.

Cost-utility analysis. An expression of the final effect of intervention in generic values similar to cost-effectiveness analysis most often used by health policy makers. Examples include fixed units of health-related gain in quality-adjusted life-years (QALYs), additional life years, etc.

Cost-effectiveness of Rosacea Treatments

70

Ala Iaconi, M.S., Chung-Hsuen Wu, Ph.D., David J. Rayhan, M.D., Brad Yentzer, M.D., Steven R. Feldman, M.D., Ph.D., and Rajesh Balkrishnan, Ph.D.

INTRODUCTION

One in three Americans has a dermatologic skin condition serious enough to require medical attention.¹ Nevertheless, there are major gaps in knowledge about the frequency, impact, etiology, and prevention of these diseases.¹ Rosacea is among the most common skin conditions dermatologists treat.² It affects more than 16 million Americans and presents itself as a challenging condition with multiple therapeutic options.³ Therefore, in this chapter we would like to narrow the knowledge gap by a presentation of rosacea's background and available evidenced-based treatment options.

METHODS

A systematic literature review was performed using PubMed of journal articles including a combination of the following key terms: rosacea, treatment, therapy, cost, and quality of life. Articles included in the review were published within the 1989–2010 period, the majority being published in 2009.

BACKGROUND

Clinically Defining Rosacea

Rosacea is a chronic inflammatory disease that affects the convexities of the facial skin.^{4,5} It typically presents with persistent erythema, flushing, edema, papules, pustules and telangiectasias of the face including the nose, cheeks, forehead, and chin.^{5,6} Affected extra facial areas are rare, but have been observed in locations prone to flushing and sun damage such as the ears, neck, upper chest, back, and the scalp.^{4,5,7,8} Secondary features include burning, stinging, edema, plaques, and phymatous changes.² In the long term, the disease can cause scarring and disfigurement, drastically affecting patients' quality of life.

Thus far, there is no laboratory benchmark test for rosacea, hence the difficulty of interpreting clinical and diagnosis data.² Despite the lack of precision, rosacea symptoms are classified by the expert panel into four 'sub-types': facial redness, bumps and pimples, skin thickening, and eye irritation.^{2,3} These translate into erythematotelangiectatic (ETR), papulopustular (PPR), phymatous, and ocular

rosacea.² Clinically heterogeneous, these phenotypes have one characteristic in common: the presence of chronic facial skin inflammation.⁹ Rosacea typically manifests itself in phases. First, transient erythema appears; then telangiectases, papules, and papulopustules develop; after which diffuse hyperplasia of the connective tissues and sebaceous glands are very likely to occur.⁸ Two other variants of rosacea not included in the classification are rosacea fulminans and granulomatous rosacea.⁷

Patients with rosacea most often present with flushing, itching, and sensitive skin.⁴ Some symptoms are more or less common in different racial groups. For example, papules and pustules are less common in African Americans. African Americans, however, are more prone to develop the granulomatous variant of rosacea.⁴ Despite the fact that there are over 16 million Americans with rosacea, the disorder is still not well understood.³ Strikingly, 78% of individuals have limited knowledge in recognizing and treating rosacea.³ Additionally, there are several dermatologic skin conditions that are similar to rosacea and need to be cautiously considered at diagnosis. Some of the conditions are acne vulgaris, seborrheic dermatitis, perioral dermatitis, contact dermatitis, photodermatitis, and lupus.⁷

Epidemiology

Rosacea affects 10% of the general population.^{4,10} It manifests itself in lighter skin populations.^{7,11} Hence, it is a very common disease in the United States and in the European Union (EU) countries.⁷ It is estimated that in the United States rosacea affects 1 in 20 adults, with certain ethnic groups being more prone to developing the disease than others.^{7,12,13} Some studies suggest that 4% of all rosacea affected patients are African-Americans, Latinos, or Asians.⁷

A lack of a uniform definition for the disease has limited exact reporting of its incidence. The peak incidence of the disease occurs during the fourth and fifth decade of life.^{12,14} Morbidity linked to rosacea usually occurs during the latter decade of life.⁷ The prevalence of the disease varies with different studies. It ranges from 0.5 to 10%.^{7,15} In a survey in Sweden the prevalence was found to be closer to the higher end, with females dominating the gender.^{7,16} Previous literature finds rosacea to be three times more

common in women, but more severe forms manifesting in men.^{8, 15, 16} Conversely, most recent data indicates both sexes to be similarly affected.¹⁵

Etiology

Rosacea is associated with a number of etiologic causes and inciting factors.⁴ The main mechanisms at cause are believed to involve an inflammatory process of the vasculature and pilosebaceous units.⁴ It can be triggered by a variety of factors such as food and beverages, weather and temperature, emotions, intense exercise, menopausal flushing, alcohol, medical conditions, and various skin care products.^{3, 9, 17} Furthermore, trigger factors are specific to each patient.¹⁷

Understanding the mechanisms of rosacea has been based both on scientific investigations and anecdotal evidence.² Some possible explanations include vascular changes, environmental factors, matrix degeneration, ultra violet radiation, reactive oxygen species, proteases, and microbial organisms such as *Demodex folliculorum* and *Helicobacter pylori*.^{2, 9} The latest molecular studies link innate immune response to the pathogenesis of rosacea.⁹ Triggering the innate immune system leads to an increase in antimicrobial molecules and cytokines in the skin.⁹ Cathelicidin is the unique molecule with some of its forms having the capacity to exhibit both vasoactive and proinflammatory properties, hence possibly affecting rosacea's descriptive events. Analysis of cathelicidin peptides in rosacea-affected individuals showed abnormal high levels of the peptides.⁹ Moreover, different forms of cathelicidin are found to be present in rosacea-affected individuals compared to those not affected. Laboratory results of skin inflammation when injecting mice with enzymes that produce cathelicidin or with peptides directly further support the linkage between cathelicidin and rosacea.⁹

There are questions yet to be answered. Approximately 40% of patients with rosacea have a relative with the disorder.¹⁷ Identification of genetic factors and gene loci that predispose affected individuals to rosacea are currently under investigation. Additionally, there is a need to understand the histologic and pathologic basis of papules and pustules and whether micro-organisms play a role in their development.¹⁷ Blushing is a neural-mediated function, therefore investigating rosacea's neurologic influences can aid toward the understanding of its pathogenesis.¹⁴ In harmony with this idea are studies suggesting an increased incidence of rosacea in Parkinson's patients.¹⁴

Quality of Life

Rosacea is a disfiguring condition that affects patients' quality of life (QoL).⁷ It can produce embarrassment, frustration, anger, stress, and depression in affected individuals.⁷ Balkrishnan et al. conducted a study investigating factors associated with the health-related quality of life (HRQoL)

in women with visible facial skin lesions, including rosacea. Findings indicate that facial blemishes are associated with significant impairment in the overall HRQoL, the effect of the lesions being mediated by self-perception and self-presentation characteristics.¹⁷ Additionally, strong correlations among fear of negative perceptions and poor HRQoL were identified.¹⁸ In a more recent study, Salamon et al. similarly shows that patients with rosacea have a lower HRQoL when compared to patients without rosacea.¹⁹

Because the facial skin is the predominant site affected, many patients express that rosacea negatively affects their social and professional interactions.² The 2007 National Rosacea Society Survey results indicate that 76% percent of the 603 respondents report their condition to lower their self-confidence and self-esteem, 41% to avoid public contact, and 70% with a more severe form of the disease report a drastic effect on their professional interactions.³ Disease-specific QoL instruments are useful in measuring patient-reported therapeutic impact of various types of treatments over time.¹⁰ Nicholson et al. developed and validated a reliable rosacea-specific instrument to more accurately measure the impact of rosacea on patient's QoL.¹⁰

TREATMENTS

Topical, Systemic, Laser/Light Therapies

Since the underlying cause of rosacea is not known, cure remains elusive.^{3, 7, 15} Therefore, treatment is targeted to control the symptoms.¹⁵ A number of therapies are available for the treatment of rosacea, including a single or combination use of topicals, oral medications, and laser/light therapy.^{4, 17} Examples of topical medications include metronidazole, sodium sulfacetamide and sulfur, azelaic acid, benzoyl peroxide, erythromycin, clindamycin, tacrolimus, and tretinoin.¹⁷ Out of these, the first three have been approved by the Food and Drug Administration (FDA) for the treatment of rosacea and the rest are used off label.¹⁷ Among oral medications, tetracyclines, macrolides, metronidazole and isotretinoin are the most commonly used.¹⁶ Minocycline and doxycycline are thus far the only two of the oral tetracyclines approved by the FDA for the treatment of rosacea.⁷ Laser and light therapies are also used, however, the high costs and limited insurance coverage prevent many patients from using laser/light treatment modalities.⁷

Although, there is no precise algorithm for rosacea treatment, tetracycline-type antibiotics are considered the gold standard. Together with topical metronidazole and azelaic acid, they are the most commonly used treatments.¹⁵ Azithromycin and minocycline-CR have been presented as possible treatments but not yet approved by the FDA.⁷ Doxycycline, the most traditional tetracycline used for the treatment of rosacea has proven to be safe and effective for short and long-term therapy while two topicals,

metronidazole and azelaic acid, have proven to be safe and effective for short-term therapy only.¹⁵ Light treatments with intense pulsed light and long-pulsed dye lasers have shown to be effective at decreasing erythema and eliminating telangiectasias.⁷ For the remaining therapy options, not enough effectiveness and safety data is yet available to make conclusive statements.¹⁵ Hence, improvements in the quality of studies evaluating rosacea treatments are desired.⁷ Furthermore, evidence for rosacea treatments in patients with darker skin is even scarcer. This is due to the fact that treatment of darker skin requires consideration of potential pigmentary alterations or keloids.⁷

The collection of rosacea treatments can be overwhelming to patients and physicians.⁷ Appropriate therapeutic strategies need to address clinical features, rosacea subtype, and the staging of the severity of lesions.⁷ Patients that have pre-rosacea symptoms can be treated with over the counter agents, while prescription therapy is most appropriate for primary and secondary rosacea features.⁷ Once sufficient efficacy is observed, oral therapy is discontinued and replaced with topical therapy.²⁰ When considering therapies for rosacea, FDA-approved therapies should be prescribed first, followed by all others.⁷

Because the four variants of rosacea (erythematotelangiectatic, papulopustular, phymatous, and granular) respond differently to various therapies, therapeutic implications are different among the phenotypes.^{2,17} Therefore, rosacea can be effectively controlled with therapy tailored to the specific subtype.²¹ For mild cases, topical metronidazole, sulfacetamide/sulfur, and azelaic acid are used, while combination therapy with oral tetracycline and topical agents is the first-line of choice for moderate papulopustular rosacea.²¹ For ocular rosacea, patients are often on long-term antibiotics and metronidazole gel.²¹ Inflammatory papules or pustules and erythematous components are treated with topical therapy, the most effective ones being azelaic acid and metronidazole.⁷ Rosacea that is refractory to topical treatments is targeted with oral antibiotics, the most commonly used being doxycycline 50 mg.⁷ Additionally, oral therapy should be considered for patients who exhibit inflammatory papules and pustules but without significant erythema.⁷ The most efficacious combination therapy is doxycycline and metronidazole gel 1%. This combination can be used by individuals with inflammatory and erythematous mild-to-moderate rosacea.⁷

Being constantly visible can produce a great deal of stress, frustration, and depression for the rosacea patient.⁷ Therefore, both symptomatic and psychological treatments are equally important.⁷ Educating patients about triggers and the controllability of the disease can help alleviate patient's psychological distress.⁷ Moreover, emphasis on continuous therapy is detrimental, as the damage is often progressive.⁷ Despite the overwhelming range of treatments available for rosacea, patients, physicians, and pharmacists can all take an active role in managing the disease and improving the QoL.

Cost-Effectiveness Studies

There is a dearth of rosacea cost-effectiveness studies. This could be attributed to several factors. One is the diverse treatment spectrum and paucity of head-to-head trials directly comparing the different treatment options.²² Second, is the lack of a standard success measure in clinical trials. Success could vary from one clinical study to another because of the differences in patient population, drug dosages or schedules, and concurrent treatment.²² Thirdly, even medications in the same category have different tolerability and adverse effects profiles, which in turn could affect patient adherence to a treatment regimen and influence efficacy and cost.²²

Thomas et al. evaluated the cost-effectiveness of the most common therapeutic regimens for rosacea. More specifically, the study investigated the cost necessary to achieve successful treatment of rosacea in 15 weeks based on efficacy data from clinical trials. Results indicate metronidazole 1% once daily gel among topicals and tetracycline 250 mg/day among oral agents to be the least costly.²² Sodium sulfacetamide/sulfur 10% and 5% lotion twice daily was the second least costly, while oral isotretinoin was on the opposite end of the spectrum. Moreover, topicals were found to have similar annual direct costs among each other, while the costs among oral agents were found to be much more dispersed.²²

Sun avoidance behavior is an important part of treatment for any rosacea patient and can be cost effective.¹⁷ Behavioral sun avoidance and the use of sunscreens present a low cost option that can be integrated into the treatment of rosacea patients. A broad-spectrum sunscreen is recommended to be applied daily alone or in combination with a topical agent, most commonly 1% metronidazole. In fact, several rosacea topical agents already contain sunscreen ingredients. Rosacea patients need to practice caution as some sunscreens can cause irritation and produce erythema. This can be minimized by mixing sunscreen preparations with protective ingredients such as silicones.¹⁷

The long-term implications of rosacea, such as rhinophyma and scarring of the face require surgical or laser intervention. These therapies present a substantial cost and patients should be advised that ineffective treatment of rosacea might require treatment by these modalities. Laser and light-based therapies can also be effective for treatment of the vascular erythema component of rosacea, but, are expensive.¹⁷ Laser therapy or treatment with intense pulsed light (IPL) can range from \$200 to \$600 USD per treatment depending on the surface area treated. These treatments and generally require 1 to 5 IPL sessions are generally needed to be repeated after a few weeks.¹⁷

Rosacea treatments are presented in Tables 70-1, 70-2 and 70-3. Table 70-1 lists various treatments available with evidence for efficacy and safety. Many published trials have limitations in the quality of evidence-based efficacy. This is due to poor design and clinical applicability.²⁰ The

TABLE 70-1—Evidence-based Treatments for Rosacea^{7,20,23}

Treatments	Evidence-Based Efficacy & Effectiveness	Safety/Side-effects
TOPICALS		
Metronidazole 0.25%, 0.75%, 1% cream, gel lotion (e.g., MetroCream, MetroGel) [†]	<ul style="list-style-type: none"> Efficacy and safety confirmed via multiple blinded, split-face, and open-label vehicle controlled studies.²³ Based on 9 trials assessing the efficacy via physician's global evaluation and patient-assessed measures, metronidazole was found to be more effective than placebo.^{7,20} Study with questionable design showed superiority of metronidazole plus sunscreen versus placebo.²⁰ 	<ul style="list-style-type: none"> Cases of allergic contact dermatitis.⁷ Mid-pruritus, skin irritation and dry skin.²⁰ Based on the results of the 9 trials, there were no significant differences in the number of adverse events between metronidazole and placebo.²⁰
Pimecrolimus 1% cream q.d.-b.i.d. (Eidel)	<ul style="list-style-type: none"> Applied b.i.d., 50% patients had clear skin and most showed at least modest improvement in a 6 wk pilot study.⁷ Four-to-eight week study found it to be no more effective than the vehicle creams.⁷ 	<ul style="list-style-type: none"> Cutaneous adverse events such as local burning, stinging, and itching present in <20% of patients.⁷
Clindamycin 1% lotion, gel, solution, pledget (Cleocin) and Erythromycin 2% solution, ointment, pledget (Akne-Mycin)	<ul style="list-style-type: none"> Data supporting the use of the two for rosacea treatment is limited.²³ 	<ul style="list-style-type: none"> Concern for emergence of antibiotic resistance.²³
Azelaic acid 15% gel [†]	<ul style="list-style-type: none"> Between-patient and within-patient trials showed clear improvement for those using azelaic acid compared to placebo.⁷ Azelaic acid 15% is clinically superior to 0.75% metronidazole in improving inflammatory lesions and erythema.⁷ Efficacy and safety supported by multiple blinded and vehicle-controlled trials when applied b.i.d.²³ A different study found that when compared to topical metronidazole, there was no statistically significant difference between the two. Physicians did however rate the azelaic acid group with a higher improvement score.²⁰ Four trials comparing azelaic acid with placebo ranging from 9-12 wks demonstrated azelaic acid superiority via physician and patients' assessments in three of the trials.²⁰ Increased strengths up to 20% have been used effectively, but not yet approved by the FDA.⁷ 	<ul style="list-style-type: none"> Azelaic has greater potential for irritation compared to 0.75% metronidazole.⁷ Although the number of adverse events was lower in the metronidazole group, there was no difference in the severity of the adverse events among the two groups.²⁰ Based on the four trials, the azelaic acid group experienced more side effects, including burning, stinging, and irritation.²⁰
Sodium sulfacetamide 10% alone or with sulfur 5% combination, lotion, cream, pledges, short-contact preparation, cleanser (Sulfacet) with or without sun-blocking agent [†]	<ul style="list-style-type: none"> Randomized vehicle-controlled and comparative studies confirm its efficacy and safety based on reductions in inflammatory lesions and erythema.²³ Sodium sulfacetamide 10% and sulfur 5% combination versus placebo was found to have superior improvement potential.²⁰ 	<ul style="list-style-type: none"> Dryness, erythema, and pruritus are some of the most common ones.²⁰
Permethrin cream 5% q.d.-q.w. (Nix)	<ul style="list-style-type: none"> Shown to be effective in case-reports of refractory rosacea diagnosed as demodicosis.²³ When compared to metronidazole, permethrin was inferior in terms of efficacy and safety as it showed no effect on pustules.²⁰ 	
Crotamiton 10% q.d.-t.i.d. (Eurax)	<ul style="list-style-type: none"> Suggested to be useful in treating rosacea when linked to <i>Demodex folliculorum</i>, but unlikely to be successful at eradicating the organism.⁷ 	
1-Methylnicotinamide 0.25% b.i.d. (MNA+)	<ul style="list-style-type: none"> Applied for 4 wks, improvement was rated as moderate to good in 26 of 36 cases and 7 patients showed no clinical response.⁷ 	

Treatments	Evidence-Based Efficacy & Effectiveness	Safety/Side-effects
Benzoyl peroxide 5%/erythromycin 3% gel	<ul style="list-style-type: none"> Compared two 4 wk therapies with metronidazole gel and found similar efficacy results.²⁰ 	
Benzoyl peroxide 5%/clindamycin 1% gel	<ul style="list-style-type: none"> Compared to placebo, patient's global assessment indicate much to slightly better improvement in outcomes for 12 wks while the physician's global assessment indicate a definite improvement.²⁰ The combination of benzoyl peroxide 5%-clindamycin 1% (BenzaClin) has been shown to be effective.²³ 	<ul style="list-style-type: none"> Burning and itching, well-known side-effects of benzoyl peroxide, were reported.²⁰
SYSTEMICS		
Doxycycline, USP (Oracea Capsules) 40 mg once daily (30-mg immediate-release and 10-mg delayed-release beads) [†]	<ul style="list-style-type: none"> Phase 3 pivotal trials demonstrate efficacy and safety for treatment of inflammatory rosacea in adults.²³ Is effective in treating inflammatory papules and pustules, but not erythema that is associated with rosacea.⁷ 	
Tetracycline 500 mg b.i.d. (Sumycin); Doxycycline 50-100 mg b.i.d. (Vibramycin); Minocycline 50-100 mg q.d. or b.i.d. (Minocin); Minocycline time-release 45, 90, 135 mg (Solodyn) [†]	<ul style="list-style-type: none"> All the therapies are utilized based on extensive clinical experience and peer-reviewed literature including some clinical trials.²³ These are the most currently used antibiotics by dermatologists.⁷ Minocycline time-release is indicated to treat only inflammatory lesions of non-nodular, moderate-to-severe acne vulgaris in patients 12 yrs and older and it is the first weight-based antibiotic oral therapy for rosacea.⁷ Oral oxytetracycline and tetracycline were compared with placebo in a total of 3 trials ranging from 4-6 wks reporting superior effectiveness for tetracyclines via physician assessment and insufficient evidence of superiority according to patients' assessment.²⁰ Additionally, 3-6 mo remission achieved upon interruption of the treatment was attributed to repeated courses of same dose therapy.²⁰ Two 8 wks studies showed no statistical significant difference in treatment between oxytetracycline and metronidazole cream.²⁰ 	<ul style="list-style-type: none"> Long-term therapy with minocycline beyond 6 mo carries an increased risk of pigmentary deposition.⁷ Possible side effects associated with tetracycline: gastrointestinal, photosensitivity, candidal vaginitis, reduction in oral contraceptive efficacy.²⁰
Isotretinoin 0.15-2 mg/kg q.d. (Accutane)	<ul style="list-style-type: none"> Reports of effectiveness for severe and/or refractory cases of rosacea.²³ Although effects may be delayed, when compared to standard therapy, a reduction in the number of papules is evident within 2 weeks.⁷ Most significant results noted in younger patients with less severe manifestations of the disease.⁷ Useful in treating and reducing phymatous changes.⁷ 	<ul style="list-style-type: none"> Blood testing of serum lipids recommended as part of clinical lab monitoring.²³ Pregnancy avoidance as precaution in female patients needed.²³ Dry sensitive skin, dry eyes, pruritis, dermatitis, myalgia, elevated liver enzymes, cholesterol and triglyceride elevation.²⁰ Possible fetal abnormalities when women become pregnant.²⁰ Routine monitor of cholesterol, liver functions, and triglycerides necessary.²⁰
Azithromycin 250 mg t.i.w. (Zithromax)	<ul style="list-style-type: none"> It is thought to act as an antioxidant and appears to be useful for treating rosacea.⁷ 	<ul style="list-style-type: none"> Minimal side-effects and lack of drug interactions could make it a good alternative for rosacea patients.⁷
Omeprazole (Prilosec) and a combination of two of the following: clarithromycin (Biaxin), metronidazole, or amoxicillin (Amoxil)	<ul style="list-style-type: none"> This is the systemic treatment for <i>Helicobacter pylori</i> advocated as a possible therapy for rosacea.⁷ Oral metronidazole alone was compared to oral oxytetracycline in one study and there was no difference at 12 wks among the two groups evaluated by physician and patient assessments.²⁰ 	<ul style="list-style-type: none"> In the metronidazole vs. oxytetracycline comparison there were no adverse events reported.²⁰

TABLE 70-1—Evidence-based Treatments for Rosacea^{7,20,23} (Continued)

Treatments	Evidence-Based Efficacy & Effectiveness	Safety/Side-effects
Penicillin 2.4 mL units/day, erythromycin 250-500 mg two-four times/day, amoxicillin or ampicillin 100-500 mg daily or twice/day (Principen), metronidazole 250 mg two-three times/day, dapsoe 50-200 mg once/day	<ul style="list-style-type: none"> Proved efficacy in treating rosacea but not commonly used clinically.⁷ 	<ul style="list-style-type: none"> Gastrointestinal, photosensitivity candidal vaginitis, reduction in oral contraceptive efficacy.²⁰ Metronidazole could be linked to mutagenicity and neuropathy.²⁰
Acitretin (Soriatane), ketoconazole (Nizoral), spironolactone (Aldactone), prednisone	<ul style="list-style-type: none"> Reported to be effective.⁷ 	
Rilmenidine	<ul style="list-style-type: none"> No significant difference in treatment when compared to placebo.²⁰ 	
Oral contraceptives, some psychoactive drugs, clonidine, naloxone, aspirin, beta-blockers, ondansetron, and cyclooxygenase-2 (COX-2) inhibitors, and selective serotonin reuptake inhibitors (SSRIs)	<ul style="list-style-type: none"> Reported for treatment of flushing in rosacea patients.⁷ 	
Oral contraceptive chlormadinone acetate/mestranol (Ovosiston) and the antiandrogen agent cyproterone	<ul style="list-style-type: none"> Suggested as effective hormonal treatments for rosacea.⁷ 	
COMBINATION THERAPIES		
Doxycycline with topical metronidazole gel 1%	<ul style="list-style-type: none"> Effective and well tolerated in reducing inflammatory lesion counts in mild-to-moderate rosacea affected patients.⁷ 	
PHOTOTHERAPY		
Multiplexed laser	<ul style="list-style-type: none"> Appears to help in reducing erythema and telangiectasia.⁷ 	
Intense pulse light (IPL) 550-670 nm	<ul style="list-style-type: none"> Particular useful for ERT.⁷ 	
Flash lamp-pumped, long-pulse dye laser, and the potassium-titanyl-phosphate laser	<ul style="list-style-type: none"> May be used to treat facial telangiectasias.⁷ 	
OTHER		
Benzoyl peroxide acetone	<ul style="list-style-type: none"> Compared to placebo, showed improvement on all measures.²⁰ 	<ul style="list-style-type: none"> Irritation and burning reported in both groups.²⁰
NONMEDICAL THERAPIES		
Moisturizers	<ul style="list-style-type: none"> Clinical assessments confirmed by biophysical measurements such as electrical capacitance, transepidermal water loss, and lactic acid stinging test suggest them as contributors to the restoration of skin barrier.⁷ Skin dryness, roughness, and desquamation were much improved. Skin sensitivity was significantly reduced.⁷ Skin properties enhanced.⁷ Skin discomfort relieved.⁷ 	
Kinetin (N6-furfuryladenine) 0.1% lotion b.i.d.—a plant cytokinin	<ul style="list-style-type: none"> Helps restore skin barrier function.⁷ Beneficial for improving rosacea symptoms, especially for patients with mild-to-moderate inflammatory rosacea.⁷ 	

Treatments	Evidence-Based Efficacy & Effectiveness	Safety/Side-effects
Combination of Oral minocycline, spironolactone, and Chibixiao (a Chinese herb)	<ul style="list-style-type: none"> Combination was found to be superior to minocycline and spironolactone alone in a trial.⁷ 	

[†] FDA approved for rosacea treatment; q.d., once daily; b.i.d, twice daily; q.i.d, four times daily; q.w., weekly (every week); t.i.w., three times weekly; mg, milligram; kg, kilogram; nm, nanometers; mln, millions; wk(s), week(s); mo, months.

TABLE 70-2—Rosacea Treatments by Subtype¹⁷

Rosacea Subtype	Therapy
Erythematotelangiectatic	<ul style="list-style-type: none"> Patients have barrier disruption and sensitivity to topical products. If minimal barrier dysfunction, metronidazole or sodium sulfacetamide-sulfur, or a combination of the two should be applied in the morning followed by sunscreen. Evening application of barrier emollient and tretinoin may be used concomitantly. For persistent irritant reactions, scaling and bright erythema: physical sunscreen and barrier-protective emollient twice daily in addition to oral antibiotics may be beneficial. Barrier protection along with isotretinoin 10 to 20 mg/daily for 3 to 4 months may lessen flushing episodes and erythema. For severe irritant responses, application of high-potency steroid ointment twice daily for 1 week, followed by once daily for 1 week and tacrolimus ointment in combination with oral minocycline once daily could be used. This regimen is replaced by topical medical regimen after 1 to 2 months. Surgical and light therapies can be selected as first-time therapy if affordable to patients.
Papulopustular	<ul style="list-style-type: none"> Initial therapy involves a combination of oral and topical antimicrobial agents. Skin sensitivity is less common, therefore, all topical therapeutic options are well tolerated. Oral tetracycline is used while isotretinoin is rarely needed. Long-term management is comprised of topical agents only. Example of an effective combination of topical regimen is metronidazole, sodium sulfacetamide-sulfur, azelaic acid, or benzoyl peroxide followed by sunscreen every morning and by a protective emollient and tretinoin cream in the evening. Vascular lasers and intense pulse light are adjunctive therapy options.
Glandular	<ul style="list-style-type: none"> Topical antimicrobials such as benzoyl peroxide and benzoyl peroxide combinations work quickly and are well tolerated. Oral therapy comprising mostly of oral tetracyclines targets papules and pustules and is continued for 1 to 3 months. Mild to moderate glandular rosacea is managed with topical retinoids and topical/oral antimicrobial therapy. Severe inflammatory or nodulocystic disease can be controlled with isotretinoin followed by topical tretinoin long-term management. Increased sebum production, large pore size, and thickened skin is most often controlled with spironolactone 25 to 50 mg daily, oral contraceptives, and isotretinoin.
Phymatous	<ul style="list-style-type: none"> Early to moderate phymatous rosacea is treated with isotretinoin. Advanced forms of the disease are targeted by surgical therapies, such as heated scalpel, electrocautery, dermabrasion, laser ablation, tangential excision combined with scissor sculpturing, radiofrequency electrosurgery, often in combination with isotretinoin.

most commonly used therapies such as doxycycline, minocycline, isotretinoin, or laser therapy, although used in practice, lack quality RCTs data.²⁰ Furthermore, an interesting observation in rosacea studies is that clinicians report higher satisfaction scores with different treatment

modalities more often than patients do. Patients' lower satisfaction scores could be affecting their adherence levels to therapy.²⁰ Table 70-2 lists the most common therapy sequence for each rosacea subtype and Table 70-3 lists rosacea treatments by subtype.

TABLE 70-3—Rosacea Treatments by Symptom²⁰

Symptoms	Treatments	
Limited pustules/papules	Topical therapies	Metronidazole, clindamycin lotion, permethrin 5% cream, tretinoin cream, sulfacetamide 10%/sulfur 5%, azelaic acid 15% gel and 20% cream.
Limited pustules/papules	Proposed therapies	Tacrolimus, topical NADH (reduced form of β-nicotinamide adenine dinucleotide).
More severe skin lesions	Oral antibiotics	Tetracycline, ampicillin, metronidazole, erythromycin.
Vascular symptoms	Pulse dye laser, intense pulsed light	
Severe or persistent rosacea	Oral isotretinoin	13-cis-retinoic acid
Flushing control	Oral hypotensives	Clonidine, rilmenidine
Rhinophyma	Oral medications, laser therapy, surgical intervention	Low-dose isotretinoin
Ocular rosacea	Oral antibiotics, topical	Tetracycline, metronidazole, fusidic acid gel

Cost Effectiveness of Treatment for Non-Melanoma Skin Cancer

Kavita Mariwalla, M.D., and Evan C. Jones M.D.-M.P.H.

INTRODUCTION

According to recent statistics from the National Cancer Institute, approximately 1 million new cases of nonmelanoma skin cancer (“NMSC”) were diagnosed in 2009¹. This figure is in line with a study completed in 1994 that estimated between 900,000 and 1.2 million cases of nonmelanoma skin cancer in that year alone². Given the steady occurrence rate of these cancers over the past decade, many have declared nonmelanoma skin cancer an epidemic with an increasing incidence in people under the age of 40^{3,4}. While several treatment modalities exist, an increased attention to cost has forced many physicians to balance therapeutic efficacy with expense.

Skin cancers can be treated by various methods including cryotherapy, electrodesiccation and curettage, topical chemotherapy, surgical excision, Mohs micrographic surgery (“MMS”), radiation therapy, and photodynamic therapy. The common goal of each of these treatment modalities is to provide a high cure rate and satisfactory cosmetic and functional result with minimal risk in a cost-effective manner. This chapter reviews the dermatologic literature relating to cost and utility. It is important to note that the majority of studies published to date have been cost comparisons, which differ from cost effectiveness analyses in that they do not take into consideration the differing outcomes of the treatment modalities⁵. This is a limitation of the current data and should be noted by the reader.

It is assumed that for all treatment modalities, the tumor must first be correctly diagnosed. Therefore, an initial evaluation (CPT code 99203), a skin biopsy (CPT code 11100), and permanent section for dermatopathology evaluation (CPT code 88305) must be added on to any cost discussed. In order to estimate these costs, the 2010 Medicare reimbursement rate can be used as a benchmark. Therefore, at baseline, before a nonmelanoma skin cancer is treated, the average cost across the United States is \$95.49 for an initial evaluation in a nonfacility setting, \$92.56 for a skin biopsy and \$93.81 for dermatopathology evaluation, based on an average of 91 reimbursement rates available at the Centers for Medicare and Medicaid Services website. The total cost

is thus \$281.86 to the health care system before the tumor itself is treated.

In this chapter, cost of cryotherapy, electrodesiccation and curettage (“EDC”), radiation therapy, surgical excision and Mohs micrographic surgery (“MMS”) will be considered keeping in mind that not all of these modalities can be used for all histologic tumor subtypes.

CRYOTHERAPY

Cryotherapy is a common procedure used to treat premalignant lesions but can also be used to treat superficial basal cell carcinomas and squamous cell carcinoma in situ. It relies on destruction through necrosis, which results from a rapid freeze followed by a slow thaw process for malignant lesions⁶. Success rate for cryotherapy treatment of malignant lesions varies and is dependent on size of the tumor and thickness. If the optimal tumor is selected, the 5-year recurrence rate may be as low as 1%⁷ or as high as 7.5%⁸. Variations in these rates have also been published and may be higher with individual dermatologists. If recurrence is to occur, it is likely to happen within the first two years and thus patients treated with this modality should be followed carefully for at least 3 years after treatment. Side effects include alopecia, atrophy, hypopigmentation, milia, hyperpigmentation, change of sensation, blistering, and incomplete treatment.

After initial evaluation and biopsy, one must assume an office visit for treatment, destruction of the malignant lesion and at least one follow-up visit to ensure complete treatment. Therefore, in addition to an initial cost of \$281.85 for diagnosis, an additional expense of two office visits (CPT code 99212) and the destruction of a malignant lesion (CPT code 11726 for example) must be considered. According to the Centers of Medicare and Medicaid website, the average reimbursement for a level two office visit across the nation in a non-facility is approximately \$39.06 and a destruction of a malignant lesion on the trunk, arms or legs (as an example) is approximately \$88.56. The total cost for cryotherapy of a single nonmelanoma skin cancer is thus the cost of diagnosis, \$281.85 plus two office

visits, and one treatment of \$166.68, making the total cost on average \$448.53.

This cost does not take into consideration any morbidity from cryotherapy, incomplete treatment, or recurrence. It should also be noted that cryotherapy cannot be used for the majority of nonmelanoma skin cancers, so that while it is a relatively low cost treatment modality, its utility is limited.

ELECTRODESICCATION AND CURETTAGE

Electrodesiccation and curettage is frequently used to treat NMSC less than 1 cm on the body and occasionally on the face. In this technique, three passes of EDC are performed using a monopolar electrosurgical device and a curette. Tissue destruction is created 3 to 4 mm beyond the clinical margin. Although this technique can be quickly performed in the office, recurrence rates up to 20% occur, requiring Mohs micrographic surgery for treatment⁹.

Rogers and Coldiron estimated costs for treatment of NMSC by varying techniques and concluded that EDC is the least expensive¹⁰; cryotherapy was not included in the analysis. The authors compared multiple therapeutic modalities for a BCC on the cheek of varying sizes (0.6 cm, 1.1 cm, 2.1 cm and 3.1 cm) as well as for a SCC on the forearm of similar varying sizes. They estimated costs by comparing the relative value unit ("RVU") for each procedure and then multiplied this total by the national average conversion factor of \$38 per RVU. The authors concluded that for a BCC on the cheek, the cost of treatment via EDC was on average \$471 (range: \$389-\$573). For a SCC on the forearm, the range was \$323 - \$472, with an average of \$392. The additional cost of initial office visit, biopsy, and diagnosis were not included in these numbers, nor was follow-up or cost of treatment after recurrence.

While EDC is cost effective, its utility, like cryotherapy is limited. Tumors that are treated should be well circumscribed, less than 1 cm in size and primary. Aggressive subtypes of BCC such as the morpheaform variant are not recommended for treatment with this technique. Side effects include scarring, prolonged healing time, incomplete treatment, and hypopigmentation. This technique is rarely used on the face, further limiting its widespread potential for treating all NMSC.

TOPICAL IMIQUIMOD

In 2004, the FDA approved Aldara cream (Graceway Pharmaceuticals, Bristol, TN) for the treatment of superficial basal cells located on the trunk, neck, and extremities measuring less than 2.0 cm in diameter in immunocompetent adults. The medication has shown clinical and histologic clearance for superficial basal cells, however 5-year follow-up data is inadequate to predict recurrence rates.

Karve et al. performed a literature review and published that for superficial basal cell carcinomas, imiquimod is

more cost effective than surgical intervention¹¹. The authors acknowledge a lack of long-term follow-up as a limitation to interpretation of their results.

Similarly, the HEIS study group-evaluated imiquimod versus surgical excision treatment for a superficial BCC measuring less than 2 cm¹². The decision analysis model assumed imiquimod 5% cream application five times a week for 6 weeks and an efficacy rate of 82%. The authors estimated that approximately 36 sachets of imiquimod would be used to complete treatment and assumed an initial dermatology visit with biopsy followed by an average of 2.5 visits after starting treatment and one visit to the primary care physician. The efficacy of surgical excision used for comparison was based upon review of 209 medical records collected from both dermatology and nondermatology services and was 97% and 90% respectively. The study showed that the mean cost per patient cured by surgical excision was 676 Euros when using a dermatologist and 1051 euros when a nondermatology service was used. For topical imiquimod, the cost per patient was 621 euros when treatment was directed by a dermatologist and 676 euros when treatment was directed by a non-dermatologist. Thus the savings of imiquimod use compared to surgical excision in a dermatologic setting was approximately 55 euros and 375 euros when the two modalities were compared in a nondermatologic setting. Under the Spanish national healthcare system, imiquimod was favorable in cost compared to surgical excision specifically for superficial basal cell.

Rogers and Coldiron estimated the cost for treatment of a BCC on the cheek with imiquimod, assuming a 20% recurrence rate and 5% initial incomplete clinical response based on phase III and 2-year follow-up studies^{13,14}. These authors assumed 30 sachets of medication were needed at a cost of \$648. For a 0.6 cm BCC on the cheek, cost was approximated at \$929. For a BCC on the cheek up to 2.1 cm in size (beyond the size recommended by the FDA to treat), cost was \$950. For a SCC on the arm, imiquimod treatment cost was \$896 for a 0.6 cm lesion and \$939 for a 2.1 cm lesion. The average cost for the BCC group (size ranging from 0.6 cm to 3.1 cm) was \$959 and for the SCC group (similar size range) was \$931. This average was more expensive than treating the SCC on the arm with excision (average \$907), but less expensive than excision on the face for a BCC (average \$1006). The authors note that these cases were for illustrative purposes only as neither advocated imiquimod use for tumors other than superficial BCC in immunocompetent patients.

Treatment failures, long-term follow-up, quality-of-life measures, patient morbidity and time away from work, while under treatment have not been taken into consideration in any imiquimod studies to date evaluating cost. Nonetheless, initial expense analysis indicates that it is reasonable to use imiquimod cream for ill-defined superficial basal cells on the body and carefully selected areas on the face. It is not advisable to use it as a first line for nodular

BCC on the face or for squamous cell carcinomas. As with all treatments, patient selection, and tumor consideration are paramount for consideration.

RADIATION THERAPY

While radiation therapy is used in select circumstances to treat nonmelanoma skin cancers, it is by far the most expensive treatment modality, as it is relegated to the hospital or facility setting and requires careful monitoring, follow-up and multiple treatment sessions. A standardized regimen for treating NMSC does not exist and most studies have varying fractional doses and treatment sessions. However, radiation can be chosen as a modality depending on the patient's other comorbidities, tumor location, and subtype of tumor. Rogers and Coldiron estimated radiation therapy using a total dose of 61 Gray subdivided into 3.5 Gray doses would be approximately \$3460 for treating a BCC on the cheek and \$3431 for a SCC on the arm. Given the complications with radiation therapy and its failure rate of 7% and recurrence rate of 10%¹⁵, it is safe to assume that this treatment modality is to be reserved for specific cases (e.g., perineural invasion) where other treatment modalities cannot be considered.

SURGICAL EXCISION

Surgical excision is the standard against which all other treatment modalities for NMSC are compared in terms of cost. The standard margin used for primary BCC and SCC anywhere on the body is at least 4 mm. After removal, the specimen is sent for permanent sectioning and the wound is immediately repaired either with a primary closure or a flap or graft. Cost for this procedure can increase if the specimen is sent for frozen sectioning or if the excision takes place in an ambulatory surgery center or hospital operating room. Recurrence rates after excision of NMSC have been published, but vary from 5% to 18%¹⁶⁻¹⁸. A published systematic literature review estimated a 5.3% 5-year recurrence rate after surgical excision for primary BCC¹⁶. For SCC, this rate ranges from 5% for low-risk lesions to 10.9% and 18.7% for high-risk lesions on the lip and ear, respectively¹⁷. Positive margins are either treated with re-excision or via Mohs surgery. Recurrence is typically treated with Mohs. In addition, if the procedure takes place in the hospital setting, preoperative clearance and anesthesia costs are an addition. Several studies have evaluated the cost of surgical excision versus other therapeutic options. As noted above, for superficial basal cells, Dominguez et al. demonstrated that under the Spanish healthcare system, surgical excision by a dermatologist is more costly than topical imiquimod 5% cream used five times a week for 6 weeks¹².

Rogers and Coldiron estimate an average cost of \$1006 for surgical excision with permanent sections and immediate repair for a BCC on the cheek compared to \$907 for

the same treatment for a SCC on the arm. The authors assumed a rate of positive margins after initial excision to be 11% and the long-term recurrence rate to be 10% based on previous studies^{19,20}. Once a patient is treated in an ambulatory surgery center and the specimen is evaluated by frozen section, the average cost increases to \$2334 for the BCC scenario and \$2200 for the SCC case. In the hospital setting, excision with frozen section costs an average of \$3085 for a BCC on the cheek (range: \$2543-\$3893 depending on size of the case) and \$2680 for a SCC on the forearm (range: \$2166-3413 depending on size). This represents a 195% -207% increase in cost over excision in the office. Rogers and Coldiron also estimate preoperative laboratory work prior to operating room excision to be about \$191 and medications and supplies for the operating room to be approximately \$200. All of these costs are of course in addition to the initial evaluation, biopsy, and diagnosis done in the dermatologist's office. Therefore, if traditional surgical excision is considered, value is best achieved when the procedure is performed in the office with permanent sections and immediate repair.

In 2004, Bialey et al.²¹ performed a cost comparison analysis of MMS versus traditional surgical excision. The study was performed at a tertiary care referral center in Connecticut. In their report, the authors looked at costs alone without taking into consideration effectiveness – in other words patient quality of life, time away from work and co-morbidities were not calculated. The group limited itself to evaluating tumors that met published criteria for MMS removal – tumors on the face and ear. They took into consideration the multiple surgery reduction policy and included preoperative laboratory tests and x-rays when calculating facility fees. However, the authors measured lesion size, rather than excision size for coding, a method which changed in 2003 (data was collected from 1999 – 2001). They evaluated 40 tumors located on or near the nose, 16 on the cheek, 14 on or in front of the ear, 12 on the forehead, 7 on the canthus and around the eye, 7 on the temple and 2 on the lip. The setting for traditional surgical excision was the office (57%), ambulatory surgery center (39%) and operating room (4%). There was also a distribution of repair types taken into consideration for Mohs (primary closure 49%, local flap 4%, granulation 44%, and skin graft 2%) and for traditional excision (primary closure 56%, local flap 29%, granulation 12%, skin graft 2%, and forehead flap 1%). The results showed the mean Mohs cost per patient for removal of facial and auricular NMSC to be \$937 and surgical excision to be \$831 (P=.04). After accounting for the cost of a second procedure for positive margins after permanent sections and excision, the cost increased to \$1029 if Mohs was used for the second procedure along with a Mohs repair, and \$944 if the positive margin was treated with another excision and an ear-nose-throat specialist repaired the wound. Thus, when comparing the cost of a second excision plus repair by a specialist to Mohs in the first place, the costs are quite comparable

(\$944 vs. \$937). There was no value assigned to patient well-being during this time or satisfaction, which is valued during a cost-effectiveness analysis and not a cost analysis. For this reason, members of this study group lead by Anne Seidler published subsequent data in 2006.

Seidler et al. compared Mohs surgery to surgical excision for facial and auricular NMSC and found that in these cases, where there is a potential for high-risk tumors because of the location over embryonic fusion plates (the “H” of the face), excision was less cost effective than Mohs²². In this study, the authors included a measurement of quality-adjusted life years based on focus group interviews and estimated costs based on a prospective sample of 98 consecutive patients with NMSC on the face and ears. The authors assumed a 5% recurrence rate of primary BCC after excision and 1% after Mohs. Each patient acted as their own control. An otolaryngologist evaluated all 98 patients and anticipated the size of the margins and repair type he would use if the patient were to undergo a standard excision (just as had been done in the 2004 study). This evaluation was then compared with the actual documented Mohs margin. If the Mohs margin extended beyond the otolaryngologist’s estimate, the authors assumed the theoretical excision margins would have been inadequate. The costs assumed that 57% of the excisions took place in an office setting, 39% in an ambulatory surgery center and 4% in an operating room. The group also assumed a distribution of repair types after Mohs and excision that consisted of healing by second intent, primary closure, flap and graft. Overall, the study concluded that surgical excision was nearly \$300 more expensive than Mohs for these specific areas and Mohs had a greater effectiveness over surgical excision by approximately 3 weeks of optimal quality of life. One limitation of this study was that the authors modeled cost based on a granulation rate of 45%, which is higher than the distribution of Mohs repair types reported by others, which show that Mohs surgeons tend to use primary closure in 69% of cases, granulation in 11%, flaps in 14% and grafts in 6%^{23,24}. Nonetheless, in comparing the two therapeutic modalities side by side, excision for tumors of the face is less cost effective than Mohs surgery. This data is critical because it not only looks at cost, but cost plus efficacy measured as patient satisfaction, morbidity, and quality of life.

Bentkover et al. compared the cost of Mohs with that of surgical excision using rapid cross-sectional frozen section for treatment of BCC on the head and neck²⁵. The authors found a cost savings for excision over Mohs, however, their evaluation was based on a capitated practice setting. A Mohs surgeon was not part of their group and all Mohs surgical procedures were outsourced as fee-for-service, thereby incurring an increased cost. The authors reported a \$150 to \$454 cost-savings benefit to excision over Mohs per tumor. For excision, all facility and excision fees were covered under global capitation, which left only the pathology fees to compare to the outsourced cost of Mohs. For

this reason, the findings of this study are discordant with others as detailed below.

MOHS MICROGRAPHIC SURGERY

Mohs micrographic surgery has been recognized to provide the highest cure rates for both primary and recurrent nonmelanoma skin cancers. Its technique relies on interpretation of frozen tissue sections by a trained MMS surgeon and translation of these findings to the clinical setting. The technique is tissue sparing and guidelines have been developed for its optimal use that include criteria such as tumor type, size, location, and recurrence²⁶. There are no guidelines, however on who may bill or perform Mohs and the result has been what many feel is an over-utilization of the MMS method. When analyzing billing codes paid by Medicare this is evident, as Mohs codes represent a disproportionate number of claims. During the past 15 years, MMS has become so prevalent that it now ranks as the single largest expenditure for all physician procedures²⁷. The utilization rate of the former main Mohs surgery CPT code, 17304 increased from 80,000 procedures in 1993 to 450,000 in 2005²⁸. While the number is alarming, it should be noted that the number of skin biopsies in the same period of time also doubled. The statistics have thus prompted a number of researchers to analyze the cost of MMS compared to traditional surgical excision for nonmelanoma skin cancer.

In 1998, Cook and Zitelli published a report analyzing a group of 400 consecutive patients referred to their office for treatment of skin cancer²⁹. The majority of patients were for basal cell carcinoma treatment (n=306), followed by squamous cell carcinoma (n=64). This study included, however, 21 patients referred for malignant melanoma. The authors compared MMS versus traditional excision in terms of cost. For each patient, they included the cost of initial evaluation, skin biopsy, permanent section pathology for diagnosis and 5 years of follow-up not included in the global postoperative period. They also assumed that tumors treated in the office by excision and permanent section would have a positive surgical margin in 11% of cases and require re-excision, additional permanent section pathology, and repair. This assumption was based on an earlier study by Cataldo et al.³⁰ Furthermore, the authors compared MMS to excision in the office with frozen section control and excision in an ambulatory surgical facility with frozen section control. In the latter two cases, 21% of tumors were assumed to have at least one positive margin as prior studies had shown that the average skin cancer excision using frozen section control required 1.21 stages to obtain negative surgical margins³¹. The authors also factored in permanent sections to confirm negative margins in all frozen section excision cases. Lastly, the authors accounted for recurrence rates, which they assumed to be 10.1%¹⁸ for traditional surgical excision and 1.0% with MMS¹⁸. For these recurrent cases, they

added on the average cost of MMS in the cases presented in the series.

Cook and Zitelli concluded that MMS is cost effective on all body locations compared to other methods of surgical excision. The difference between office excision with permanent section and MMS was less than \$100, using 1996 RBRVS values for Western Pennsylvania. On the head/neck region the cost for office excision was calculated to be \$1201 versus \$1278 for MMS and \$905 on the trunk versus \$964 for MMS in the same location. Office excision with frozen section was more costly with ambulatory surgical facility excision and frozen section being the most expensive. The authors attribute the value of Mohs to the bundling of excision with microscopic evaluation that occurs in the MMS codes. In addition, there is an inestimable cost associated with tissue preservation, especially on the face. Bumstead and Ceilley reported that conventional surgery removes 180% more tissue than MMS in primary cutaneous malignancies and 347% more tissue than MMS in recurrent tumors³². Smaller wounds can often heal by secondary intention thus eliminating the cost of repair and if repaired, the smaller wounds often lead to better cosmetic and functional results. The authors conclude that MMS is thus a cost-effective treatment with a high intrinsic value that compares favorably to traditional surgical excision.

Rogers and Coldiron agreed with such findings. In their study, MMS averaged \$1263 to treat a BCC on the face and \$1131 to treat a SCC on the arm. These authors discuss that the loss of the multiple surgery reduction exemption has decreased the cost of MMS by 9-25%. Although MMS is still slightly more expensive than office-based excision, they felt that Mohs had certain unquantifiable positive effects. For example, MMS has the lowest recurrence rate of all treatment modalities, resulting in a decreased number of second excisions for positive margins and fewer office visits. In addition, MMS results in a small surgical defect with a consequently smaller repair³³. The authors thus concluded that the slight increase in cost compared to surgical excision was of value, thereby giving MMS greater cost effectiveness.

Mosterd et al. evaluated 5-year follow-up data and evaluated the economics of MMS for recurrent basal cell carcinoma of the face³⁴. The study followed 198 patients with primary BCC treated with MMS and 199 patients with primary BCC treated with surgical excision. They also compared the cost of treatment of 102 patients with recurrent BCC treated with surgical excision to 100 patients with recurrent BCC treated with MMS. At 60 months, there were 11 recurrences in the primary BCC arm (4 after MMS and 7 after excision). In the experimental arm treating recurrent BCCs, 31 of 102 tumors were not completely excised after primary excision. After re-excision, 8 remained incompletely excised and had to be treated with MMS. At 60 months, there were 12 recurrences in the recurrent BCC study population; two after MMS and 10 after surgical excision. Given the 5-year data, the authors then calculated the

incremental cost effectiveness ratio ("ICER") for treating a primary BCC versus a recurrent BCC with MMS. This ratio is used in health economics to assess the value of a new therapy compared to a traditional therapy based on efficacy and cost. The group concluded that the ICER for primary BCC was 23,454 euros, while for recurrent BCC it was 3,171 euros per recurrence avoided. Since no threshold exists for the treatment costs of BCC, the group used a comparison value of hospital costs associated with treating a recurrent tumor (2568 euros). Thus, although MMS for primary BCC may not be cost effective, for recurrent BCC, the data suggests that it should be considered a cost-effective treatment.

Mosterd's study is important for several reasons. First, it highlights the need to assess cost effectiveness using a timeline of at least 5 years. For example, Essers et al. examined the cost-effectiveness of MMS versus surgical excision for facial basal cells but followed primary BCC cases for 30 months and recurrent cases for 18 months rather than 60³⁵. The authors found that the recurrence rate between MMS and surgical excision for primary BCC at 30 months was 0.0091. They divided the mean difference in cost by this effect difference and found an incremental cost of 29,231 euros per recurrence avoided. For recurrent BCC, the effect difference was 0.032, leading to an ICER of 8,094 euros. This is double the value when compared to 60-month data. The differences highlight the need for long-term studies to truly evaluate efficacy for any treatment modality. Second, these two studies give insight to an important assumption when discussing cost analysis – ultimately the payor and system in which the treatment is delivered make the difference. For example, in the two studies reviewed above, both Mosterd's group and Essers group evaluated data in the Netherlands where the Mohs margin was 3 mm rather than the standard 1 mm used in the United States³⁶. Furthermore, both studies utilized a separate pathologist to evaluate tissue, thereby increasing costs. Lastly, the data in both papers is derived from patients who were treated in a hospital setting, which studies in the United States have shown to be the most expensive treatment method for tumor extirpation.

CONCLUSION

Multiple options exist for the physician when considering treatment of a NMSC. Because of the high incidence of these tumors, cost must be evaluated when choosing a therapeutic modality. While cryotherapy is the least expensive of all options, its utility is severely limited. Similarly, EDC and imiquimod provide acceptable results in comparison to cost, but again, can only be used in specific situations. Radiation is the most expensive, but if it is called for, there are not appropriate other substitutes for that kind of therapy. The real decision for the practitioner is whether to recommend excision or MMS for patients with NMSC. It is clear from the published data that if one is to recommend MMS based on recommended guidelines, it is cost

What We Know

- The high incidence of nonmelanoma skin cancer is considered an epidemic with an increasing rate in people younger than the age of 40.
- Practitioners in the current US healthcare system must consider cost when recommending therapy for cutaneous malignancies.
- Cryotherapy is the least expensive option for NMSC destruction but is limited in utility.
- Electrodesiccation and curettage is inexpensive, however, the morbidity associated with this treatment makes it unsuitable for destruction of tumors on the face and those greater than 2 centimeters.
- Imiquimod cream is a relatively new entrant into the marketplace for nonmelanoma skin cancer treatment and although it is comparable in cost to surgical excision, long-term recurrence rates are not yet available limiting analysis of its cost effectiveness.
- Surgical excision performed in the office with immediate repair is the most cost-effective for tumors that are not in high-risk areas. If margins return positive or there is recurrence, this modality loses its cost effectiveness completely.
- Mohs micrographic surgery is comparable in cost to traditional surgical excision with frozen section, as well as surgical excision performed in an ambulatory surgery center or the operating room. Compared to the latter two cases, it can be argued that Mohs is of better value and more cost effective. For tumors on the face, Mohs as the primary treatment modality is more cost-effective in terms of pure dollars and in terms of quality-adjusted life years for the patient.

effective. Even off the face, MMS is comparable in cost to traditional surgical excision. The key for the dermatologist is to consider cost in the overall picture of the patient's health, tumor type and location. Cost should be balanced with efficacy as the dermatologist decides the surgical, destructive or treatment modality most appropriate for the tumor site on their patients.

Evidence Based Approach

Adherence to Treatment

72

Michelle M. Levender, M.D., Rajesh Balkrishnan, Ph.D.,
and Steven R. Feldman, M.D., Ph.D.

INTRODUCTION

Physicians today have the luxury of a veritable armamentarium of medications that have been tested in clinical trials and found to be highly efficacious for their respective indications. Yet, in clinical practice, many of these same medications fail to affect the same degree of success in treatment.¹ This is true particularly in the management of many chronic diseases and has left many an experienced physician scratching their head in dismay. In a long-term study of psoriasis patients on psoralen-UVA (PUVA) therapy, Jones-Caballero et al. incidentally observed that of patients who had been switched from PUVA to biologic therapy, 42% still had moderate to severe disease at the close of the study. This was surprising given that the response rate of moderate to severe psoriasis in clinical trials is as high as 70 to 80%.² A similar disparity can be found with use of topical calcipotriene for psoriasis, which used alone in clinical trials results in clearing or almost clearing of plaques in 70% of patients.³ In contrast, in clinical practice calcipotriene must be used in combination with topical corticosteroids to achieve comparable results.⁴ In fact, the explanation for such consistent discrepancies between responses in clinical trials versus clinical practice is simple, it is adherence. Adherence is defined as the extent to which patients follow the agreed-upon recommendations of their health care provider, is at the root of both the variability of response to treatment between individual patients and the discrepancy between response in clinical trials versus clinical practice.⁵ This chapter will first examine a variety of dermatologic phenomena that can be explained by adherence, then outline measures of adherence, and finally discuss factors affecting adherence and strategies to improve adherence in practice.

TACHYPHYLAXIS

A classic tenet of dermatologic teaching has been that prolonged use of topical corticosteroids results in decreased response over time, a phenomenon known as tachyphylaxis. This has been attributed to a down-regulation of steroid receptors with repeated exposure, although it has been difficult to demonstrate in controlled clinical trials.⁶ In practice, tachyphylaxis can be successfully overcome by

switching to a different topical corticosteroid of comparable potency. This effective strategy for managing tachyphylaxis should raise a red flag about its etiology—if indeed the cause was down-regulation of steroid receptors, a simple switch to a different corticosteroid should not correct the problem, and yet it does. The best evidence suggests that tachyphylaxis is not “the more you use it, the less it works.” Rather, based on studies showing that patients’ use of topical medications decline over time,^{7–9} tachyphylaxis is likely a function of poor adherence: “the less you use it, the less it works.”¹⁰

ATOPIC DERMATITIS

It is not uncommon to find that children with severe atopic dermatitis (AD) refractory to all topical medications will clear rapidly during a short hospitalization in which they are treated only with topical triamcinolone. This is remarkable considering these children have often failed other more potent steroids and combination therapies, and yet it is a widely recognized phenomenon. Previous explanations proposed was a result of removing the child from exposure to dust mites or a stressful environment at home. The notion that spending the night in an unfamiliar hospital room is less stressful to a young child than their own home is preposterous. The actual explanation lies in adherence behavior. In fact, the evidence suggests these children get better in the hospital because they are actually getting the treatment. Krejci-Manwaring et al. studied adherence behavior to twice-daily 0.1% topical triamcinolone ointment in an 8-week study of children with mild to moderate AD. The medication was dispensed with a Medication Event Monitoring System (MEMS™) cap, which enabled the recording of every time and date the medicine was opened. Patients and their parents were not aware they were in a formal study and they did not know their adherence was being monitored until the end of the study. Over the 8-week study period, the overall adherence rate was 32%. This study minimized the effects of a clinical trial on patient adherence and thus was more representative of actual practice.⁹ It is no wonder then that patients eventually fail topical outpatient therapy and improve on mid-potency steroids during brief hospitalizations. Medications work much better when patients actually use them.

ACNE

Acne can be challenging to treat, in no small part, because many of the patients are teenagers and young adults. Achieving adherence in these patients can be even more challenging than doing so in adults. In a study on adherence behavior in college students to a variety of treatments, only 36% of students were found to complete their prescribed treatment; adherence to acne medication was even worse: only 12.5%.¹¹ Adherence rates were better in a 12-week clinical trial on techniques to improve adherence in teenagers to daily 0.1% adapalene gel. This study included four arms. The standard of care group had return visits at 6 and 12 weeks, the frequent visit group had return visits at 1, 2, 4, 6, 8, and 12 weeks, the electronic reminder group received a daily text message, or e-mail reminder to use their medicine, and the parental reminder group enlisted the parent to give the teenager a daily verbal reminder to use their medication. In the standard of care group, adherence started at approximately 70%, dropping to 40% over the course of the study. Adherence in the frequent visit group was slightly better, starting at 80% and dropping to 50% over the study period. Electronic reminders had minimal effect on adherence; rates were approximately equal to the standard of care group. Interestingly, parental reminder had a negative effect on adherence; adherence rates were lowest in this group.¹² Even in clinical trials, with a once daily medication and frequent visits, teenagers are only about 50% adherent with treatment. Adherence in clinical practice can be expected to be even less than that found in clinical trials. Predicting adherence rates of less than 50% (probably significantly less when treatment involves more than one medication), it is not surprising that treating acne in teenagers may result in suboptimal outcomes.

PSORIASIS

In surveys of psoriasis patients, reported adherence rates range from approximately 50 to 60%.^{13–16} Studies comparing self-reported adherence rates and rates obtained objectively via electronic medication monitors (like MEMS™ technology) consistently find that self-report significantly overestimates adherence.^{8,15,17,18} Carroll et al. found adherence rates of 55% versus 90%, as measured by MEMS™ and self-report, respectively⁸ Zaghloul et al. had similar findings: 61% versus 92%.¹⁵ Thus, the poor adherence rates of 57%¹³ and 61%¹⁴ from two anonymous surveys of psoriasis patients can be presumed to reflect even more abysmal actual adherence rates.

Even when given the added motivations found in clinical trials, including being paid for participation, having more frequent visits, and being told adherence is being studied, psoriasis patients still exhibit suboptimal adherence behavior. In an 8-week study of adherence in psoriasis patients, patients were instructed to apply 6% salicylic

acid gel (a combination gel with 0.1% tacrolimus ointment or placebo) twice daily. These patients were explicitly instructed that how they took their medicine would be monitored and they had four visits over 8 weeks. Initial adherence at 1 week was 85%, but dropped to 51% over the course of the study, for an overall rate of 55%.⁸ An ingenious Danish study used data from pharmacies to assess adherence in clinical practice. They found that psoriasis patients had the lowest adherence rates of all groups studied and that 4 weeks after being given a prescription, 44% of psoriasis patients had not even filled their prescription.¹⁹ Of the 56% who did fill their prescriptions, one can only imagine what smaller percentage then went on to actually use it as directed.

It has been suggested that the presence of particularly thick, rock-like, “coral reef” plaques in psoriasis is a marker for resistance to topical treatment, a sign of highly refractory disease, because the medication cannot penetrate. Coral reef psoriasis may be a marker of resistance to topicals, but it isn’t because topical treatments don’t penetrate: diseased skin has poor barrier function, even when hyperkeratotic.^{20,21} More likely, the patients who present with coral reef plaques are very nonadherent patients. When medication actually makes contact with these plaques, they respond quite well to treatment as was demonstrated in a case report.²² One might presume that patients with such severe disease would be highly motivated to get well and therein, would be more likely to use their medications. And yet, studies show that the opposite is true: patients with more severe disease exhibit lower adherence rates than patients with milder disease.^{14,15}

SCALP PSORIASIS

Scalp psoriasis can be one of the most frustrating conditions to treat, for both patients and providers. No matter what treatment or combination of treatments is tried, these patients do not seem to get better. Looking at the problem through the lens of adherence helps in understanding why scalp psoriasis is so difficult to treat. Adherence research shows that people will not take antibiotics for even a week for a bothersome problem and that patients do not do well using their topical medications for chronic skin diseases. Applying medications to the scalp is far more difficult than any of these other tasks. Treating scalp psoriasis is difficult, not because the disease itself is recalcitrant to treatment, rather, it is difficult because it is nearly impossible to get patients to apply medications to their scalp.

Many other explanations have been offered to explain refractory scalp psoriasis. It is widely thought that the fact that patients scratch and Koebnerize their scalp can explain scalp psoriasis, yet this same action on other areas of their bodies does not cause the psoriasis plaques to be as uniquely resistant to treatment as is scalp psoriasis. Others propose that the scale of scalp psoriasis blocks

the penetration of topical agents.¹² In fact, normal scalp exhibits percutaneous absorption similar to the axilla;²⁰ penetration is likely even greater in diseased scalp. Clinical trials support this; rapid clearance of scalp psoriasis is achieved when topical clobetasol is applied to the scalp without the use of keratolytic medications.^{23,24} Scalp psoriasis responds very poorly to treatment for three simple reasons: poor adherence, poor adherence, and poor adherence.

SKIN CAP

"Flash, March 10, 1997" Writing in their diary published in *Cutis*, Drs. Walter and Dorinda Shelley wrote, "The big news is Skin Cap, coming out of Spain, now sweeping the country as an over-the-counter spray therapy for psoriasis. Make no mistake about it, it is good. One of our friends said, "I don't have any psoriasis practice. They all use Skin Cap.... No longer do the patients need steroids inducted, ingested, or injected, and any more methotrexate or PUVA visits. It seems unbelievable that a product not even requiring prescription can be so effective."²⁵ Skin CapTM was advertised as a zinc pyrithione spray also containing the detergent sodium lauryl sulfate. The product showed unprecedented efficacy. It was only later discovered that the product actually contained clobetasol propionate. This surprised dermatologists because the same ingredient in ointment form was commonly used to treat psoriasis, with far less impressive effect. Moreover, the widely accepted teaching was that an ointment vehicle was more effective than a drying spray. It was speculated that the zinc was acting synergistically with the clobetasol, accounting for the increased potency of Skin CapTM. A study was done in which lesions on both sides of the body were treated with clobetasol foam. One side also received zinc pyrithione spray and the other side the spray vehicle. They found that the zinc spray was of no added benefit.²⁶

The dramatic results achieved by Skin CapTM are well explained by adherence. The spray worked better than clobetasol ointments did in practice because patients used it more and the reasons for this improved adherence illustrates some important principles in adherence. The spray was easier to apply and better tolerated than a messy ointment. Patients probably felt more comfortable because they had less fear about side effects (no one told patients it contained a strong steroid). Compared to an over the counter medicine, clobetasol sounds very scary when prescribed with the warning "This is the most powerful steroid in existence and using it too much is dangerous." Finally, patients may have been more likely to use Skin CapTM because they paid for it themselves. People in general are more likely to use or value something when they buy into it. Thus, what seemed to be a revolution in psoriasis therapy in effect was actually a revelation in understanding how much adherence mediates the relationship between treatment and outcome (Figure 72-1).

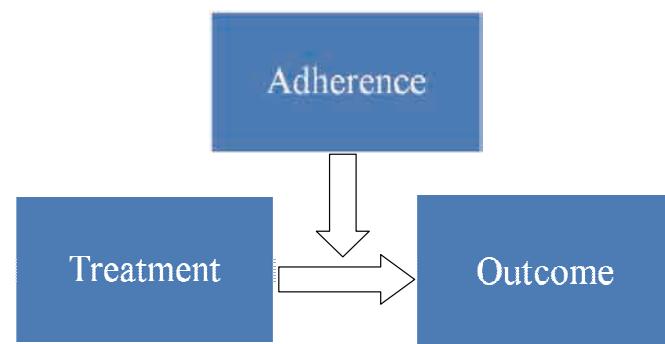

FIGURE 72-1 Adherence mediates the relationship between treatment and outcome.

MEASURES OF ADHERENCE

Because adherence has such a powerful affect on outcome, it is critical that providers monitor adherence. Adherence may be measured in a variety of ways including self-report, pill counts or medication weights, serum drug levels, using pharmacy data, and using electronic monitors. As previously mentioned, in clinical trials on adherence, rates obtained by self-report grossly overestimate rates obtained more objectively using electronic monitors.^{8,15,17,18} Unfortunately, while ideal for trials, electronic monitors are not practical for assessing adherence in clinical practice. Pharmacy data may be useful for objectively determining if patients procure medication, but they are a step removed from whether the patient uses the treatment, in addition to not being particularly practical for providers.

In clinical practice, blood test monitoring for drug levels is a straightforward and objective approach, however, this often overestimates adherence because patients tend to be better about using their medications around the time of an office visit, a phenomenon called "white coat compliance" (one of the most illustrative examples of this phenomenon is the tendency for people to floss more before going to the dentist).^{8,9,27} Counting pills or weighing a topical medication is a practical and seemingly objective way to assess adherence in practice, but patients are wily and may dump their medication to hide their poor adherence behavior. To improve the reliability of pill counts, instead of prescribing 60 tablets for a bid dosing and having the patient return in a month, either prescribe 70 tablets or prescribe 60 but have patients come back before the month is over. That way, if the bottle is empty, the physician can distinguish a bottle that has been emptied because of good adherence from one that was emptied to hide poor adherence.¹²

Although it is probably the least reliable, simply asking patients about their adherence to treatment may represent the most reasonable assessment option for most providers. An evidenced-based review of the literature was done to evaluate self-report instruments used to measure medication adherence in patients with chronic disease.¹⁷ Eleven self-report instruments for the measurement of adherence were identified. While all produced an estimate

of adherence that correlated with actual behavior, the correlation was not strong for any of the measures. None of the scales had been tested in patients who had dermatologic disease and/or used topical medications. Validity was higher for more objective adherence outcomes such as electronic monitoring systems as compared to self-report measures. To encourage honest self-reporting, the physician may ask, “It can be hard to use the medicine every day. How often are you missing doses: every day or every other day?” Moreover, as a rule, providers should probably just assume most of their patients are not using their medications as much as prescribed, nor as much as they report. Providers then can proactively minimize poor adherence in all their patients by adopting some basic strategies.

BARRIERS TO ADHERENCE

Many interacting variables influence adherence, which in turn mediates the relationship between treatment and outcome (Figure 72-1). The best evidence on causes of nonadherence in skin disease patients comes from work by Kimball and colleagues who studied the relative importance of factors contributing to nonadherence in psoriasis patients using topical corticosteroid. They surveyed 53 patients from the outpatient clinic. Reported nonadherence was 40% (although we suspect it was much higher as self-report underestimates how poor adherence is). The most important reasons for nonadherence included frustration with medication, efficacy, inconvenience, and fear of side effects. They also found that patients who reported not receiving instructions on topical treatment duration used their treatments longer than those who had received instructions.¹³

The factors that affect adherence can be classified as internal factors and external factors (Figure 72-2). The patient’s motivation to get better (or lack thereof) is a critical internal factor: some patients may not be motivated, a common factor underlying poor use of sunscreens in young people. The effects of skin cancer typically do not occur until later in life, something teenagers do not think about. As mentioned earlier, one might expect that patients with more severe disease would be more motivated to use their medications, while in actuality, data shows these patients are less likely to be adherent.^{14,15} Resignation may be a common cause of treatment failure in patients with chronic diseases like psoriasis, as evidenced by how many prescriptions go unfilled.¹⁹ Many people with psoriasis do not even come in for treatment, having given up hope, while others come in for the office visit, but don’t use the recommended treatment (or may not even purchase it) because they feel it is hopeless.

Conversely, patients may be motivated to get better but may not have the tools to effectively adhere to treatment. Often patients are not given adequate instructions on how to use their medications,²⁸ and even when they are, many

Internal Factors	External Factors
<ul style="list-style-type: none"> • Age • Poor motivation to get well • Secondary gain from illness • Feeling of hopelessness/ resignation about condition • Poor understanding of the disease • Unrealistic or inaccurate expectations of treatment • Psychiatric comorbidities • Lack of trust in the doctor • Lack of trust in or fear of the treatment • Fear of side effects 	<ul style="list-style-type: none"> • Weak physician-patient relationship • Complex treatment regimen (frequent dosing and/or multiple agents) • Poorly tolerated vehicle • Side effects and toxicities • Slow-acting medication • Cannot afford treatment • Limited access to treatment • Inadequate instructions provided on how to use medications • Long interval between follow-up visits

FIGURE 72-2 Factors contributing to poor adherence.

patients forget the instructions they were given. It generally takes about 6 minutes after leaving a doctors’ office for people to forget the instructions. Psychiatric comorbidities like depression may interfere with patients’ ability to carry out their treatment. Age is another important factor as children and teenagers are less likely to be adherent with treatment. Patients’ understanding of their disease and their expectations for treatment can play a critical role, as does their understanding of the treatment itself and expectations about side effects. Patients may not use treatments because they do not trust their doctor, the medical profession, or medications. Of profound importance is the patient’s trust in their doctor and the quality of the doctor-patient relationship. Seventy percent of adherent patients reported that they were using their medication because they believed their doctor was a compassionate advocate.²⁹

Many external factors influence adherence as well, including regimen complexity, treatment cost and availability, topical vehicle, and medication side effects. The time it takes a medication to work is critical, as is the patient’s response to treatment. For example, if a medication takes weeks to work, but the patient is expecting a “quick fix”, then that patient may stop using the medication, thinking that it failed. Conversely, if the patient has rapid initial success with a particular treatment, he or she may be more likely to continue using it. Other important considerations over which physicians have considerable control include the quality of the physician-patient relationship, plans for follow-up visits, and clarity of instructions provided. In general, while it is easy to write a prescription, it is much harder for the patient to follow through. For every patient, with every treatment, we should anticipate potential barriers to adherence and take steps to minimize them before they interfere with treatment. In dermatology, with all the topical medications we prescribe, it is far more difficult to adhere to medication than it is in other fields where only a pill may be needed.³⁰

STRATEGIES TO IMPROVE ADHERENCE

A Strong Doctor-Patient Relationship is Essential to Good Adherence

A wide variety of interventions may be sensible for improving patients' adherence behavior, although few have been rigorously studied. The doctor-patient relationship provides the critical foundation on which good adherence is built. As mentioned earlier, a majority of adherent patients attribute their good adherence to having a caring provider.³¹ Impressions began as soon as patients walk in the door. The office should have a pleasant appearance, with friendly staff. Posted signs regarding payment and insurance should be avoided as they send the wrong message about priorities. In the patient encounter, body language is important. The physician should make eye contact and smile. Patients feel less rushed and perceive a visit as lasting longer when the physician sits down.²⁹ Utilizing active listening techniques conveys the message that the physician cares. Similarly, laying hands on a patient during an examination provides tangible evidence to the patient that they are receiving a careful examination; using a lighted magnifier is another prop that can be used to reinforce this perception. Providing contact information when patients have questions later reinforces the message that the patient is cared for. Incorporating these basic steps into practice helps to provide the foundation of a strong doctor-patient relationship, which in turn facilitates good adherence and good patient outcomes (Figure 72-3).

Initial Adherence Fosters Long-term Adherence

Another avenue to good adherence lies in the ability to achieve good initial adherence (Figure 72-4). To this end, a promising approach appears to be the use of an office visit.²⁷ White coat compliance is a well-characterized phenomenon in which patients use their medication better around the time of office visits.^{32,33} A study was done to improve adherence and outcomes in patients with AD. The study attempted to achieve better adherence in patients

with AD by combining use of an easy-to-apply medication (instead of a traditional ointment) and more frequent return visits. Forty-one subjects with mild-to-moderate AD were treated with desonide hydrogel 0.05% twice daily, and disease severity was measured at baseline and weeks 1, 2, and 4. In order to improve adherence in the first week, subjects were told to expect a follow-up phone call on day 3. Adherence was measured in the study using electronic monitors. In contrast to the behavior of atopic patients treated with triamcinolone, in whom adherence drops by about 60-70% in 3 days, mean adherence to the desonide hydrogel declined much more slowly, from 81% on day 1 to 50% by day 27. The investigators concluded that the easier to use vehicle, the increased follow-up, and the good efficacy achieved by better adherence in the first days/week of treatment contributed to the better adherence outcomes. A literature review by the authors identified 15 studies, which commented on the relationship between adherence and office visits; 14 of 15 studies found that office visits had a positive effect on adherence.

Much in the same way that first impressions are important, seeing good results early on will cause the patient to trust their doctor, to trust in their medication and to continue using the treatment long term, thus achieving better long-term adherence. A fast-acting medicine should be used when possible; if a slow acting medication is necessary, pair it with a fast acting medication initially to help secure good initial adherence. Ensure patients get the best results by giving them the tools to use their medications correctly. Instructions for use of medication can get complicated quickly in addition to the fact that patients forget 50% of verbal directions given during a visit.³⁴ Prevent confusion by providing clear written instructions with all medications.

Incorporating a new habit into everyday life can be challenging—even the most motivated individual may forget to use their medicine. Simple memory aids may help patients maintain good adherence. A common suggestion is to tie the medication to an already established habit. This could mean taping a topical acne medication to the toothpaste tube or placing topical antifungal medication on top of the shoes. The effect of daily reminders has been studied in several clinical trials. A study on teenagers with acne examined the effect of several interventions, including daily

- Office staff should be friendly and professional
- Office is clean and well-maintained
- Posted signs convey message that patient care is the priority
- Make eye contact, smile, and shake hands with the patient
- Sit down during the encounter
- Do not interrupt the patient's opening monologue
- Be an active listener
- Show empathy
- Touch the patient's skin during examination
- Solicit patient input and questions
- Give patients contact information

FIGURE 73-3 How to create a strong doctor-patient relationship.

- Use fast-acting medications; if a slow-acting medication is being used, pair it with a fast-acting medication initially
- Provide written instructions on treatment
- Educate the patient about their condition and provide realistic expectations for treatment outcome
- Schedule an early follow-up visit
- Use motivational interviewing techniques
- Help the patient to identify memory aids to help them remember to use the medicine

FIGURE 74-4 Ways to secure good initial adherence.

reminders, on adherence to daily 0.1% adapalene gel. Daily electronic reminders via e-mail or text message had no effect on adherence, with rates comparable to the standard of care group. The intervention of more frequent office visits resulted in the best adherence rates, while daily reminders from parents actually resulted in worse adherence rates than no intervention at all.¹² Contrary to the prior study, Armstrong et al. found that an electronic reminder, in the form of daily text messages, was a very effective intervention to improve adherence to daily sunscreen use. They asked 70 adult volunteers from the general population to apply sunscreen daily for 6 weeks; half of participants received a daily text message reminder. Measuring adherence using electronic monitors, they found a mean adherence of 30% in the control group versus 56% in the group that received text messages.³⁵ Perhaps the disparate results of the two studies can be attributed to the study population, suggesting that text message reminders are helpful for adults but not teenagers. Nonetheless, memory aid strategies can be helpful in improving adherence; which memory aid will work for a given patient will vary, so some experimentation may be necessary.

Treatment Regimen Can Make or Break Adherence

Treatment choice is abound with implications for adherence (Figure 72-5). Perhaps the most straightforward way to improve adherence is to simplify treatment. Many skin conditions, including acne, are treated with multiple treatments. Combination products are now available that simplify treatment and can improve patients' adherence. This was tested in acne patients by assessing adherence to a combination topical medication applied once daily compared to daily applications of two separate generic subcomponents. In this randomized trial, 26 teenagers with mild to moderate acne vulgaris received 12 weeks of once daily clindamycin phosphate 1.2%–tretinoin 0.025% gel (CTG) or separate daily applications of clindamycin and tretinoin (C gel + T cream). Adherence was monitored in the study objectively using electronic monitoring caps. The CTG group had a median adherence of 88% compared to only 61% in the C gel + T cream group. In addition to using combination treatments, once or twice daily dosing regimens may achieve better results than more frequent dosing. Consider the psoriasis patient with coral reef plaques: while our instinct in these patients may be to add penetration enhancers or switch to more potent and risky treatments, adding additional medicines is counterproductive if poor adherence was caused by the complexity and time-consuming nature of the initial treatment. Paring down the regimen, these patients often achieve rapid improvement using a treatment that had previously been “ineffective.”¹² Simplifying treatment regimens may be a valuable means of improving adherence behavior.

- Explain all treatment options clearly
- Involve the patient in choice of treatment
- Solicit the patient's opinion and beliefs about treatment options
- Choose a vehicle that the patient will use
- Create a simple treatment regimen: use less frequent dosing and combination products when possible
- Explain side effects and use them to advantage when possible
- Be aware of the cost of medicines and do not prescribe medications that the patient cannot afford
- Ensure the patient can access the treatment

FIGURE 72-5 Treatment considerations to optimize adherence.

In the case of topical medications, selection of the appropriate vehicle is essential. The traditional teaching that ointments are the most effective vehicles for dry skin conditions like psoriasis has been debunked. A literature review of outcomes in psoriasis patients treated with clobetasol in a variety of vehicles revealed that ointments had comparable, rather than superior efficacy.³⁶ Lessons from Skin Cap™ and scalp psoriasis illustrate the fundamental principle that the most effective vehicle is the one the patient is most willing to use.

Side effects of treatment are important to consider, including both real and perceived side effects. The strength of the physician-patient relationship may help overcome patients' fears. A simple discussion with a trusted physician can reassure the patient that the proposed medication is safe enough to use. Unexpected side effects can quickly lead to discontinuation of a medication. Forewarning patients that burning or dryness is a normal reaction to the medication and will subside with use—or better yet, that such a reaction is “a sign the drug is working”—may keep patients from discontinuing treatment. In fact, if the patient is experiencing such a side effect, it means he or she is using the medication, and thus it probably is working.²⁹

CONCLUSION

There is very strong evidence that nonadherence is a ubiquitous problem in dermatology. The cost of poor adherence and resulting treatment failure is high, resulting in prolonged morbidity, medication switches, and office visits. Estimates suggest that poor adherence costs in excess of 100 billion dollars annually in the United States and is responsible for 10% of all hospitalizations.^{37–39} Physicians should expect some degree of poor adherence in all patients and should proactively address adherence in treatment planning. There is not yet enough evidence to make an adherence treatment plan for every situation. Adherence behavior is very complex and affected by a multiplicity of factors. Improving adherence is, at this point, largely an art, rather than an evidence-directed matter. Some generalizations can be made. However, first, we ought to assume that our patients may not use their medication as directed unless we take great pains to see that they do. We should give our patients the sense that we are trustworthy, caring

doctors committed to helping them get well. We should involve them in the choice of treatment, finding a treatment regimen and delivery system they feel they can live with. We should not overemphasize risks, and we should help patients see improvement quickly, often by encouraging

good adherence with a follow-up visit or other contact shortly after initiating treatment. Making sure the patient uses the medicine well, initially improves patients' trust in the medication, and encourages more regular use, in turn, improving outcomes.

What We Know

- Patients' responses to treatment are quite variable. Poor adherence to treatment may account for much of the variability.
- Many patients are poorly adherent to topical treatment.
- Patients' self-reported adherence behavior often overestimates true adherence.
- Patients often don't fill their prescriptions.
- When patients do fill their prescriptions, they often do not take the medication as directed.

- Use of topical medications often declines over time, and this may be the best explanation for the commonly observed phenomenon of "tachyphylaxis" to topical corticosteroids.
- Physicians can improve their patients' adherence behavior.
- Text messages and office visits increase patients' adherence to treatment.

Ethnic Issues in Evidence-Based Dermatology

Ahmad Reza Hossani-Madani, M.D., M.S., and Rebat M. Halder, M.D.

INTRODUCTION

There has been an increased interest, by dermatologists, in learning about conditions as they relate to skin of color. However, a study found that from 1996–2005, teaching events at annual meetings of the American Academy of Dermatology (AAD), focusing on skin of color, have remained at 2%.¹ According to the US Census Bureau, the United States will be more racially and ethnically diverse by midcentury, with the nation projected to be composed of 54% minority by 2050.² There have been efforts to elucidate structural/functional differences, reactions to the environment (ultraviolet radiation, chemicals, pathogens, trauma, medications, etc.), uncommon conditions that present commonly (in certain ethnic groups) and common conditions that present uncommonly in those of darker skin pigmentation. Additionally, efforts have been made to understand differences in access to healthcare, clinical research and health insurance, by the federal government, to impact healthcare disparities. It is our effort in this chapter to highlight the meaning of skin of color, followed by a discussion of ethnic issues as they relate to epidemiology and healthcare disparities in dermatology and then conclude with a brief overview of the structure and function and cutaneous reaction patterns of skin of color.

DEFINITION OF SKIN OF COLOR

According to the Skin of Color Society, skin of color is defined as those individuals of Asian, Hispanic/Latino, African, Native American and Pacific Island descent.³ Another definition states that skin of color identifies individuals of particular racial and ethnic groups who share similar cutaneous characteristics and disorders, as well as reaction patterns to those disorders and other cutaneous stimuli, with individuals generally having darker skin hues.⁴ The term “ethnic skin” has also been used interchangeably in the scientific literature to denote all groups other than Caucasian.

The above descriptions warrant a discussion of the meanings of the words “race” and “ethnicity.” Race, as defined by the Oxford dictionary, as each of the major divisions of humankind, having distinct physical characteristics

or a group of people sharing the same culture, language, etc; an ethnic group.⁵ The Oxford dictionary defines the term “ethnic” as a group of people having a common national or cultural tradition.⁵ The definitions of race and ethnicity vary; however, according to the source.

The use of race in science and medicine have been a topic of considerable debate. This stems from the origins of the term, with the term first used by human divisions created by Carolus Linnaeus and the proper term first used by Johann Blumenbach, in the 18th and 19th centuries. Linnaeus divided humans into four main groups: (1) Europeans (2) Americans (3) Asiatics and (4) Africans. His description of Europeans as “fair...gentle, acute, inventive...governed by laws” is in stark contrast to “obstinate, content free” Americans, “sooty, severe, haughty, covetous” Asians, and “crafty, indolent, negligent” Africans.⁶

Blumenbach first used the term “race” in his classification of humans into five divisions: (1) Caucasian (2) Mongolian (3) Ethiopian (4) American and (5) Malay. Blumenbach felt that “in the same way that we classify races and generations of horses and poultry, of pinks and tulips, so also, in addition, must we class the varietes of mankind which exist within their common original stock.” In his description of “Negroes,” he states:

I am of the opinion that after all these numerous instances I have brought together of negroes of capacity, it would not be difficult to mention entire well-known provinces of Europe, from out of which you would not easily expect to obtain off-hand such good authors, poets, philosophers, and correspondents of the Paris Academy; and on the other hand, there is no so-called savage nation known under the sun which has so much distinguished itself by such examples of perfectibility and original capacity for scientific culture, and thereby attached itself so closely to the most civilized nations of the earth, as the Negro.⁷

The classifications of the above individuals, whether positive or negative, started divisions that exist to the present day. This had led some scientists and physicians to support the abandonment of the usage of race, seeing it as a social and cultural construction devoid of scientific or anthropologic evidence, in preference of the usage of ethnicity or no descriptor at all.^{8–10} As a matter of fact, the

American Anthropological Association, in a 1999 position paper, stated that:

It has become clear that human populations are not unambiguous, clearly demarcated, biologically distinct groups. . . . Throughout history whenever different groups have come into contact, they have interbred. The continued sharing of genetic materials has maintained humankind as a single species. Any attempt to establish lines of division among biologic populations is both arbitrary and subjective.¹¹

Despite the debate, the Office of Management and Budget (OMB), of the Federal government continues to recognize a minimum of five racial categories: (1) American Indian or Alaska Native (2) Asian (3) black or African American (4) Native Hawaiian or Pacific Islander and (5) white. The OMB also recognizes two ethnic categories: (1) Hispanic or Latino or (2) Not Hispanic or Latino. In a statement, they mention that the racial and ethnic categories should not be interpreted as being primarily biologic or genetic in reference, but may be thought of as social and cultural characteristics, as well as ancestry. They further state that respondent self-identification should be facilitated as much as possible. They give no definition of race/ethnicity, or of the categories mentioned above.¹²

In the field of dermatology, individuals of particular “races” may range in skin pigmentation from light to dark, making generalizations of dermatologic disease into specific “races” problematic. However, until more appropriate descriptors of skin pigmentation become available, we will continue the rest of the chapter using the broad categories defined by the federal government, realizing that those descriptors have their limitations.

EPIDEMIOLOGY OF SKIN DISEASES IN DIFFERENT ETHNIC GROUPS

Efforts to quantify the number of patients presenting with certain skin conditions in different ethnic groups has proven difficult because of the lack of large comprehensive datasets. Most of the data is derived from retrospective analyses of private or academic clinic patient populations. This leads to difficulties with extrapolation because of the effects of patient demographics, referral patterns, clinic expertise, clinic location, etc. leading to variations.

If we take the epidemiologic descriptors incidence and mortality, we find that varying federal statistics (Surveillance Epidemiology and End Results [SEER]) are available for melanoma, nonepithelial skin cancer, mycosis fungoides (and Sézary syndrome), cutaneous T-cell lymphoma and Kaposi sarcoma. Prevalence data are incompletely available for melanoma and not available for the rest within that dataset. Data representing reasons to visit a dermatologist may be seen in the National Ambulatory Medical Care Survey (NAMCS) and the National Health and Nutrition Examination Survey (NHANES). We will begin with SEER data on cutaneous melanoma and then briefly explore the

NAMC and NHANES studies, and lastly mention observations from private clinics.

Cutaneous melanoma accounts for approximately 78% of the skin cancer deaths in the United States. SEER data from 2002–2006 indicate that the incidence of melanoma per 100,000 persons was highest in Non-Hispanic whites (26.7) followed by Hispanic whites (4.6), Hispanics (4.5), American Indian/Alaska Natives (3.3), Asian/Pacific Islanders (1.4) and blacks (1). Mortality rates, per 100,000 persons, were highest for Non-Hispanic whites (3.3), then American Indian/Alaska Natives (0.9), Hispanic whites (0.8), Hispanics (0.7), and, lastly, Asian/Pacific/Islander (0.4) and blacks (0.4).¹³ (Table 73-1) Superficial spreading melanoma was the most common histologic subtype in Non-Hispanic whites, Hispanic whites and Asian/Pacific Islander. Acral lentiginous melanoma was the most common subtype in blacks (American Indian/Alaska Native not included in analysis).¹⁴ As we can see, Non-Hispanic whites have the highest incidence and mortality rates than all of the other groups. However, if we look at stage at diagnosis and 5 year survival rates, we see that 34% of blacks present with regional or distant stages compared to 12% in whites and blacks have a 77.7% 5 year survival compared with 92.9% in whites.¹³ Limited data are available for other skin cancers, as they relate to race/ethnicity. Available statistics are shown in Table 73-2. We will now turn to the NAMC and NHANES studies.

The NAMCS study is conducted by the federal government, and looks at data for the primary diagnosis for patients visiting non-federal dermatologists. Data from the NAMCS studies revealed that some type of acne was the number one primary diagnosis in all racial groups except American Indian/Alaska Natives (Table 73-3). Other skin conditions found by race and ethnicity may be found in Table 73-3.

A second large prevalence dataset is the NHANES study. A dermatologic component to the study was carried out in the 1971–1974 period. Data for race/ethnicity were

TABLE 73-1—Melanoma of the Skin (2002–2006)

Race/Ethnicity	Prevalence	Incidence	Mortality
White	729,213	22.9	3.0
Hispanic	N/A	4.6	0.8
Non-Hispanic	N/A	26.7	3.3
Black	2,570	1	0.4
Asian/PI	N/A	1.4	0.4
AI/AN	N/A	3.3	0.9
Hispanic	N/A	4.5	0.7

Asian/PI	0.2	N/A	12.9	4.4
AI/AN	N/A	N/A	10.8	3.6
Hispanic	0.9	N/A	16.7	5.4

*Incidences for Non-Hodgkins Lymphoma includes non-cutaneous variants

(Adapted from Horner MJ, Ries LAG, Krapcho M, Neyman N et al. *SEER Cancer Statistics Review, 1975–2006*. Bethesda, MD : National Cancer Institute, 2009.)

recorded as white, black, or other during their assessments, with Hispanic/Latinos categorized as white. 16,351 patients were classified as white, 4,163 were black, and 235 were other. The top five conditions for whites in decreasing order were: (1) acne vulgaris (2) dermatophytosis (3) seborrheic dermatitis (4) atopic dermatitis and (5) psoriasis. For blacks they were: (1) dermatophytosis (2) acne vulgaris (3) seborrheic dermatitis (4) atopic dermatitis and (5) ichthyosis/keratosis. For “other” they were: (1) dermatophytosis (2) acne vulgaris (3) atopic dermatitis (4) seborrheic dermatitis (5) verruca vulgaris. (15) The NHANES data are more of historical interest, for they do not stratify patients according to current race and ethnic groups, they do not represent current race and ethnic changes and they preceded managed healthcare.

The last source of epidemiologic data comes from the practices of academic and private dermatologists. The sources of patients, referral patterns, aggregation of data from different dermatologists, and over or underreporting are areas of discrepancies when viewing these studies. An overview of all academic and private surveys of diseases in ethnic skin are beyond our scope; however, detailed information may be found elsewhere^{15–17} We will briefly highlight unique diseases in different ethnic groups, from selected surveys, below.

We will first look at dermatologic entities seen in blacks. Hazen in 1935,¹⁸ reported that diseases occurring “more frequently in the Negro than in the white race are as follows: chloasma, cicatrix, permatitis papillaris capillitii, dermatosis papulosa nigra, dermatitis vegetans, erythema ab igne, fibroma, granuloma inguinale, tinea tonsurans, keloid, pellagra, pityriasis corporis, pityriasis faciei, pyoderma, scabies, miliary lupoid (tuberculosis), tuberculosis lichen and vitiligo. Kenney et al., 1961¹⁹, found certain “dermatoses peculiar to Negroes,” including: (1) pigmentary changes (2) dermatosis papulosa nigra (DPN) (3) pseudofolliculitis barbae (4) dermatitis papillaris nigra (acne

keloidal nuchae) and (5) perifolliculitis capitis abscedens et suffodiens (dissecting cellulitis of the scalp). Halder et al., 1983,²⁰ found greater proportions of blacks seeking care for pigmentary disorders, alopecia, and keloids. We may also add acral lentiginous melanoma as occurring more often in blacks.

Asians are known to have the following conditions occur more often: melasma, post-inflammatory pigmentation, lichen amyloidosis, photodamage (as dyspigmentation or wrinkling), alopecia, and eczema (in children).¹⁷

Hispanics/Latinos experience the following conditions with greater frequency: Hermansky-Pudlak syndrome, erythema dyschromicum perstans (ashy dermatosis), melasma, post-inflammatory hyperpigmentation, pigmented basal cell carcinoma.¹⁷ Melanoma has also been on the rise in this population, as alluded to above.

Lastly, Native Americans have been reported to have increased presentations of the following cutaneous diseases: photodermatoses (including hereditary polymorphic light eruption or actinic prurigo), collagen vascular disease (systemic sclerosis) and acanthosis nigricans (perhaps secondary to diabetes mellitus).¹⁷ However, large scale epidemiologic studies on Native Americans are lacking, and information comes from small case reports.

DISPARITIES IN HEALTHCARE, CLINICAL RESEARCH, AND HEALTH INSURANCE

To begin this section, we must define what we mean by healthcare disparities. The definition of “healthcare”, by the Institute of Medicine (IOM), is “the continuum of services provided in traditional healthcare settings, including public and private clinics, hospitals, community health centers, nursing homes, and other healthcare facilities, as well as home-based care.” The IOM further defines “disparities in healthcare” as “racial or ethnic differences in the quality of healthcare that are not attributed to access-related factors

TABLE 73-3—National Ambulatory Care Survey (NAMCS) – 1993-2002 – Top 10 Primary Diagnoses by Racial/Ethnic Group for Non-Federal Dermatologists in the United States

White	Black	Asian	Native Hawaiian/Pacific Islander	Hispanic or Latino	American Indian/Alaska Native
Other acne	Other acne	Other acne	Other acne	Other acne	Viral warts, unspecified
Actinic keratosis	Unspecified cause	Unspecified cause	Other seborrheic keratosis	Unspecified cause	Rosacea
Viral warts, unspecified	Seborrheic dermatitis, unspecified	Benign neoplasm of skin, site unspecified	Acne	Acne	Scabies
Unspecified cause	Other atopic dermatitis and related conditions	Other atopic dermatitis and related condition	Viral warts, unspecified	Other psoriasis	-
Malignant Neoplasm of skin, site unspecified	Acne	Other psoriasis	Sebaceous cyst	Viral warts, unspecified	-
Benign neoplasm of skin, site unspecified	Other psoriasis	Viral warts, unspecified	Other atopic dermatitis and related condition	Sebaceous cyst	-
Other psoriasis	Alopecia, unspecified	Other seborrheic keratosis	Dermatophytosis of nail	Psoriasis	-
Acne	Noncodable diagnosis/insufficient for coding	Urticaria, unspecified	Malignant neoplasm of skin of other and unspecified parts of face	Actinic keratosis	-
Other seborrheic keratosis	Keloid scar	Acne	Unspecified cause	Benign neoplasm of skin, site unspecified	
Eczema	Viral warts, unspecified	Sebaceous cyst	Lichenification and lichen simplex chronicus	Alopecia areata	-

(Adapted from Taylor SC, Summers P. Defining Skin of Color. In: Kelly AP, Taylor SC, editors. *Dermatology for Skin of Color*. New York: McGraw-Hill; 2009. 8–15.)

or clinical needs, preferences, and appropriateness of intervention.”²¹ However, the Agency for Healthcare Research and Quality (AHRQ) of the U.S. Department of Health and Human Services recognizes that there isn’t a consensus on the definition in their National Healthcare Disparities Report (2003).

Five theories have been proposed that may explain why certain racial/ethnic groups experience disease and healthcare differently. They are the racial-genetic model, the health-behavior model, the socioeconomic status (SES) model, the psychosocial stress model, and the structural-constructivist model. Briefly, the racial-genetic model states that inherent genetic factors in racial groups may account for differences in disease manifestations. The health-behavior model states that voluntary behaviors, adapted by certain groups, leads to perceived differences in health (e.g., high caloric intake and low physical activity). The

SES model believes that research is confounded by social and economic factors, related to income, poverty, and access to health insurance. The psychosocial stress model was proposed after the SES model failed to completely account for healthcare disparities. It states that stresses associated with institutional and interpersonal racism may be the root of disparities. Lastly, the structural-constructivist model, although unclear, attempts to view racism as a dual entity. The structural component is the constraint of individuals by external social structures, created by the shared and distributed expectations of others. The constructivist aspect is the construction of a cognitive representation of the reality of life out of an amalgam of socially shared understandings distributed within a society. Although one theory does not fully account for the totality of disparities, these concepts have been used in public health research.²² These concepts have also become

a focus of the federal government, to further understand and possibly eliminate healthcare disparities, which we will examine below.

Within the realm of clinical research, the National Institutes of Health (NIH) Revitalization Act of 1993 (PL 103–43) was passed, which required the creation of guidelines for the inclusion of women and minorities (and their subpopulations) in research. These guidelines, published in 1994 and amended in 2000, cover all biomedical and behavioral research involving human subjects (including clinical trials), supported by the NIH. The guidelines affect all age groups, with inclusion of women and minorities mandated, regardless of cost.²³

The United States Congress, realizing differences in healthcare in minority groups through clinical research, established the Healthcare and Quality Act (Public Law 106–129) in 1999. The act commissioned the IOM and the AHRQ to develop reports on the disparities in healthcare delivery in minority groups in 2003. The AHRQ was further instructed to report progress on healthcare disparities, annually, in the National Healthcare Disparities Report (NHDR). We will first look at U.S. census data and then examine the 2008 version of the NHDR.

The U.S. Census Bureau, in their 2008 Income, Poverty, and Health Insurance report, found that blacks had the lowest median income (\$34,218) compared to all other racial and ethnic groups, in 2008. Hispanics had the second lowest median income, making \$37,913 in 2008. The median incomes for blacks and Hispanics were 62% and 68% of Non-Hispanic whites, respectively. Asians had greater median income, \$65,637, as compared to Non-Hispanic whites (\$55,530). In terms of poverty, blacks had the highest rates of poverty (24.7%, 9.4 million individuals), followed by Hispanics (23.2%, 11 million), Asians (11.6%, 1.6 million), and Non-Hispanic whites (8.6%, 17 million). Lastly, the uninsured rate was highest for Hispanics (30.7%, 14.6 million), then blacks (19.1%, 7.3 million), Asians (17.6%, 2.3 million), and Non-Hispanic whites (10.8%, 21.3 million). From the above data we can discern that blacks and Hispanics have the lowest median incomes, greatest rate of poverty, and highest rates of being uninsured.

The 2008 NHDR, although, not specifically addressing dermatologic disease, did report on disparities in access to medical care, and disproportionate burden of diseases that may affect dermatologic care. Blacks had a 9.4 times greater rate of new AIDS cases, greater rate of lower extremity amputations in diabetics, and lack of prenatal care in the 1st trimester as compared with whites. Asians had issues with timeliness of care, while American Indians and Alaska Natives experienced differences in prenatal care and colorectal cancer screening. Hispanics also experienced a higher proportion of new AIDS cases, as compared to whites. Lastly, poor individuals were more likely to have communication disparities with their provider and have a greater proportion of patients with delay in care.²⁴

Within the field of dermatology, specifically as it relates to skin of color, there is dearth of quality scientific data in the form of blinded trials, especially regarding structural and functional differences between ethnic groups. As well, there is a severe lack of randomized controlled trials for evaluation of skin diseases and their treatment in skin of color. Many published reports of treatments of dermatologic diseases in skin of color are anecdotal and lack necessary scrutiny in their evaluation. At a meeting of the National Institutes of Arthritis and Musculoskeletal Disease and Skin Disease (NIAMS) in 2000, on healthcare disparities in dermatology, Taylor stated that:

A review of the literature reveals a marked paucity of basic science research on skin of color. Many of the basic science research studies involving the structure of skin of color (e.g., those aimed at understanding the human cutaneous appendages such as the apocrine gland) date back to the early part of this century. They involve small numbers of subjects, and were not blinded. This inadequate research base regarding skin of color highlights the need for blinded, scientific investigations involving larger numbers of subjects from each of the various racial groups.²⁵

This lack of basic data makes inferences about racial differences in presentation of skin and hair disorders infirm. Additionally, formulation of treatments for ethnic skin disorders may be hindered, because of poor quality of foundational data.

With regard to a lack of basic science, randomized clinical, and epidemiologic research involving those with skin of color, the NIAMS has outlined a strategic research plan to reduce and eventually eliminate healthcare disparities as they relate to rheumatologic and dermatologic disease. They have indicated research priorities for five diseases: (1) lupus (2) scleroderma (3) osteoarthritis (4) vitiligo and (5) keloids. They acknowledge that these entities affect one or more racial and ethnic minorities with greater frequency, earlier, or with greater severity than whites.²⁶ In their report, they state that African American women have a three times higher incidence and mortality, earlier presentation and more serious complications with lupus than white women. They further state that nine times more women than men have lupus, and that lupus is also more common in women of Hispanic, Asian, and Native American descent. With regards to scleroderma, they report that while it affects members of all ethnic groups, it is particularly prevalent in certain Native American people, with a genetic susceptibility site identified in Choctaw Native Americans of Oklahoma. Although vitiligo affects all racial and ethnic groups, they state that psychologic and social consequences are particularly profound in people of color. Lastly, they recognize that keloids are seen predominantly in African American individuals.²⁶

In terms of skin cancer, we have seen, as alluded to in the SEER data in the last section, that those of darker

pigment have lower rates of developing invasive melanoma as compared with Non-Hispanic whites. However, those individuals that do develop invasive melanoma tend to do worse than their Non-Hispanic white counterparts (more advanced stage at diagnosis and worse 5-year survival rate). Suggested causes may be advanced stage at diagnosis, increased rates of melanoma in non-sun-exposed sites, a more aggressive form of disease, lack of adequate skin cancer education, decreased use of sun protection, decreased likelihood to undergo full body skin examination and language barriers.²⁷

Even with greater federal emphasis placed on reducing healthcare disparities, in both research and clinical settings, recruitment of racial and ethnic minorities has proven difficult.²⁸⁻³⁰ This may stem from medical mistrust, lack of transportation, need for child care, loss of income when seeing a physician, communication barriers, cultural barriers, misperceptions, or lack of legal immigration status. Furthermore, lack of use or nonuniform use of racial and ethnic descriptors in the scientific literature also presents challenges when interpreting data from basic and clinical research.

From our discussion, we may glean that there are healthcare disparities amongst racial and ethnic groups that cannot be accounted for by socioeconomic status alone. Efforts have been made by the NIH and federal government to identify, understand, and ramify those differences. This requires the use of language interpreters, improvement of cultural sensitivity of physicians, increase in the number of minority researchers and clinicians, community-based outreach programs and creation of large, current datasets examining the burden of skin disease, especially amongst those of color. We will now turn to a discussion of structural and functional differences in Skin of Color.

BRIEF OVERVIEW OF STRUCTURAL AND FUNCTIONAL DIFFERENCES OF SKIN OF COLOR

Studies investigating skin and hair structure and function in various ethnic groups have revealed interesting differences in the epidermis, dermis, and hair follicles. It is our objective to briefly examine those differences, in that order. As we proceed, keep in mind that research on ethnic skin differences has been done on small sample sizes, with sometimes conflicting results. Although we will highlight certain differences, more research needs to be done to confirm those relationships. A summary of the findings is shown in Table 73-4.

Epidermis

The epidermis is divided into five layers: (1) stratum corneum (2) stratum lucidum (3) stratum granulosum (4) stratum spinosum and (5) stratum basale. There are

four main cell types in the epidermis: (1) keratinocytes (2) melanocytes (3) Langerhans cells and (4) Merkel cells. We will begin by describing differences in the stratum corneum and then proceed to differences in melanocyte/melanosome structure and function.

Various properties of the stratum corneum have been examined in ethnic skin, including the number of cell layers, corneocyte size, phenotype and desquamation, lipid content, barrier function (transepidermal water loss), water content, pH, and microflora.

Black skin may have more corneocyte cell layers than white patients, as evidenced by greater number of tape stripplings (21.8 vs. 16.7 stripplings).³¹ However, there has been no demonstrable difference in the thickness of the stratum corneum between blacks and whites, which may be secondary to increased cohesiveness of the cells in the stratum corneum.³¹

There have been no differences found for both corneocyte size and maturation between blacks, whites, and Asians. The desquamation rate, lipid content, barrier function (transepidermal water loss), and water content between blacks, whites, Asians, and Hispanics has shown conflicting results, depending on the study.³²

Blacks have been found to have a lower skin pH after three skin stripplings than whites, and blacks have lower pH on their cheeks than whites. Blacks have also been found to have increased numbers of *Candida albicans* (150%) and anaerobic bacteria (650%) on their skin than whites.³²

We will now turn to differences in the pigmentation between those of dark skin and those of fair skin. It has been shown that the number of melanocytes does not differ amongst racial groups.³³ However, observable differences are attributed to differences in melanosome number, size, aggregation, number in the basal layer, distribution, and total melanin content.

Blacks have a greater number of melanosomes in the epidermis than whites. Melanosomes are also larger and denser in blacks compared with whites. Darker-skinned blacks tend to have their melanosomes distributed as closely packed doublets, residing mostly in the basal layer, with a decreasing melanosome gradient as we travel up the stratum corneum. Fair-skinned whites have smaller and less melanosomes, which tend to be aggregated and located mainly in the stratum corneum, with less melanosomes in the basal layer than blacks. This can vary with lighter-skinned blacks and darker-skinned whites, which show intermediate features between dark-skinned blacks and fair-skinned whites. In addition to these epidermal differences, we will now examine differences in dermal structure.

Dermis

The dermis is divided into the upper papillary and the deeper reticular dermis. Cells that reside within the dermis include fibroblasts, macrophages, mast cells, and

TABLE 73-4—Differences in Structural and Functional Characteristics of Ethnic Skin

	Blacks (Darker skinned)	Whites (Fair skinned)	Asians	Hispanics
Epidermis				
Corneocyte Surface Area	911 μm^2	899 μm^2	909 μm^2	
Stratum corneum thickness	5-19.1 μm	5-19.1 μm		
Stratum corneum Layers	21.8 cell layers	16.7 cell layers		
Spontaneous Desquamation	?	?	?	
Transepidermal Water Loss (TEWL)	?	?	?	?
Conductance Stratum Corneum Lipid Content	Higher ?	Lower ?	?	Higher ?
Dryness Eumelanin: Pheomelanin	Higher Highest	Lower Lowest	Intermediate (East Indians)	
Melanocyte number	No significant difference (1054 melanocytes/ mm^2)	No significant difference (1241 melanocytes/ mm^2)		
Gene Expression of Tyrosinase	No significant difference	No significant difference		
Melanosomes	1. >200 melanosomes 2. Located mostly in basal layer 3. Larger, more oval, denser 4. No limiting membrane 5. Closely packed doublets 6. Degrade slower 7. Distribute throughout entire epidermis Greater	1. < 20 melanosomes 2. Located mostly in stratum corneum 3. Smaller, less oval, less dense 4. Limited membrane 5. Aggregated with spaces between them 6. Degraded faster Lesser	1. Aggregated and more compact than Whites 2. Fewer basal cell melanosomes	
Total Melanin Content				
Dermis				
	1. Thicker 2. More compact 3. Less distinct papillary and reticular layers 4. Loosely stacked, smaller collagen fiber bundles	1. Thinner 2. Less compact 3. More distinct papillary and reticular layers 4. Larger collagen fiber bundles		
Melanophages	Larger			
Fibroblasts	1. Larger 2. More biosynthetic organelles 3. More multinucleated			
Mast Cells	1. Larger granules 2. 15% more parallel-linear striations	1. Smaller granules 2. 30% more curved lamellae 3. Tryptase reactivity confined to peripheral area of granules		
Nerve Fiber Network Elasticity	No significant difference ?	No significant difference ?		?
Cutaneous Appendages				
Sebaceous Glands	Larger, greater sebum production	Smaller, less sebum production		
Apocrine Glands	Larger, greater number, more fluid secretion	Smaller, less numerous, less fluid secretion		
Mixed Apocrine-Eccrine Glands	More	Less

(Adapted from Oresajo CO, Pillai S, Richards GM. Structure and Function of Skin and Hair in Pigmented Races. In: Halder RM, editor. *Dermatology and Dermatological Therapy of Pigmented Skins*. New York: Taylor and Francis; 2006, p. 3–16.)

circulating immune cells. The dermal matrix is composed of collagen (produced by fibroblasts), elastic fibrous tissue, and “ground substance” (glycoproteins, proteoglycans, and glycosaminoglycans). We will look at differences in these structures as they relate to race and ethnicity.

The dermis of blacks has been found to be thicker and more compact than that of whites.³⁴ The differentiation of the papillary and reticular dermis is more difficult in blacks as compared to whites. Blacks have loosely-stacked, smaller collagen fiber bundles and many collagen fibrils and glycoprotein fragments, while whites have more distinct papillary and reticular dermal structures, larger collagen fiber bundles, and occasional fiber fragments.³² The fibroblasts in blacks are larger and are more multinucleated than whites.³² The mast cell number and size have not been found to be different between races; however, blacks do have larger mast cell granules than whites.³² Lastly, there does not seem to be an appreciable difference in the nerve fiber network and there are conflicting results relating to elasticity of the dermis.³²

Cutaneous Appendages

Cutaneous appendages are derivatives that include sebaceous glands, sweat glands, and hair, amongst others. Sweat glands may be further divided into apocrine (develop at puberty and found in axillae, anogenital area, face, scalp, external auditory canal, and mammary glands), eccrine (found all over body, especially palms and soles), and apocrine glands (develop at puberty, axillae only).

Beginning with the sebaceous glands, we find that blacks have larger and more productive glands than whites.³² Second, apocrine glands have been found to be larger, greater in number, and more productive in blacks compared to whites.³² Third, there has been no difference found between races for eccrine glands.³² Lastly, black skin has been found to have more apocrine sweat glands than whites.³²

When considering hair from different races, we notice that blacks, although having no differences in chemical composition, show interesting structural differences from whites and Asians when looking at hair cross section, fiber shape, diameter, tensile strength, distribution, moisture, and anchoring.³⁵

When examining hair cross-sections, we notice that blacks have an elliptical shape, while Asians have more of a round shape, and whites intermediate between the two. Hair fibers appear as a twisted oval rod with pronounced flattening in blacks and cylindric in whites and Asians. The hair diameter is greatest in Asians, intermediate in whites, and variable in blacks. Black hair seems to have less tensile strength as compared with whites and Asians, perhaps leading to more breakage. Additionally, blacks have, on average, less follicular units per square millimeter than whites or Asians, but tend to have more hair per follicular unit. Lastly, blacks tend to have less hair moisture and less elastic fibers anchoring the hair in place than whites.³⁵

OVERVIEW OF CUTANEOUS REACTION PATTERNS OF SKIN OF COLOR

From the above discussion, we see that differences exist in skin structure, which translate into differences in function and responses to the physical environment. These differences may be understood as cutaneous reaction patterns in those with darker skin pigmentation. A study of reaction patterns alleviates the need to discuss all skin diseases that manifest differently in darker skin, while providing a basis with which to understand them all. Although various classifications of cutaneous reactions in dark skin exist, we will focus on three predominant patterns, first proposed by Brauner³⁶ and modified by Andersen and Maibach,³⁷ with representative examples. These include: (1) pigment lability (hyper- or hypopigmentation) (2) mesenchymal responses (fibromatosus and granulomatous) and (3) follicular responses.

Pigment Lability

In order to understand pigment lability, we must first define the term. We will use the definitions of Nordlund et al. to differentiate between two different types of chromophores – defined as all chemicals and structural items that impart color to the skin. “Pigment” will be used to describe “melanotic” chromophores (relating to the melanocytes and melanin), differentiating them from those chromophores composing other elements of the skin, which include hemoglobin, carotenes and collagen.³⁸ Lability, as defined by the Merriam-Webster dictionary, means readily or continually undergoing chemical,

physical, or biologic change or breakdown (unstable).³⁹ Therefore, pigment lability will refer to the instability of the melanocytic system in response to internal and external stimuli, with deviations from the normal manifesting as hyperpigmentation, hypopigmentation, or depigmentation. Hyperpigmentation may occur because of increased melanin production (hypermelanosis) or number of melanocytes (hypermelanocytosis). The melanin may be distributed to the epidermis, dermis, or both. Similarly, hypopigmentation is caused by the decreased number of melanocytes, or decreased melanin production, melanosome biogenesis, transport, and transfer.³⁸ Representative entities, among darker-skinned individuals, include

What We Know

- Despite the limitations of the concept of race, divisions along racial lines continue to enter clinical research because of their use by the federal government.
- Epidemiologic data on skin diseases, especially as they relate to different ethnic groups, is limited. However, from the available data for malignant melanoma, we may discern that, although, Non-Hispanic whites have the highest incidence and mortality rates than all of the other groups, blacks have a more advanced disease presentation and poorer 5-year survival rate than whites. Also, in terms of melanoma incidence, Hispanic whites and Hispanics follow Non-Hispanic whites, per 100,000 persons. Alaskan/Pacific Islanders follow Non-Hispanic whites in regards to melanoma mortality rates.
- From the available data, we may say that there are certain dermatologic conditions that are found with greater frequency in certain ethnic groups. Blacks have an increased frequency of pigmentary disorders, alopecia, keloids, dermatosis papulosa nigra, and acne keloidalis nuchae. Asians present more frequently with pigmentary disorders, eczema, lichen amyloidosis, and photodamage. Hispanics frequently display pigmentary disorders, erythema chromatium perstans, and increased rates of melanoma. Native Americans may show greater presentations of photodermatoses, collagen vascular diseases, and acanthosis compared with other races. However, large studies on the incidence, prevalence, and morbidity of dermatologic diseases in the various ethnic groups are needed in order to further clarify these relationships.
- Five theories to explain healthcare disparities include: (1) racial-genetic model (2) health-behavior model (3) socioeconomic status model (4) psychosocial stress model and (5) structural-constructivist model.
- Healthcare disparities, found to exist by the federal government, led to the development of the NIH revitalization act of 1993 (inclusion of women and minorities in all biomedical research supported by NIH) and the Healthcare and Quality Act of 1999 (commissioned AHRQ to develop annual healthcare disparities reports from 2003).
- Blacks and Hispanics have the lowest median incomes, greatest rates of poverty, and highest rates of being uninsured, according to the 2008 U.S. Census report.
- There is a lack of quality basic science and clinical dermatologic research in those with skin of color. Increased recruitment of minority groups is needed in randomized controlled trials to ensure equality of access to treatment and extrapolation of research to all groups.
- The National Institutes of Arthritis and Musculoskeletal Diseases and Skin proposed a plan to reduce healthcare disparities in five disease categories: (1) lupus (2) scleroderma (3) osteoarthritis (4) vitiligo and (5) keloids.
- Despite federal efforts to reduce healthcare, clinical research, and health insurance disparities, recruitment of racial and ethnic minorities has proven difficult.
- Some structural differences exist in the epidermis, dermis, and cutaneous appendages of blacks compared to whites, including: (1) more corneocyte layers (2) greater number, denser, and more distributed melanosomes (3) larger, more multinucleated fibroblasts (4) larger mast cell granules (5) increased number and production of apocrine, sebaceous, and apocrine glands and (6) tightly curled, less dense, drier, less anchored hair
- Three general cutaneous reaction patterns in darker skin include: (1) pigment lability (2) mesenchymal response (fibromatous and granulomatous) and (3) follicular response

postinflammatory hyper-/hypopigmentation, vitiligo, melasma, erythema dyschromicum perstans (ashy dermatosis), congenital Mongolian spots, Nevus of Ota, Nevus of Ito, Nevus of Hori, idiopathic guttate hypomelanosis, nevus depigmentosus and pityriasis alba

Mesenchymal Response

The second predominant reaction pattern of darker skin types is the mesenchymal response, which includes both the fibromatous and granulomatous reactions types. The term mesenchyme represents an embryonic precursor to connective tissue. Mesenchymal stem cells (MSC) are capable of differentiating into chondrocytes (cartilage), osteocytes (bone), tenocytes (tendon), adipocytes (fat) and myocytes (muscle). Fibroblasts are also derived from MSCs and are responsible for the production of collagen. Keloids, which represent an abnormal deposition of collagen (fibroplasia) in the dermis in response to trauma, skin tension, infection, endocrine factors and genetic factors, are found with a higher incidence (5-16 times) in black individuals.⁴⁰ This may be secondary to the larger, more nucleated fibroblasts of blacks compared to whites, mentioned above, and/or the interaction of fibroblasts with melanocytes.⁴⁰ Asians and Hispanics also seem to have an intermediate incidence of keloids as compared with blacks and whites.⁴⁰

The second type of mesenchymal response is the granulomatous reaction. Granulomas are aggregates of histiocytes that tend to occur in the dermis or subcutaneous tissue. One such granulomatous disorder that occurs with greatest frequency in blacks is sarcoidosis.⁴¹ This disease entity can have a more severe course and more extensive, variable skin manifestations in blacks.⁴¹

Follicular Response

This last reaction pattern involves a greater predilection, in those of darker skin, for the pilar apparatus. This may be because of structural differences in cutaneous appendages (sebaceous, apocrine, and apocrine glands) or hair cross section, fiber shape, diameter, tensile strength, distribution, moisture, and anchoring. Diseases that present in a follicular pattern include follicular tinea versicolor, follicular eczema, dermatosis papulosa nigra, acne keloidalis nuchae, pseudofolliculitis barbae, pomade acne, papular pityriasis rosea, papular lichen planus, secondary syphilis, perifolliculitis capitis abscedens et suffodiens, and alopecias (traction and central centrifugal cicatricial alopecia).^{42,43}

Dermatoepidemiology and Evidence-based Dermatology Training During Residency

Lauren McLaughlin, OMS-I, B.S., Robert P. Dellavalle, M.D., Ph.D., M.S.P.H., and Cory A. Dunnick, M.D.

Dermatoepidemiology explores dermatologic illness and its management at the population level. The simplest definition for dermatoepidemiology may be the study of “disease occurrence in a population”.¹ In order to determine prevalence of a specific skin disease, there must be defined criteria for the diagnosis of the disease. The affected population can then be studied to determine risk factors, transmission, treatment, and prevention strategies for a given disorder. Notable historic examples of dermatoepidemiology include the characterization of poxvirus, clinical patterns, seasonal appearances, expected target populations, resistance and ultimately public health intervention, and prevention with vaccination, which has led to the eradication of smallpox.² While clinical therapy treats illness to benefit the individual, dermatoepidemiology examines disease risk and whether population or environmental factors can promote preventive and treatment strategies.

Dermatoepidemiology constitutes an important foundation for dermatology training as it encompasses observation and deduction. Dermatoepidemiology includes primary prevention (health promotion and protective measures), secondary prevention (early detection and treatment), and tertiary prevention (limitation of disability).³ Clinical dermatoepidemiology tracks clinical outcomes in individual patients, and generalizes these observations to population subsets.

Understanding the principles of epidemiology is critical to an understanding of evidence-based medicine. Physicians must be able to analyze medical literature to determine the validity and applicability of conclusions relative to their patient population. In order for this to occur, residents must be trained in the language and concepts of epidemiology including the appropriate use of statistical tests and detection of confounding factors and bias. They must also be able to rate the evidence based on the study design.⁴ Most medical students receive some introduction into medical epidemiology during medical school;

however, these concepts need to be reinforced during residency. In fact, studies have shown a low level of epidemiologic knowledge among practicing physicians.⁵

The Dermatology Residency Review Committee requires that dermatology residents demonstrate knowledge of epidemiologic sciences, but there is little published on Dermatoepidemiology Education during Dermatology Residency.⁶ A notable exception is the dermatoepidemiology curriculum at Case Western Reserve University, which implemented a monthly lecture series for dermatology residents.^{7,8} The Case Western Reserve University DermatoEpidemiology curriculum was based on the Epidemiology Curriculum for Dermatologists developed by the International DermatoEpidemiology Association.^{7,9} They evaluated their curriculum and found that residents preferred interactive discussions over lecture format as well as case-based learning from the dermatology literature.

Indeed, other medical disciplines use a journal club format to teach principles of epidemiology and evidenced-based medicine.¹⁰ The Primary Medical Education program (PRIME Curriculum) at the University of California San Francisco has been particularly successful in fostering resident scholarship as part of the Internal Medicine Residency Program at UCSF.¹¹ The PRIME Curriculum consists of a didactic curriculum to reinforce key concepts of evidence-based medicine followed by weekly afternoon small group journal clubs. The PRIME Program's didactic lecture series is similar to curriculums recommended by the International DermatoEpidemiology Association and that used by Case Western Reserve University, (Table 74-1).^{7,9,11}

Dermatoepidemiology resources for dermatology resident education include the following: (1) The International Dermatoepidemiology Association, established in 1996 in order to provide resources for those interested in the epidemiology of skin disease⁹, (2) European

TABLE 74-1—Epidemiology Curriculum Comparison

International Dermatoepidemiology Association	Case Western Reserve University	PRIME Epidemiology Curriculum UCSF
Overview of Dermatoepidemiology	Overview of variables, tests and statistics	Overview of epidemiology study types
Validity	Validity and reliability of screening tests	How epidemiology data are presented
Bias in studies	Bias in studies and mortality	How to design a research question
Evidence-based medicine	Case control studies and measures of risk	Study design and sampling
No evidence of effect	Hypotheses testing, error and p-values	Issues in measurement
Case control studies	Quality of life studies	Causal inference
Quality of life studies	Systematic reviews	Qualitative biostatistics 1
Systematic reviews (Meta-analysis)	Confounding	Qualitative biostatistics 2
Defining disease(s) for a study	Health services research	Computer skills
Confounding	Randomized-controlled trials	Research ethics
Health services research		Systematic review Meta-analysis

Dermato-Epidemiology Network (EDEN), established in 1995 to improve links between European countries and further develop the role of epidemiology, clinical research, and health services research in dermatology,¹² (3) www.ebDerm.org,¹³ and (4) the Cochrane Skin Group, which prepares, maintains and disseminates systematic reviews of clinical interventions in dermatology.^{14,15} These resources help meet the obligation to ensure exposure to dermatoepidemiology—one of the vital subdisciplines of the specialty and their use will lead to increasing the relevance of epidemiology in dermatology.⁴

Electronic Resources For Evidence-Based Dermatology

Farzam Gorouhi, M.D., Ai-Lean Chew, M.B., Ch.B., and Howard I. Maibach, M.D.

This chapter contains summarized lists of useful web sites in the field of evidence-based dermatology. As our readers are familiar with many of these web sites, we avoid explicit explanations.

Available general medical search engines as well as selected evidence-based search engines, and databases are shown in Tables 75-1 and 75-2 respectively.

TABLE 75-1—General Medical Search Engines

Database	Web site	Notes
PubMed	http://www.ncbi.nlm.nih.gov/pubmed/	Comprises over 20 million citations for biomedical literature from MEDLINE, life science journals, and online books.
EMBASE	http://www.embase.com/	Covers 2,000 biomedical titles not currently offered by MEDLINE
Scopus	http://www.scopus.com/home.url	The largest abstract and citation database of research literature and quality web sources covering nearly 18,000 titles

TABLE 75-2—Evidence-based Search Engines, and Databases

Database	Web site	Notes
The MEDION database	http://www.mediondatabase.nl/	References and abstracts of published diagnostic studies and diagnostic systematic reviews
PubMed Clinical Queries	http://www.ncbi.nlm.nih.gov/corehtml/query/static/clinical.shtml	Systematic search engines to find relevant randomized trials, systematic reviews, and genetic studies.
Trip Database	http://www.tripdatabase.com/index.html	The most comprehensive database to search for all available evidence including systematic reviews, guidelines, randomized trials, etextbooks and patient information
Cochrane Central Register of Controlled Trials (CENTRAL)	onlinelibrary.wiley.com/o/cochrane/cochrane_clcentral_articles_fs.html	Contains approximately 640,000 records of published randomized trials (updates frequently)
Cochrane Database of Systematic Reviews (Cochrane Reviews)	onlinelibrary.wiley.com/o/cochrane/cochrane_clsysrev_articles_fs.html	Consists of more than 5,000 Cochrane systematic reviews
Database of Abstracts of Reviews of Effects (DARE)	http://www.crd.york.ac.uk/CMS2Web/SearchPage.asp	Non-Cochrane systematic Reviews (more than 14000) plus Cochrane reviews. Produced by Center for Reviews and Dissemination (CRD)
Health Technology Assessments (HTA) Database	onlinelibrary.wiley.com+cochrane_clhta_articles_fs.html	Completed and ongoing health technology assessments (approximately 10000) from around the world. Produced by centreCenter for Reviews and Dissemination (CRD)
NHS Economic Evaluation Database	http://onlinelibrary.wiley.com/o/cochrane/cochrane_cleed_articles_fs.html	Systematic identification of economic evaluations from around the world and appraising their quality (approximately 30000). Produced by Center for Reviews and Dissemination (CRD)
ACP Journal Club	http://www.acpj.org	Provides summaries of selected original and review articles in the medical literature
Clinical Evidence	http://www.clinicalevidence.org	Provides current evidence-based reviews of the treatments for more than 260 conditions.

Evidence-based organizations are presented in Table 75-3.

TABLE 75-3—Evidence-based Organizations/Main Web Sites

Organization	Web site	Note
Dermatology-Related organizations		
Cochrane Skin Group	http://skin.cochrane.org/	The Cochrane Skin Group is a network of people from all over the world committed to producing and updating reviews of trials relating to skin conditions.
American Dermato-Epidemiology Network	http://www.facebook.com/group.php?gid=156000547744724 http://groups.google.com/group/adenetwork?pli=1	It was established by a group of international dermat-epidemiologists with the aim of furthering research in epidemiology and health services research in dermatology
European Dermato-Epidemiology Network	http://eden.dermis.net/eden/content/e02eden/e01aims/e01programm/index_ger.html	It is a European group aimed at: 1 improving the role of epidemiology in dermatology 2 sharing expertise 3 producing high quality work 4 contacting isolated groups and encouraging them to join in
EBDERM	http://208.106.170.94/	It was made to enhance dermatology resident education in the area of evidence-based medicine, and promote evidence-based practice through education and searching tools.
General Sites		
Center for Health Evidence	http://www.cche.net/	The Center for Health Evidence provides a range of information and communication services to a variety of health organizations and professional associations. It includes American Medical Association's "Users' Guides to the Medical Literature"
National Institute for Clinical Excellence (UK)	www.nice.org.uk	The National Institute for Health and Clinical Excellence (NICE) provides guidance, sets quality standards and manages a national database to improve people's health and prevent and treat ill health
Centre for Evidence-Based Medicine	http://www.cebm.net/index.aspx?o=1001	It was established in Oxford as the first of several UK centers with the aim of promoting evidence-based healthcare.

Table 75-4 summarizes the main databases for guidelines.

TABLE 75-4—Clinical Guidelines

Site	URL	Notes
National Guideline Clearinghouse	http://www.guidelines.gov/index.asp	Evidence-based clinical practice guidelines; sponsored by the Agency for Health Care Policy and Research, American Medical Association, and the American Association of Health Plans
CPG Infobase	http://www.cma.ca	Clinical practice guidelines produced in Canada by a medical or health organization, professional society, government agency, or expert panel
American Academy of Dermatology (AAD)	http://www.aad.org	Guidelines provided by AAD; for Dermatology (AAD) members only
British Association of Dermatology (BAD)	http://www.bad.org.uk	Guidelines by BAD; public access

Grey literature refers to a body of materials that cannot be found easily through conventional channels such as publishers. It is not a dominated resource in medical

literature but it can be valuable for some topics. Table 75-5 enlists two main sources of searching grey literature in biomedical sciences.

TABLE 75-5—Grey Literature

System for Information on Grey Literature in Europe (OpenSIGLE)	http://opensigle.inist.fr/	bibliographical references of reports and other grey literature (GL) produced in Europe until 2005
ProQuest LLC (Dissertation and theses)	http://proquest.umi.com/pqdweb?nocfc=1	700 active university publishing partners, and publish more than 60,000 new graduate works each year

A selection of dermatology online textbooks and web sites is shown in Table 75-6.

TABLE 75-6—Dermatology Online Reference Texts and Educational Material

Site	URL	Notes
EMedicine Textbook	www.emedicine.medscape.com/dermatology	Comprehensive medical online text, including sections on dermatology, emergency medicine, internal medicine, and surgery
The Electronic Textbook of Dermatology	http://www.telemedicine.org/stamford.htm	<i>Textbook of Dermatology</i> , produced by the Internet Dermatological Society
Approach to the Ddermatology Patient	http://www.angelfire.com/md2/liaquatian/Dermatology.pdf	<i>MCCQE 2000 Review Notes and Lecture Series</i>
Botanical Dermatology	http://bodd.cf.ac.uk	Online Reincarnation of Mitchell and Rook's <i>Botanical Dermatology</i>
Dermnet NZ	www.dermnetnz.org	New Zealand Dermatological Society Incorporated. Launched on March 1996
The Language of Dermatology	http://eduserv.hscer.washington.edu/dermUW/lang	Tutorial of terms used in morphologic diagnosis from the University of Washington
Virtual Hospital Site	http://www.vh.org/Providers/Lectures/PietteDermatology/BasicDermatology.html	Basic introduction to dermatology
University of Indiana— Virtual Dermatology	http://erl.pathology.iupui.edu/cases/dermcases/dermcases.cfm	Presents 20 interactive case studies for continuing medical education
Skindex	http://www.skindex.com	Website with dermatology news, articles, reviews, 5 cases for CME, and images from Thomas Fitzpatrick

The main online only dermatology journals and newsletters are mentioned in Table 75-7.

TABLE 75-7— Online Only Dermatology Journals or Newsmagazines

Journal	URL	Notes
Dermatology Online Journal	http://dermatology.cdlib.org	Peer-reviewed electronic-only journal, PubMed cited
Internet Journal of Dermatology	http://www.ispub.com/journal/the_internet_journal_of_dermatology.html	Online only journal, indexed with Google Scholar, Embase, Scopus
Dermatology Times	http://www.dermatologytimes.com	Dermatology news magazine
Cosmetic Surgery Times	http://cosmeticsurgerytimes.com	News magazine for cosmetic dermatologic surgery
Laser News	http://www.lasernews.net	Multimedia e-journal of laser dermatology

There are additional online tables that are only available on the book's web site free of charge. All tables will be updated online periodically.
