Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

Clinical Research Fellow
Department of Dermatology and Cutaneous Surgery
University of Miami
Miller School of Medicine
Miami, Florida, USA

Tsu-Yi Chuang, M.D., M.P.H. [21]

Clinical Professor
Department of Dermatology
University of Southern California
Los Angeles, California, USA;
Staff Physician
Department of Dermatology
Desert Oasis Healthcare
Palm Springs, California, USA

Jennie T. Clarke, M.D. [59]

Assistant Professor of Dermatology
Department of Dermatology
Penn State Hershey Medical Center
Hershey, Pennsylvania, USA

Christa De Cuypere, M.D. [40]

Department of Dermatology
AZ Sint-Jan
Brugge, Belgium

Parastoo Davari, M.D. [16]

Postdoctoral Scholar
Department of Dermatology
University of California, Davis
Sacramento, California, USA

Mark Davis, M.D. [10]

Professor of Dermatology
Mayo Clinic
Rochester, Minnesota, USA

Brittney DeClerck, M.D. [42]

Dermatopathology Fellow
University of Colorado
Denver, Colorado, USA

Robert P. Dellavalle, M.D., Ph. D., M.S.P.H. [4, 46, 74]

Department of Dermatology
University of Colorado School of Medicine
Aurora, Colorado, USA;
Chief, Dermatology Service
Department of Veteran Affairs Medical Center
Denver, Colorado, USA

Yahya Dowlati, M.D., Ph.D. [28]

Consultant Dermatologist and Dermatopathologist
Director, Center for Research and Training in Skin
Diseases and Leprosy
Tehran University of Medical Sciences
Tehran, Iran

Jodi K. Duke, M.P.H., C.P.H. [4]

University of Colorado School of Pharmacy
Aurora, Colorado, USA

Cory A. Dunnick, M.D. [74]

Associate Professor
Department of Dermatology
School of Medicine
University of Colorado Denver
Denver, Colorado, USA

Julia Escandon, M.D. [50]

Research Fellow
Department of Dermatology & Cutaneous Surgery
University of Miami Miller School of Medicine
Miami, Florida, USA

Dina Farshidi, M.D. [13]

Student, David Gerten School of Medicine-UCLA;
Anderson School of Management-UCLA
Los Angeles, California, USA

Nasim Fazel, M.D., D.D.S. [16]

Clinical Associate Professor
Department of Dermatology
University of California, Davis
Sacramento, California, USA

Steven R. Feldman, M.D., Ph.D. [15, 70, 72]

Professor, Department of Dermatology, Pathology,
Public Health Sciences
Wake Forest University Health Sciences
Winston-Salem, North Carolina, USA

Hermann Feldmeier, M.D. [7, 30]

Professor of Tropical Medicine
Institute of Microbiology and Hygiene
Charité University Medicine Berlin
Buchholz, Germany

Nicole Fett, M.D [33]

Assistant Professor
Department of Dermatology
University of Pennsylvania;
Staff Dermatologist
Department of Medicine
Philadelphia VA Medical Center
Philadelphia, Pennsylvania, USA

David Fiorentino, M.D., Ph.D. [35]

Assistant Professor
Departments of Dermatology and Medicine
(Rheumatology)
Stanford University School of Medicine
Stanford, California, USA

Alireza Firooz, M.D. [20, 28]

Associate Professor of Dermatology
Center for Research and Training in Skin Diseases
and Leprosy
Tehran University of Medical Sciences
Tehran, Iran

Rene Gonzalez, M.D. [46]

Professor of Medicine
University of Colorado Denver
Denver, Colorado, USA

Farzam Gorouhi, M.D. [1, 11, 16, 20, 75]

Postdoctoral Scholar
Department of Dermatology
University of California, Davis
Sacramento, California, USA

Alice B. Gottlieb, M.D., Ph.D. [62]

Chair and Dermatologist in Chief
Harvey B Ansell Professor of Dermatology
Tufts Medical Center and Tufts University School
of Medicine
Boston, Massachusetts, USA

Marta Grazzini, M.D. [63, 65]

Department of Dermatology
University of Florence
Firenze, Italy

Aditya K. Gupta, M.D., Ph.D., F.A.A.D., F.R.C.P.(C) [31]

Division of Dermatology
 Department of Medicine
 University of Toronto
 Toronto, Ontario, Canada;
 Mediprobe Research Inc.
 London, Ontario, Canada

Rebat M. Halder, M.D. [73]

Professor and Chairman
 Department of Dermatology
 College of Medicine
 Howard University
 Washington DC, USA

Anne Han, M.D. [49]

Wound Fellow
 Department of Dermatology
 Johns Hopkins Medical Institutions
 Baltimore, Maryland, USA

Christopher B. Hansen, M.D. [6]

Assistant Professor
 Department of Dermatology
 University of Utah School of Medicine
 Salt Lake City, Utah, USA

Cameron Harrison, M.D [47]

Department of Dermatology
 Stanford University
 Redwood City, California, USA

Masoumeh Hassani, M.D. [20]

Research Fellow
 Center for Research and Training in Skin Diseases
 and Leprosy
 Tehran University of Medical Sciences
 Tehran, Iran

Tom Hodgkinson, M.Sc. B.Sc. (Hons) [66]

Post Graduate Student
 Bayat Laboratory
 Plastic & Reconstructive Surgery Research
 Manchester Interdisciplinary Biocentre
 University of Manchester
 Manchester, England, UK

Maria Hordinsky, M.D. [19]

Professor and Chair
 Department of Dermatology
 University of Minnesota
 Minneapolis, Minnesota, USA

Ahmad Reza Hossani-Madani, M.D., M.S. [36, 73]

Clinical Research Fellow
 Department of Dermatology
 College of Medicine
 Howard University
 Washington DC, USA

William W. Huang, M.D., M.P.H. [41]

Chief Resident
 Department of Dermatology
 Rush University Medical Center
 Chicago, Illinois, USA

Sara Hylwa, B.S. [10]

Visiting Medical Student for Research
 Mayo Clinic
 Rochester, Minnesota, USA
 Medical Student
 University at Buffalo
 Buffalo, New York, USA

Ala Iaconi, M.S. [70]

Doctoral Fellow
 Department of Clinical
 Social and Administrative Sciences;
 College of Pharmacy
 University of Michigan
 Ann Arbor, Michigan, USA

Yuri T. Jadotte, M.D. [14]

Department of Dermatology
 New Jersey Medical School
 Newark, New Jersey, USA

Evan C. Jones M.D.-M.P.H. [71]

Associate Professor and Chair
 Department of Dermatology
 Stony Brook University Hospital
 East Setauket, New York, USA

Swetha Kandula, M.D., F.A.C.P. [8]

Dermatology Resident
 Indiana University School of Medicine
 Department of Dermatology
 Indianapolis, Indiana, USA

Ravneet Kaur, M.D. [13]

Resident
 UCLA-Olive View Medical Center
 Sylmar, California, USA

Ali Khamesipour, Ph.D. [28]

Microbiology/Immunology
 Associate Professor
 Center for Research and Training in Skin Diseases
 and Leprosy (CRTSDL)
 Tehran University of Medical Sciences (TUMS)
 Tehran, Iran

David A. Khan, M.D. [12]

Professor, Department of Medicine
Division of Allergy & Immunology
University of Texas Southwestern Medical Center
Dallas, Texas, USA

Alireza Khatami, M.D., M.S.P.H. [1, 28]

Assistant Professor of Dermatology
Center for Research and Training in Skin Diseases
and Leprosy
Tehran University of Medical Sciences
Tehran, Iran

Gene Kim, M.D [18]

Assistant Professor of Dermatology and Pathology
University of Southern California
Los Angeles, California, USA

Youn H. Kim, M.D. [47]

Professor of Dermatology
Stanford Cancer Center;
Director, Multidisciplinary Cutaneous Lymphoma
Program
Stanford, California, USA

Alexandra B. Kimball, M.D., M.P.H. [69]

Associate Professor of Dermatology
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts, USA

Seema Kini, M.D., M.S [58]

Department of Dermatology
Emory University
Atlanta, Georgia, USA

Robert S. Kirsner, M.D., Ph.D. [50]

Vice Chairman & Stiefel Laboratories Professor
Department of Dermatology & Cutaneous Surgery
University of Miami Miller School of Medicine
Miami, Florida, USA

Sailesh Konda, M.D [39]

Resident, Department of Medicine
Boston University Medical Center
Boston, Massachusetts, USA

Carrie Kovarik, M.D. [48]

Assistant Professor
Dermatology, Dermatopathology, and Infectious
Diseases
University of Pennsylvania
Philadelphia, Pennsylvania, USA

Michael Krathen, M.D. [62]

Dermatology Resident
Tufts University School of Medicine
Boston, Massachusetts, USA

Joseph C. Kvedar, M.D. [2]

Associate Professor of Dermatology
Harvard Medical School;
Director, Center for Connected Health
Partners HealthCare Systems, Inc.
Boston, Massachusetts, USA

Athanassios Kyrgidis, M.D., D.D.S., M.Sc. [54]

Research Fellow
Clinic of Oral Maxillofacial Surgery;
Faculty of Dentistry;
1st Clinic of Otorhinolaryngology-Head and
Neck Surgery;
Faculty of Medicine
Aristotle University of Thessaloniki
Thessaloniki, Greece

Gerald S. Lazarus, M.D. [49]

Professor of Dermatology;
Chair Dermatology
Johns Hopkins
Bayview Medical Center;
Director Johns Hopkins Wound Center
Johns Hopkins Medical Institutions
Baltimore, Maryland, USA

Delphine J. Lee, M.D., Ph.D. [67]

Director
Department of Translational Immunology
John Wayne Cancer Institute
Santa Monica, California, USA

Tracy Leong, M.D. [24]

PGY-2, Department of Dermatology
Loma Linda University Medical Center
Loma Linda, California, USA

Michelle M. Levender, M.D. [72]

Clinical Research Fellow
Center for Dermatology Research
Department of Dermatology
Wake Forest University School of Medicine
Winston-Salem, North Carolina, USA

Anna Levin, M.D. [19]

Department of Dermatology
Mayo Clinic Arizona
Scottsdale, Arizona, USA

Xinaida T. Lima, M.D. [69]

Department of Dermatology
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts, USA

Torello Lotti, M.D. [63, 65]

Professor
Department of Dermatology
University of Florence
Firenze, Italy

Jacqueline De Luca, M.D. [15]

Transitional Year Resident
University of Hawaii
Honolulu, Hawaii, USA

Boris D. Lushniak, M.D., M.P.H. [56]

Assistant Commissioner FDA;
Assistant Surgeon General USPHS;
Adjunct Professor Dermatology USUHS
Bethesda, Maryland, USA

Howard I. Maibach, M.D. [3, 11, 68, 75]

Professor, Department of Dermatology
UCSF Medical Center
San Francisco, California, USA

Kavita Mariwalla, M.D. [71]

Assistant Professor
Department of Dermatology
Dermatologic Surgery
State University of New York
Stony Brook University Hospital
East Setauket, New York, USA

Nicole Mau, M.D. [42]

Department of Dermatology
Medical College of Wisconsin
Wauwatosa, Wisconsin, USA

Shawna McCarty, M.D. [24]

PGY3 Resident
Department of Dermatology
Loma Linda University Medical Center
Loma Linda, California, USA

Lauren McLaughlin, OMS-I, B.S. [74]

Student
Rocky Vista University College of Osteopathic
Medicine
Parker, Colorado, USA

Michael Patrick McLeod, B.S., M.S. [44]

University of Miami Miller School of Medicine
Miami, Florida, USA

Terri Lynn Meinking, M.D., Ph.D. [29]

President
Global Health Associates of Miami (GHAM)
Miami, Florida, USA

Natalia Mendoza, M.D. [23]

Center for Clinical Studies
Houston, Texas, USA

Andrew Messenger, M.B.B.S., M.D., F.R.C.P. [55]

Consultant Dermatologist
Department of Dermatology
Royal Hallamshire Hospital
Sheffield, UK

Michael Messina, M.D., [24]

PGY3 Resident
Department of Dermatology
Loma Linda University Medical Center
Loma Linda, California, USA

Danielle M. Miller, Ph.D., M.D. [32]

Instructor, Harvard Medical School
Department of Dermatology
Lahey Clinic Medical Center
Burlington, Massachusetts, USA

Associate Professor
Department of Dermatology and Cutaneous
Surgery
School of Medicine
University of South Florida
Tampa, Florida, USA

Jeffrey R. Smith, M.P.H [24]

Senior Medical Student
Texas Tech University School of Medicine
Lubbock, Texas, USA

Ally-Khan Somani, M.D., Ph.D., F.A.A.D. [8]

Assistant Professor, Department of Dermatology
Director, Dermatologic Survey and Cutaneous
Oncology Division
Indiana University School of Medicine
Indianapolis, Indiana, USA

Najwa Somani, M.D., F.R.C.P.C. [8, 37]

Assistant Professor
Departments of Dermatology and Anatomic
Pathology
Indiana University
Indianapolis, Indiana, USA

Richard D. Sontheimer, M.D., Ph.D. [6]

Professor, Department of Dermatology
University of Utah School of Medicine
Salt Lake City, Utah, USA

Phyllis Spuls, M.D., Ph.D. [9]

Dermatologist
Department of Dermatology
Academic Medical Centre
University of Amsterdam
Amsterdam, The Netherlands

Berndt Stenberg, M.D., Ph.D. [53]

Associate Professor
Department of Public Health and Clinical Medicine
Dermatology and Venereology
Umea University
Umea, Sweden

Andrea L. Suárez, M.D., Ph.D [46]

New York Presbyterian Hospital/Weill
Cornell Medical College of Dermatology
New York, New York, USA

Hong-Liang Tey, M.D. [26]

Associate Consultant
National Skin Center
Clinical Tutor
National University of Singapore
Singapore

Patricia Ting, M.Sc., M.D. [69]

Division of Dermatology & Cutaneous Sciences
University of Alberta
Edmonton, Alberta, Canada

Diane Turvy, M.D., M.S. [8]

Indiana University School of Medicine
Indianapolis, Indiana, USA

Stephen Tyring, M.D., Ph.D. [57, 23]

Clinical Professor of Dermatology
Microbiology & Molecular Genetics and Internal
Medicine

University of Texas Health Science Center
Webster, Texas, USA

David Vidal, M.D., Ph.D. [60]

Department of Dermatology
Hospital de Sant Joan Despí Moisès Broggi
Barcelona, Spain

Ruth Ann Vleugels, M.D [34]

Director, Connective Tissue Disease Clinic
Department of Dermatology
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts, USA

Victoria P. Werth, M.D. [17, 33]

Chief of Dermatology
Philadelphia V.A. Medical Center;
Professor of Dermatology
Department of Dermatology
University of Pennsylvania
Philadelphia, Pennsylvania, USA

Gregory J. Wing, B.S. [4, 46]

Department of Dermatology
University of Colorado School of Medicine;
Denver Veteran Affairs Medical Center
Denver, Colorado, USA

Uwe Wollina, M.D. [40]

Professor and Head
Department of Dermatology and Allergology/Academic
Teaching Hospital Dresden-Friedrichstadt
Dresden, Germany

David T. Woodley, M.D. [18]

Professor and Chair
Department of Dermatology
The Keck School of Medicine
University of Southern California
Los Angeles, California, USA

Chung-Hsuen Wu, Ph.D. [70]

Humana/CHA/The University of North Carolina
Pharmaceutical Outcomes Post-Doctoral Fellow
Division of Pharmaceutical Outcomes & Policy
Eshelman School of Pharmacy
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina, USA

Jashin J. Wu, M.D. [13]

Director of Clinical Research
Associate Residency Program Director
Department of Dermatology
Kaiser Permanente Los Angeles Medical Center
Los Angeles, California, USA

Brad Yentzer, M.D. [70]

Department of Dermatology
Wake Forest University School of Medicine
Winston-Salem, North Carolina, USA

Hamed Zartab, M.D., M.Sc. [28]

Post-Doctoral Fellow
Center for Research and Training in Skin Diseases and
Leprosy (CRTSDL)
Tehran University of Medical Sciences (TUMS)
Tehran, Iran

Preface

This book is for practitioners at any stage of their career who have clinical, teaching, or research interests in the management of cutaneous diseases. It is critical to attempt to manage patients based on evidence based principles; however, it is even more important to remember that relying on the best evidence is not the only factor in delivering the best care for each patient. Patients' beliefs and preferences should also be considered. This is why the individual patient is the central focus of evidence based decision making. Physicians are not only dealing with facts and odds (e.g. handling a computerized stock market trading system) but also a human being with feelings, intelligence, judgment, fears, preferences, and values. Having said that, we believe this book will be more useful for patients if the physician applies the recommendations in the light of the patient's conditions and healthcare provider's competencies. Additionally, the hierarchy of evidence is always important. This basically means that even though systematic reviews and randomized controlled trials are the best available resources, it is not enough to limit your analyses to the best evidence. In a recent study, Golder et al. performed a comprehensive meta-analysis to assess the level of agreement or disagreement in the estimates of harm derived from meta-analysis of RCTs as compared to meta-analysis of observational studies. They noted that observational research can be as credible as randomized trials when investigating side effects of a drug. It is also essential to utilize the major models to report different types of studies such as CONSORT for randomized controlled trials, PRISMA (formerly QUOROM) for systematic reviews and meta-analyses, STROBE for observational studies and STARD for diagnostic studies. These guidelines were not created to impose rigid structural disciplines. They only require the authors to include all of the items from a checklist properly and explicitly anywhere in the manuscript. We suggest that our readers use these tools to interpret any published report or to design and report their own projects. "Evidence based medicine" is a growing phenomenon; however, it has not been fully integrated into medical education in the field of dermatology. We encourage all dermatology faculty members specifically dermatо-epidemiology experts to

develop a well defined explicit strategy to integrate EBM better into their residency/clerkship training programs.

In this second edition, we have reduced the content of the chapters on "principles of evidence based medicine", as we assume many of those principles have been engraved in the minds of our readers. Additionally, we avoid using detailed epidemiological language unless it is necessary to convey a specific concept. Thus, you will find a small number of introductory chapters in parts of this book. We have introduced new sections including a section entitled "Diagnosis of a cutaneous disease," where diagnostic evidence in dermatology is briefly reviewed. Studies on risk factor analysis for cutaneous diseases are also reviewed in a new section. Furthermore, specific modalities were examined in order to obtain more detailed evidence based details on efficacy and safety. At last but not least, cost effectiveness studies are another new focus in this book. We do not attempt to review all dermatological diseases in this book but rather bring up new horizons in evidence based dermatology. Our mission is to introduce and encourage the use of different evidence-based strategies among our readers in their daily practice and, if applicable, in their teaching/education. Please remember that evidence based learning is a lifelong process not a two day workshop.

We are honored to be a part of a legendary team of 140 outstanding contributors from the States and 14 other countries.

We would also like to thank Mr. Martin Wonsiewicz, President of PMPH-USA, Mr. Jason Malley, Executive Editor, Ms. Shirley Blum, Executive Assistant – Editorial, and Ms. Surinder Sharma, Production Manager, for their extraordinary and visionary insight, full support and hard work.

The editors strongly encourage the readers to comment on the contents of the book and inform them of any corrections. They will be acknowledged in the next edition. We also welcome any general recommendations to help improve the next edition.

Diagnosis

Studies and Systematic Reviews on Diagnostic Test Accuracy

Alireza Khatami, M.D., M.S.P.H., and Farzam Gorouhi, M.D.

*"A smart mother makes often a better diagnosis than a poor doctor"**

August Karl Gustav Bier (1861–1949)¹

INTRODUCTION

Diagnostic tests are a group of interventions that are used for differentiation between individuals who do or do not have a particular condition, such as a disease. The optimal goal of a diagnostic test is to identify those who will benefit from certain therapeutic or preventive interventions and to determine the prognosis of the condition.^{2,3} Figure 1-1 shows the correlation between test threshold, intervention threshold, and the proper situation for using a diagnostic test.

David Sackett, the father of modern evidence-based medicine (EBM), defined this as "the conscientious, explicit, and judicious use of current best evidence in making clinical decisions regarding the care of individual patients."⁴ This definition implies that EBM should answer all clinical questions about the diagnosis, prevention, treatment, and prognosis of a disease. Unfortunately, in the earlier years of the development of EBM, it mostly focused on therapeutic interventions. Dr. Gordon Guyatt and his colleagues at McMaster University started to establish a more explicit methodology for EBM around two decades ago.⁵ This trend has since been extensive and ever changing. However, many physicians and academicians still have limited competency

BOX 1-1—Abbreviations that are Commonly Used in this Chapter

DOR:	Diagnostic odds ratio
EBM:	Evidence-based medicine
+LR:	Positive likelihood ratio
-LR:	Negative likelihood ratio
NPV:	Negative predictive value
PPV:	Positive predictive value
QUADAS:	Quality Assessment of Diagnostic Accuracy Studies
ROC curve:	Radio operating characteristics curve
SROC curve:	Summary radio operating characteristics curve
STARD:	Standards for Reporting Diagnostic Accuracy

to integrate EBM as a tool in their routine clinical practice, as well as in the area of therapeutic interventions, and dermatologists are no exception.

Because of the wide spectrum of relevant entities in dermatology, a vast spectrum of diagnostic tests are used in this field. For example, several methods can be used in the diagnosis of cutaneous leishmaniasis. These include direct smears, culturing on certain media, histopathologic examination, isoenzyme assay, and the polymerase chain reaction (PCR).^{6–9} Further, different diagnostic methods are used

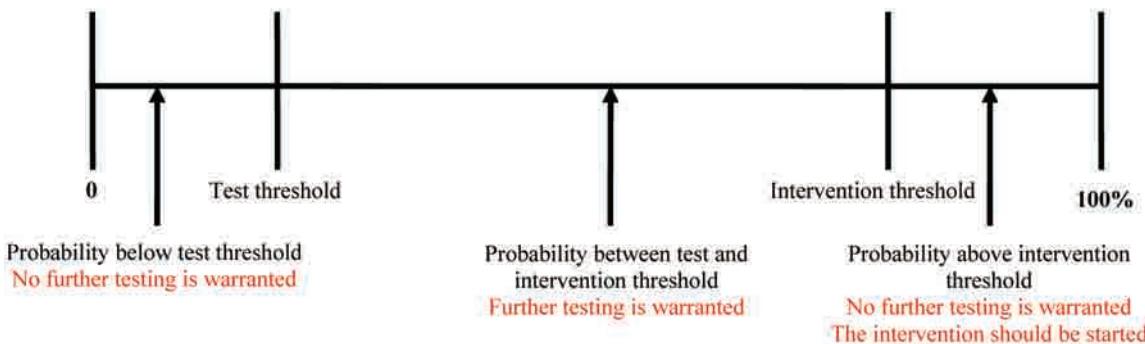

FIGURE 1-1 Proper place for requesting a diagnostic test on the continuum probability of diagnosis for making decision for administration of a certain intervention.

¹ Some quotations always remain memorable just like this quotation by Dr. August Bier (German surgeon, 1861-1949).*

for accurate diagnosis of pigmented skin lesions. Besides routine histopathologic examination, other groups of diagnostic tests, such as immunohistochemistry, dermoscopy, and confocal microscopy, may be used.^{10–12}

Unfortunately, the problem is sometimes more profound. For some cutaneous diseases, such as pemphigus vulgaris, there is no definitive “gold standard” test, and this makes it even more difficult for dermatologists to reach an accurate diagnosis and adopt the optimal approach for a patient. There is no universally accepted single test for pemphigus vulgaris based on worldwide expert opinion surveys.^{13,14} Diagnostic options for pemphigus vulgaris are histopathologic examination of a biopsy specimen, direct and indirect immunofluorescence, a Tzanck smear, and use of the Nikolsky sign. None of these methods, alone or in combination, can provide a completely accurate diagnostic tool for this condition. This part of the problem cannot be immediately solved by EBM; therefore, it is necessary to acknowledge that the problem always exists and that it should be considered.

This brings up a philosophical question: Why do physicians diagnose an abnormal condition? Is this only for determining treatments? The short answer is “no,” because a diagnosis can also enlighten the patient in terms of the details of the disease and its risk factors and prognosis.¹⁵

Let us imagine that a physician is not 100% sure that a patient has any of the following dermatoses: atopic dermatitis, allergic contact dermatitis, irritant contact dermatitis, and drug-induced bullous disorder.

Sometimes an exact diagnosis is not essential to guide therapy because the mainstream treatment of choice (corticosteroids) would be similar for all these diseases. Nonetheless, it is still important to obtain an exact diagnosis. For example, most bullous drug eruptions are resolved once the causal drug is removed. In atopic dermatitis and allergic and irritant contact dermatitis, prevention of acute flares and the subsequent development of chronic lesions are indicators for successful treatment. Therefore, if the possible cause can be narrowed down to a specific contact allergen, the disease can be controlled more efficiently.

The need for accurate tests to aid proper decision making is critical at two important levels: clinical practice and health policymaking. In addition, novel diagnostic technologies support the growing need for a diagnostic evidence-based approach.^{2,16} There is a similar current trend in dermatology.

In this chapter, we briefly review important issues related to the quality of design and reporting in diagnostic studies. These studies can provide raw data for systematic reviews and may provide the highest level of available evidence in the absence of systematic reviews.

STUDIES ON DIAGNOSTIC TEST ACCURACY

It is obvious that diversity is seen among diagnostic tests and related studies. However, the accuracy of a diagnostic

test is the main concern for physicians. We have therefore chosen the diagnostic accuracy of a test as the starting point for further discussions on basic issues in a diagnostic study, as well as those concerning diagnostic systematic reviews. Some recapping information on the main outcomes of this type of study is provided below.

MAJOR OUTCOME MEASURES AND BASIC DEFINITIONS IN DIAGNOSTIC ACCURACY STUDIES

Let us consider that the results of the gold standard and index tests are dichotomous. This is actually an oversimplification for most of these diseases, because both the disease-positive and disease-negative populations may represent a spectrum of responses to testing. For example, different subtypes of cutaneous melanoma have different levels of aggression. Additionally, some melanoma tumors are localized (stages I and II), some are metastasized to sentinel lymph nodes (stage III), and some have distant metastases (stage IV). Conversely, the disease-negative population may consist of patients with any other type of skin cancer or dermatologic condition, or disease-free subjects. Therefore, a dichotomy of this type is not a perfect paradigm, although it is the most acceptable default. A 2-by-2 table is used to define the main outcomes in a diagnostic accuracy test (Table 1-1).

Based on the data in Table 1-1, the definitions of major outcomes are:

- Sensitivity = The proportion of participants with the condition of interest who have a positive test result ($a/a + c$)
- Specificity = The proportion of participants without the condition of interest who have a negative test result ($d/b + d$)

The following mnemonics may be helpful to remember the roles of highly sensitive and highly specific tests in a clinical setting:¹⁷

- a. SnNOUT, which means a negative result of a test, which is highly sensitive for presence of a condition, rules out that condition.

		TABLE 1-1—A 2 by 2 Table	
		Condition of interest	Total
Test result [†]	+	-	
	a	b	$a + b$
-	c	d	$c + d$
Total	$a + c$	$b + d$	$a + b + c + d$

* Presence of condition of interest (+) is based on the result of the gold standard test. [†] Test result reflects result of the index test. a = true positives (TP), b = false positives (FP), c = false negative (FN), d = true negatives (TN), $N = a+b+c+d$.

- b. SpPIN, which means a positive result of a test, which is highly specific for a condition, rules in that condition.
- False positive rate = The proportion of participants without the condition of interest who have a positive test result ($b/b + d$)
 - False negative rate = The proportion of participants with the condition of interest who have a negative test result ($c/a + c$)
 - Positive predictive values (PPV) = The proportion of participants with a positive test result who have the condition of interest ($a/a + b$)
 - Negative predictive value (NPV) = The proportion of participants with a negative test result who do not have the condition of interest ($d/c + d$)
 - Test accuracy = $(TP + TN)/N$ = The proportion of those tested in which the index test gives the correct answer $(a + d)/(a + b + c + d)$
 - Positive likelihood ratio (+LR) = sensitivity/(1-specificity)
 - Negative likelihood ratio (-LR) = (1-sensitivity)/specificity

A test can diagnose the condition of interest accurately if it has a +LR greater than 10. Positive LR values more than 2 and more than 5 are considered as clinically useful and clinically very useful, respectively. A test can rule out a condition correctly, if it has a -LR less than 0.1.¹⁷

- Pre-test probability = The prevalence of the condition of interest
- Post-test probability = The probability of the condition of interest after using a likelihood ratio (LR) nomogram, which works as a graphical calculator based on Bayes' theorem (Figure 1-2).^{1,2}
- Odds (pre-test and post-test odds) = Odds are defined as the probability of a certain event occurring (P) divided by the probability of that event not occurring (1-P). Therefore, it is possible to convert pretest probability to pretest odd and posttest odd to post probability. The great advantage of using odds is the possibility of direct calculation of posttest odds and therefore posttest probabilities using LRs.¹
- Diagnostic odds ratio (DOR) = $+LR/-LR$

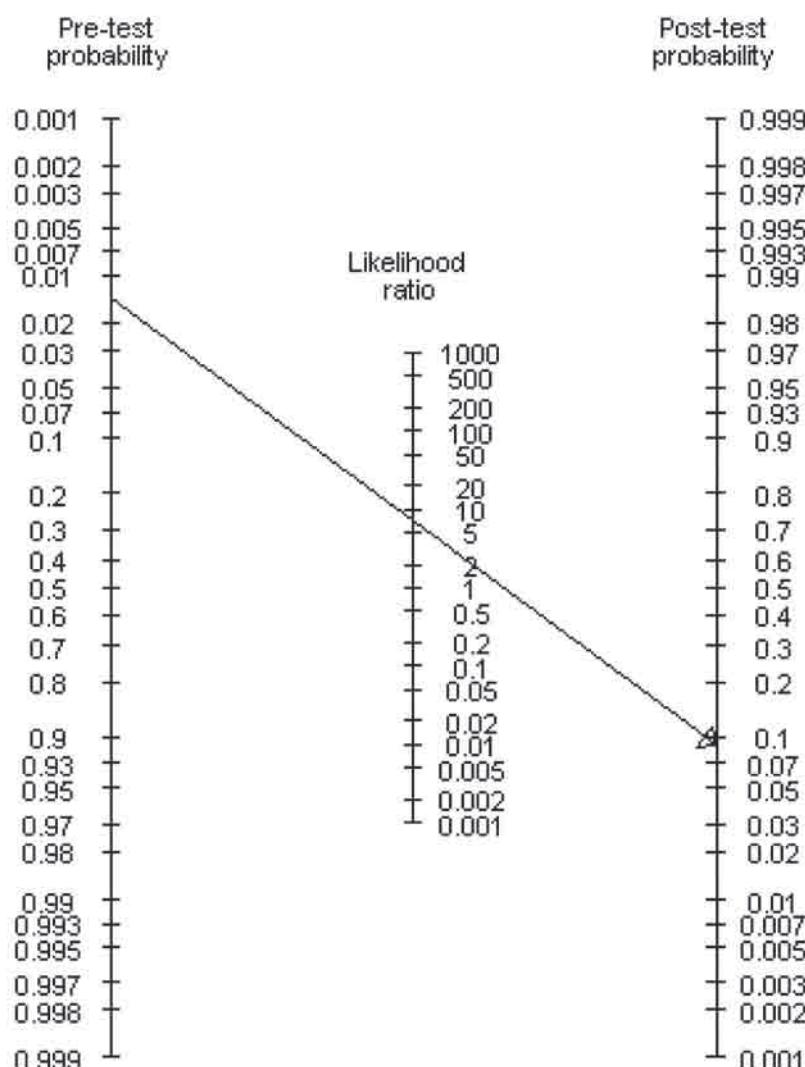

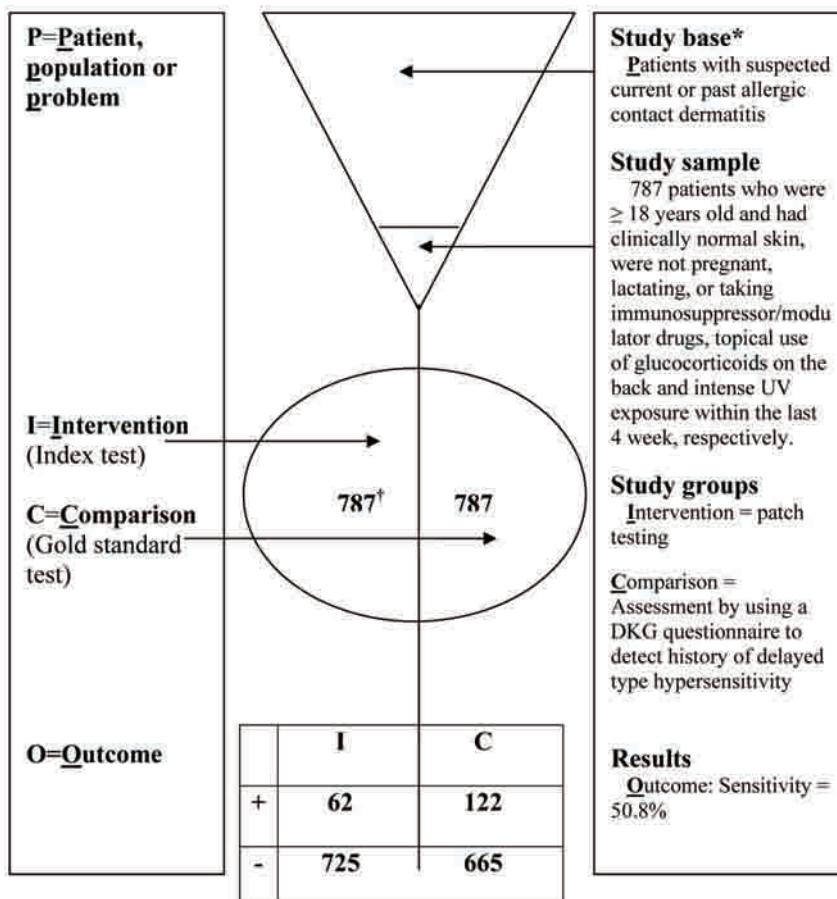

FIGURE 1-2 A Fagan plot or Bayes nomogram for calculating post-test probability when pretest probability and the likelihood ratio of a diagnostic test are known. To use this plot, a straight line should be drawn from the pre-test probability of a condition to the likelihood ratio of the test. This line should be continued until it intersects the post-test probability. This point shows the post-test probability.

It can be read as either the ratio of odds of positivity in disease relative to odds of positivity in non-diseased or the ratio of the odds of disease in test positives relative to odds of disease in test negatives.¹⁸

- Receiver Operating Characteristics (ROC) curve = This measure is suitable when a diagnostic test has different cut points for presence of a certain condition (e.g., disease). This curve is produced by scatter plotting of sensitivity against 1-specificity of different cut points of a diagnostic test. In ROC curve method, the area under the curve (AUC) is used to measure the performance of the test. Similar to LRs, ROC curve combines sensitivity and specificity to measure the test accuracy.

The most commonly utilized indices to assess the performance of a diagnostic test are “sensitivity” and “specificity.” If they were both more than 80%, because of the rule of thumb, the test could be considered as a good one. However, it is obvious that the performance of a test highly depends on the aim of its use. Other outcomes such as PPV and NPV as well as likelihood ratio and consequently diagnostic odds ratio can be used for assessment of the accuracy of the test. PPV and NPV, in contrast to sensitivity and specificity, depend on the prevalence (pretest probability) of the condition of interest in the population. If a ROC curve is to be used, a test with an AUC more than 80% is usually considered as a “good” test.¹⁷

EVIDENCE-BASED APPROACH TO DIAGNOSTIC STUDIES

Principles of evidence-based approach to diagnostic studies are not different from evidence-based approach to other types of studies. They are:

1. Framing a well-built answerable clinical question
2. Searching for the current best evidence systematically
3. Appraising the found evidence critically
4. Applying the evidence to the patient
5. Evaluation of the previous steps

The following sections mainly focus on the first three steps of EBM and the chapter is continued with a discussion about systematic reviews on diagnostic test accuracy.

A Well-Built Clinical Question

Evidence-based approach to diagnostic studies always starts with a well-built clinical question. EBM pioneers suggested the use of PICO acronym, which represents Population/Intervention, Comparison, and Outcome. It is appropriate for formulating questions concerning diagnostic studies.^{19,20} Figure 1-3 shows PICO components for a question about a diagnostic test using graphic appraisal tool for epidemiologic studies (GATE). It visualizes the

FIGURE 1-3 Graphic presentation of PICO components in a clinical question concerning a diagnostic test using a GATE frame. One advantage of using a GATE frame is that it facilitates framing the steps of EBM through using a picture. UV, ultraviolet; DKG, German Contact Dermatitis Research Group. *The exemplary study is based on the data from parts of a study by Dickel et al.²² † The total number of participants in this study was 787. ALL participants have tested by both intervention (index) and comparison (gold or reference standard) tests.

critical appraisal.²¹ The first step in a diagnostic systematic review is also asking a well-built clinical question. More details will be provided on characteristics of each PICO component at the critical appraisal section.

Hierarchy of Evidence in Diagnostic Studies

Herein, the hierarchy of evidence for diagnostic studies from different dimensions will be discussed. It has been well established that the highest level of evidence in therapeutic studies is systematic review of homogeneous randomized controlled trials (RCTs) followed by high-quality individual RCT. The hierarchy of evidence for diagnostic studies is not that much straightforward.^{5,19} Part of this complexity is related to what is considered as “*hierarchical model of efficacy*” of diagnostic studies (Table 1-2).¹⁹ For the sake of simplicity, we will only discuss the hierarchy of evidence concerning studies on diagnostic test accuracy in this chapter.

It has been generally agreed that the best study design for diagnostic accuracy assessment of a test is cross-sectional. Such a study is conducted on a random or consecutive sample of patients (or suspicious patients). ALL participants would undergo a blind comparison using both index and gold standard tests.^{19,21} Index test is the test, which is under study. The gold standard, which is also known as gold standard, is the most accurate available test for determining the presence or absence of the condition of interest.²³ There are three main reasons for assessing the accuracy of an index test: (1) replacement: which means that a new test is to be replaced an existing test, (2) triage: which means that the new test is planned to assist to make decision on whether the existing test is indicated or not, and (3) add-on: which means that the new test would be performed to provide more information on the tested individual after the existing test was performed.²⁴ In Tables 1-3 and 1-4, we provide two hierarchies of evidence for diagnostic test studies. The former (Table 1-3) is not limited to the studies on diagnostic test accuracy, but the latter (Table 1-4) is.^{22,25}

TABLE 1-2—Hierarchy Model of Efficacy in Diagnostic Test Studies¹⁹

Level	Assessed efficacy	Example(s)
1	Technical	Quality of image produced by a digital dermoscopic system
2	Diagnostic accuracy	Sensitivity and specificity
3	Diagnostic thinking	+LR and -LR
4	Therapeutic	Decisions concerning changes in the treatment of patients according to the test result
5	Patient outcome	Quality of life
6	Societal efficacy	Cost-effectiveness

TABLE 1-3—Hierarchy (Strength) of Evidence in Diagnostic Tests Studies

Level of evidence	Study type
1a	Systematic review with homogeneity of level 1b studies
1b	Validating cohort study with good reference standard
1c	Absolute SPins* and SNouts†
2a	Systematic review with homogeneity of level 2b studies
2b	Exploratory cohort study
2c	Outcome researches
3a	Systematic review with homogeneity of level 3b studies
3b	Nonconsecutive studies or without consistently applied reference standard
4	Case series or poor or nonindependent reference standard
5	Expert opinion without critical appraisal

*Specificity rules positives in, †Sensitivity rules negatives out.
(Adapted from the Oxford Center for Evidence-Based Medicine website.²⁵)

Searching for Diagnostic Studies

The second step in EBM, is performing a well-defined “search.” Two elements are crucial to perform a productive search: (a) resources: which is related to “where” someone has to look for the best evidence, and (b) search strategy: which determines how someone has to look for the evidence.

TABLE 1-4—Hierarchy (Strength) of Evidence in Diagnostic Test Accuracy Studies with Regard to Bias-Freeness

Level	Study type
I	A systematic review of level II studies
II	A study of test accuracy with: an independent, blinded comparison with a valid reference standard, among consecutive persons with a defined clinical presentation
III-1	A study of test accuracy with: an independent, blinded comparison with a valid reference standard, among non-consecutive persons with a defined clinical presentation
III-2	A comparison with reference standard that does not meet the criteria required for Level II and Level III-1 evidence
III-3	Diagnostic case control studies
IV	Study of diagnostic yield (no reference standard)

*Specificity rules positives in, †Sensitivity rules negatives out.
(Adapted from Merlin et al.²³)

Resources

It is difficult to provide a flawless summary of information sources because of their diversity. However, we recommend starting with some of the popular and easy to search electronic databases in medical sciences such as PubMed, MEDLINE, EMBASE, ISI Web of Knowledge and MD Consult.²⁶ Furthermore, SCOPUS can be used as one of the most comprehensive databases. There are some databases like Meta-analyses van Diagnostisch Onderzoek (MEDION), which specifically indexes diagnostic studies.²⁷ If the aim of the search is to look for secondary evidence such as systematic reviews following databases will be useful: Cochrane Library including the Database of Abstracts of Reviews of Effects (DARE) and Cochrane Central Register of Controlled Clinical Trials (CENTRAL), Turning Research Into Practice (TRIP) database, and databases available from Center for Review and Dissemination (CRD) at University of York, UK including Health Technology Assessment (HTA) database.²⁸⁻³⁰ Certain utilities such as Clinical Queries in PubMed are also helpful to locate systematic reviews.³¹

Another important resource is the so-called “grey literature” which encompasses resources that are not usually found through searching books, articles, and aforementioned databases. These include dissertations, research reports from governmental or non-governmental organizations, institutes and companies, and most conference abstracts and proceedings. There were two databases known as the European Association for Grey Literature Exploitation (EAGLE) and System for Information on Grey Literature (SIGLE), which are widely used for searching grey literature. Currently, OpenSIGLE which has been launched by Institute for Scientific and Technical Information–National Centre for Scientific Research covers all former records of SIGLE as well as the data added by

EAGLE members.³² A well-built list of main electronic databases with their URL addresses is provided by Kelly.²⁶

Search Strategy

The search strategy is dictated by the well-built explicit clinical question, which reflects the aim of the study. Some publications defined sensitive and specific search strategies for locating diagnostic studies.^{33,34} Table 1-5 shows the differences between the most sensitive, the most specific, and the most accurate search strategies in MEDLINE to find diagnostic studies in family medicine journals. Validity of each search strategy is based on its DOR.²⁵ It is important to remember that sensitivity and specificity of search strategies are different in various databases. Bachmann and his colleagues developed accurate search strategies to locate diagnostic accuracy studies in EMBASE.³⁴ Nevertheless, experts argue against routine use of predefined electronic filters for retrieving studies on diagnostic test accuracy.^{32,35}

Developing a proper structure based on the main components of the clinical question is another approach. The following is an example from Cochrane Collaboration.³⁵ Eisinga starts building the search structures by keeping the main components of the review question (i.e. index test(s), target condition, gold standard, and patient description). The first two components have to be used in all search structures, which she suggests. Eisinga's search structures are:

- Index test(s) AND target condition
- Index test(s) AND target condition AND patient description
- (Index test(s) OR reference standard) AND target condition
- (Index test(s) OR reference standard) AND target condition AND patient description

TABLE 1-5—Examples of Search Strategies for MEDLINE to Locate Diagnostic Test Accuracy Studies in the Journals Concerning Family Medicine³³

Content of the search strategy	Characteristic of the strategy	Sensitivity % (95 % CI)	Specificity % (95 % CI)	DOR % (95 % CI)
Sensitivity and specificity (exploded) (sh) Specificity (tw) False negative (tw)	Most accurate	73.3 (63.3-83.3)	98.4 (97.9-98.9)	170
Sensitivity and specificity (exploded) (sh) Specificity (tw) False negative (tw) Accuracy (tw) Screening (tw)	Most sensitive	89.3 (82.3-96.3)	91.9 (90.8-93.0)	95
Sensitivity and specificity (exploded) (sh) Specificity (tw)	Most specific	70.7 (60.4-81.0)	98.5 (98.0-98.9)	158

CI, Confidence interval; DOR, Diagnostic odds ratio sh, MEDLINE subheading;
tw, text word

To increase the sensitivity of these searches, which may cost the precision of them she recommends using: (1) a range of terms including text words and subject headings like MeSH, (2) advanced search techniques for example “explode” subject headings to retrieve more specific terms, (3) synonyms, related terms, variant spellings, acronyms, abbreviations, and (4) truncation and wildcards. To increase the precision of the search she suggests: (1) proper use of limits (e.g. limiting to “human” studies) (2) excluding irrelevant publication types (e.g., case reports), (3) Careful use of proximity operators, where available, and (4) use of subheadings with specific subject headings.

As an example, Dwamena has built a search structure based on second Eisinga's platform. Dwamena described a four-step search method in MEDLINE. He suggested a combination of Boolean operators including “OR” and “AND” as well as all subheadings of conditions and tests of interest through “Explode”, truncation and wildcards to find diagnostic studies². The steps are as follows: (1) searching for population, which is based on methods and criteria for the selection of the study population, (2) adding the “index test” to the previous search, (3) adding the outcome of interest or target condition, and (4) restricting the result of the third step by limiting it to for example “humans,” etc. He has used “breast cancer” as an example to demonstrate the functionality of this four-step search. He could locate 108 potentially eligible studies out of 181132 citations that he found at the end of the first step of his search.² More explicit information on searching the evidence is available in the *Cochrane Handbook for Systematic Reviews of Diagnostic Test Accuracy* and is highly recommended for those who intend to perform a systematic review on diagnostic test accuracy.³²

Critical Appraisal (Quality Assessment) of Studies on Diagnostic Test Accuracy

Like all other studies, diagnostic test accuracy studies may be affected by biases or variations.^{13,34} It is of paramount importance to assess a diagnostic accuracy study with regard to potential variations and biases. Common biases in diagnostic accuracy are as follows.^{16,36-38}

Patient-related biases are related to recruitment in studies:

Spectrum bias

To investigate the risk of this bias in a study, two important issues should be considered: (1) recruitment of a suitable group of patients for the study, and (2) use of a proper sampling method. The main issues concerning the recruited patients are demographic characteristics, such as patients' age, and the clinical characteristics of their disease, such as its severity. It is also important that the spectrum include patients suffering from diseases that can

be differentiated from the disease of interest. These issues may be influenced by the study setting, eligibility (i.e., inclusion and exclusion criteria), and design issues. Biases caused by improper definition of eligibility criteria are one of the main concerns in this field. Limited challenge bias is a specific type of spectrum bias. This form of bias occurs when diagnostically difficult cases are not included in the study, and it leads to overestimation of test characteristics such as the sensitivity and specificity of the index test. In a diagnostic case-control study, the accuracy of the index test would be assessed between healthy controls and a group of patients, and it is easy to understand that such a design would overestimate the accuracy of the test that is being evaluated.

Selection bias

A prospective consecutive sampling of patients who meet eligibility criteria for the study is recommended. A random sample of eligible patients may also be considered. If the patients who are recruited for the study have not been chosen through appropriate sampling methods, then the study will be prone to selection bias.³⁶

If the diagnostic study does not recruit the subjects randomly (demonstrating selection bias) and there is a trend toward selecting patients with more severe disease (spectrum bias), then this would boost the assessed accuracy of the index test.

Another source of bias is test-related issues. Although information bias can be caused by issues related to the gold standard or index test, other biases are caused only by the gold standard test. These biases include:

Information bias

Awareness of the results of either the index test or the gold standard test before knowing the results of the other test can influence the results of the second test. The resultant bias is called test review bias or diagnostic review bias. Proper blinding of the interpreters can control this bias.

Asymmetric awareness of clinical information at the time of interpretation of either test may also cause a similar form of bias known as clinical review bias. In this context, “asymmetric information” refers to the fact that one of the diagnostic tests is performed and/or interpreted in the presence of more clinical information, while no such information is available within the other test(s), including the gold standard or routine practice. Information bias usually results in overestimation of the accuracy of the test.

Misclassification bias

This bias occurs when the gold standard test cannot accurately differentiate between those who have the condition of interest and those who do not. Hence, it will misclassify study participants. The effect of this bias on the accuracy of

the index test depends on whether the index test causes the same error.^{36,37}

Partial verification bias

This bias occurs when patients with a positive index test are more likely to be referred for the gold standard and therefore to be included in the study. In these circumstances, the result of the index test is the basis for cross-verification with the gold standard. This bias is also known as primary selection bias, work-up bias, and sequential order bias.³⁸ This bias leads to overestimation of sensitivity with variable effects on specificity.

Differential verification (double gold standard) bias

This bias occurs when a part of the index results is verified by another gold standard. In this bias, some patients will receive gold standard 1 and the other gold standard 2, while all will undergo the index test. This usually results in overestimation of test accuracy.

Incorporation bias

This bias occurs when index and gold standard tests are not completely independent. Hence, the index test is used to establish a final diagnosis and is therefore effectively a part of the gold standard. Incorporation bias usually leads to overestimation of the diagnostic accuracy of the test.

Another group of biases is caused by changes in the disease because of a long delay between administration of the index and gold standard tests.

Biases caused by changes in disease

If the time for cross validation between the index test and gold standard test is too long, the severity of the disease may change, and these changes may produce a different result for the test that is performed later. These changes may be categorized into three major groups: (1) increase in the severity of disease, which is known as disease progression bias and is associated with more severe disease at the time of performing the latter test, (2) recovery bias, which is caused by recovery or improvement of the disease during the interval between performance of the tests, and (3) treatment paradox bias, which occurs when patients receive a therapeutic intervention after administration of the first test that results in cure or improvement of their disease. Both disease recovery bias and treatment paradox bias are associated with less severe disease at the time of administration of the second test. Assuming that the patients were first assessed by the index test, the accuracy of the index test will be underestimated because of disease progression

bias and overestimated because of disease recovery and treatment paradox biases.

Leeflong and colleagues have considered “excluded data” as a potential source of bias, usually leading to overestimation of the accuracy of a test.³⁶

In addition to withdrawals and uninterpretable test results, which may be covered under biases caused by data exclusion, the sponsorship of a study should also be considered at the time of the quality-assessment process.

Whiting et al. have correctly stated that the distinction between bias and variation is not always clear. Therefore, they consider almost all potential errors deriving from the patients (population) as variations. They also identify errors caused by test execution, test technology, and observer variability as variations.¹⁶

To help achieve this stage of EBM, several tools have been developed.^{39,40} As recommended by the Cochrane Handbook of Systematic Reviews of Diagnostic Test Accuracy Studies, items of Quality Assessment of Diagnostic Test Accuracy Studies (QUADAS) may be used for quality assessment of individual studies.³⁹ Since its development, QUADAS has been commonly used for assessing the quality of eligible studies in several systematic reviews of diagnostic tests and its application has also been evaluated.⁴¹ QUADAS has an important advantage: it does not rely on summary score points.⁴¹ Commenting on the adequacy of each assessed item is strongly recommended.³⁶

High-quality reporting of a study is necessary if a valid quality assessment is to be performed. The quality of reporting of the accuracy of diagnostic tests was less than optimal and required improvement. For this reason, a group of experts in this field launched the Standards for Reporting of Diagnostic Accuracy (STARD) initiative, resulting in a 25-item checklist and a flowchart.^{42,43} STARD is a counterpart to the better known Consolidated Standards on Reporting Trials (CONSORT) checklist and flowchart, which was developed before STARD to improve the quality of reporting of clinical trials.⁴⁴

DIAGNOSTIC SYSTEMATIC REVIEWS: GENERAL ISSUES

The distinguishing difference between a systematic review and a narrative review is a systematic approach to the relevant literature in the former. Indeed, the very first stage of performing a systematic review is to develop a protocol. The systematic review should be conducted according to this protocol. So in contrast to a narrative review, all steps of conducting a systematic review including its aim and objectives, eligibility (i.e., inclusion and exclusion) criteria for the studies, and search strategy are pre-defined. Systematic reviews on diagnostic test accuracy follow the same track. It is expected that the authors of a systematic review clearly state these issues in their review. The main components of a diagnostic systematic review report are

introduction, aim and objectives, methods, results, discussion and conclusion.

Introduction

This part summarizes the important “knowns” and “unknowns” about the subject of the study and contains the rationale for performing the systematic review. Introduction usually ends with uttering the aim and objectives of the systematic review.

Aim and Objectives

This part reflects the well-built clinical question and may mention either explicitly or implicitly. It may become a separate section or could be incorporated in different parts of the introduction and/or search strategy.

Methods

Search strategy

A clear and repeatable search strategy is an essential component of any type of systematic review. It should contain all the used “keywords”. If there are different search strategies for different databases, it should be explicitly addressed. The limits of the search should also be included in the search strategy.

Resources

All resources including electronic databases, hand-searched journals, and any material from so-called grey literature should be clearly addressed.

Selection of studies

The eligibility criteria for inclusion and exclusion of the studies should be defined beforehand and have to be followed meticulously. The author(s) of a systematic review should state clearly how they have looked for eligible studies. Important issues to be looked for in the “selection of studies” and part of a systematic review are study design, participants, target condition, and index, comparator and gold standard tests. The most common method for study selection is to review the titles and abstracts (when available) of the retrieved articles rapidly and decide about their eligibility based on the provided information in those part of the articles. If the authors do not find this information for decision-making, then the most reliable act is to obtain the full-text of the article to judge about the existing uncertainty. Two members of the systematic review team usually do this step independently and then the results will be discussed together. If they do not agree on few titles or abstracts, full-text of all articles with questionable eligibility

may be found and reviewed. An alternative approach is to ask a third reviewer for final decision making, particularly when the number of the debatable articles is large.

Data extraction

It is important that the authors of a systematic review mention how they extracted the data from the included primary studies. It is also expected to be done based on an a posteriori plan. Data extraction forms should be developed according to the quality assessment tools.³⁶ Appropriate data extraction is a prerequisite for a valid critical appraisal. Again, it is suggested that two independent reviewers do the data extraction.

Quality assessment (critical appraisal)

As it has already mentioned in this chapter, critical appraisal of the quality of individual studies is crucial for performing a valid systematic review. In order to perform this step, the authors of a systematic review should consider all questions concerning the qualities of included studies beforehand and clearly address them.

Methods for exploring heterogeneity of the studies

There are several reasons for heterogeneity in different studies of the same topic. They include (a) design-related issues such as limiting the biases and confounders, (b) differences in patient selection, (c) baseline disease severity, and (d) definitions of outcome measures.⁴⁵ With regard to diagnostic accuracy test studies, an important cause of heterogeneity is known as “threshold effect.” This effect occurs when different cut-offs (thresholds) are considered for determining sensitivity, specificity, and likelihood ratios in different studies. When threshold effect exists, a negative relation between sensitivity and specificity and a positive relation between sensitivity and 1-specificity exists.^{3,46,47} In general, heterogeneity in included studies of a diagnostic systemic review is a rule rather than an exception.⁴⁸ This fact cannot prevent pooling the data from heterogeneous studies, unless the heterogeneity would be statistically significant. Thus, exploration of heterogeneity should be clearly sought and explained.

Methods for pooling of the data: systematic review versus meta-analysis

A plan for pooling the data including the summary outcomes should be clearly stated. As a reminder, systematic review and meta-analysis are two different types of studies: while systematic review is a systematic search of evidence through predefined criteria, meta-analysis is the statistical method for combining results from different

studies and providing outcome summaries. Therefore, systematic reviews do not need to contain meta-analyses and meta-analyses are not necessarily performed on the studies in systematic reviews.

Meta-analysis

The ultimate goal of a meta-analysis is to give an overall summary coherent with all observed data (i.e., findings of the included studies). This summary should be highly precise. To accomplish this goal, a weighted average of the effect size of studies is typically used. The rationale for it is that the larger studies are more informative. Deviations of studies from the overall summary should be explored and reasons for such deviations are expected to be explained.⁴⁸

Traditionally, two statistical models were used to perform meta-analysis in a therapeutic systematic review: fixed-effects and random-effects methods. While in fixed-effects model, the inference is conditional on the studies actually done, in the random-effects models, the inference is based on the assumption that the studies, which are included in the analysis, constitute a random sample of some hypothetical population of studies.⁴³ Examples of fixed-effects models analyses are Mantel-Haenszel and Peto methods. One of the most famous examples of random-model analyses is DerSimonian and Laird method. This brief discussion about the fixed- and random-effects models can give the readership some acquaintance with what is mentioned about meta-analysis methods for diagnostic test accuracy studies. However, the monograph in epidemiology and biostatistics, by Petitti, has provided an interesting discussion on the difference between the two models. We recommend reading it to those who would like to obtain more information on this subject.⁴⁵

When meta-analysis for diagnostic accuracy studies is planned, it is important to remember that commonly used characteristics of the test performance such as sensitivity and specificity and positive and negative likelihood ratios are paired. DOR is an exception and is summarized as a single measure. SROCs are also among most frequently reported summary measures in this kind of systematic reviews.

Harbord and his colleagues discussed six methods for meta-analysis of diagnostic accuracy studies.⁴⁹ The first four methods are frequently used and simple:

1. Simple pooling (a fixed-effect method)
2. Separate random-effects meta-analyses of sensitivity and specificity
3. Separate random-effect methods of positive and negative likelihood ratios
4. Littenberg-Moses summary receiver operating characteristics (ROC) curve

They also considered two more statistically rigorous methods known as:

5. Bivariate random-effects meta-analysis
6. Hierarchical summary ROC curve analysis

These rigorous methods are both based on hierarchical models.

Detailed discussion about the characteristics of these models is beyond the scope of this chapter. Briefly, they have recommended using the hierarchical methods for doing meta-analysis in diagnostic test accuracy studies as the standard methods.⁴⁹

Information about techniques for evaluation of publication bias should also be provided in the report.

Results

Several parts may be present in the “results” section of a diagnostic systematic review. Some parts may be only applicable to those systematic reviews that do not contain a meta-analysis.

Exploring heterogeneity

Appropriateness of pooling the data and the possibility of performing a meta-analysis has to be addressed at this part of a systematic review.

It is important to look for the description of pooling the data. Homogeneity of the studies can be explored using graphs, but its existence should be confirmed by performing statistical tests. Like therapeutic systematic reviews, I-squared (I^2) may be used as a measure for assessing the existing heterogeneity. I^2 measures the amount of variability caused by heterogeneity.⁴⁹ There are other methods which have been used for assessing heterogeneity in meta-analysis, including Cochrane Q and G^2 .^{46,50} Usually small numbers of studies are included in a diagnostic test accuracy systematic review, so either Cochrane Q or G^2 has low power and is frequently unable to detect the existing heterogeneity.⁴⁶ If the studies are too heterogeneous to be pooled in one or more groups, summary estimates of the results may be misleading and a clear simple statement of each study characteristics would be more appropriate.

Summary of quality assessment of the included studies

Using QUADAS for the quality assessment of the included studies in a systematic review has been discussed in earlier parts of this chapter.³⁹ It is also possible to demonstrate a quantitative summary of the quality assessment results for those studies by making bar charts based on the items recommended by QUADAS for that process (Figure 1-4).^{36,39}

Summary of pooled data

The Littenberg-Moses method, which was used in 34 diagnostic tests accuracy systematic reviews, is the most

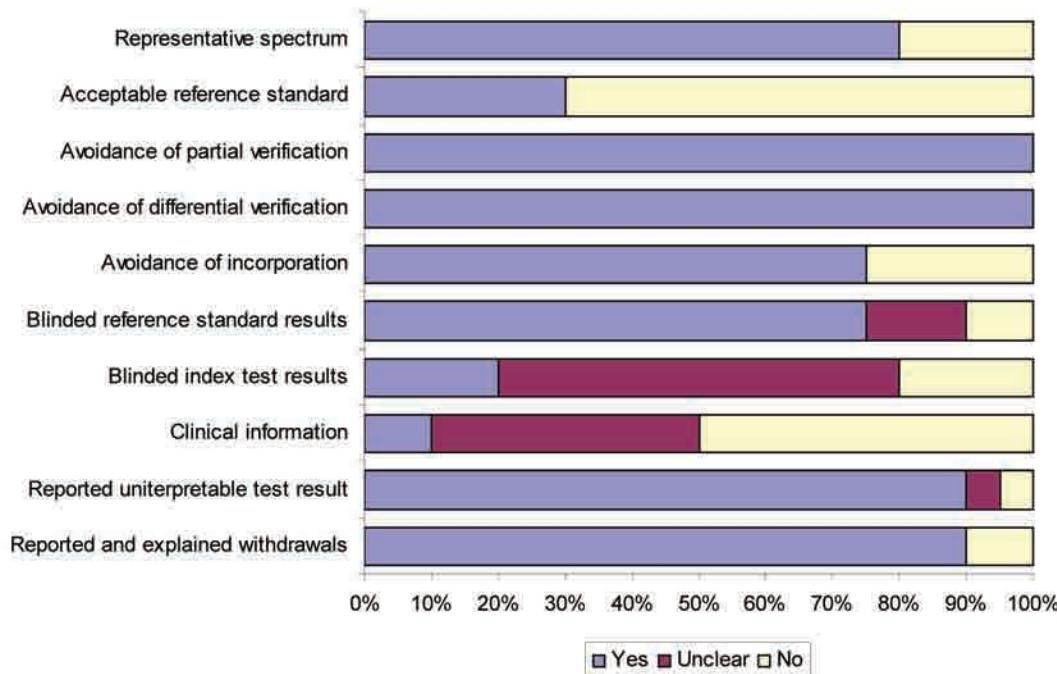

FIGURE 1-4 An exemplary bar chart based on simulated data, which is commonly used to summarize the results of quality assessment of primary studies in a diagnostic test accuracy systematic review based on some items of QUADAS. Each bar represents a certain item in QUADAS. Please notice that it is assumed that not all QUADAS items have been assessed. Data are presented as percentage of included studies.

common (41%) method for providing summary measure.⁴⁹ Meta-analysis of likelihood ratios and summary of predictive values derived from meta-analysis of likelihood ratios (29%) were the second most commonly used summaries. It is also possible to provide summaries of sensitivity and specificity as well as DOR.^{16,49} Please notice that simple pooling of sensitivity and specificity is usually inappropriate because this approach ignores threshold difference. At this section, we will provide a brief description of graphic techniques used in demonstrating these test accuracy summaries with some examples.

- Forest plots:** These plots are among commonly used graphs for displaying results of a meta-analysis. Point estimates of individual studies are shown as points or boxes, which are sometimes proportional to the sample size of each study. Confidence intervals are shown as horizontal lines. Summary of the pooled data is commonly demonstrated as a diamond, which the center represents the point summary estimate and its tips shows the confidence interval.^{51,52}

Forest plots are informative and easy to understand. In diagnostic tests, accuracy studies, the outcomes of interests are usually in pairs (i.e. sensitivity and specificity, positive predictive value and negative predictive value, and likelihood ratio for a positive test and likelihood ratio for a negative test). This is why forest plots come in pairs for diagnostic studies. DOR is an exception and a single forest plot is enough for showing characteristics of different studies. The summary DOR

should be calculated from sensitivities and specificities of each individual included in the study, not from the pooled sensitivity and specificity of those studies. Using the free downloadable software Meta-DiSc version 1.4,^{47,48} we drew forest plots for sensitivity and specificity, positive and negative likelihood ratios, and DOR with simulated data from 12 imaginary diagnostic test studies (Figures 1-5, 1-6 and 1-7).

2. Summary Receiver Operating Characteristics (SROC) curve

We drew a SROC with simulated data from 12 imaginary diagnostic test studies using “Meta-DiSc”,⁴⁷ (Figure 1-8). The Littenberg-Moses method was applied in Meta DiSc to draw this graph.

- Information on publication bias.** The most common way to present the publication bias is to use a funnel plot. However, it is important to mention that while a funnel plot can potentially facilitate visual detection of the publication bias, statistical techniques are needed for precise interpretation of the data. Diagnostic log odds ratio can be used as the measure for study precision and 1/square root of effective sample size can be applied as the measure for its effect size. A proper regression analysis may be used for detection of statistical significance. Usually a P smaller than 0.1 is considered as significant for the slope coefficient of the regression line.^{2,53} However, some experts in diagnostic systematic reviews mention that these methods of statistical assessment are not proper for assessing publication bias in this type of systematic reviews.³²

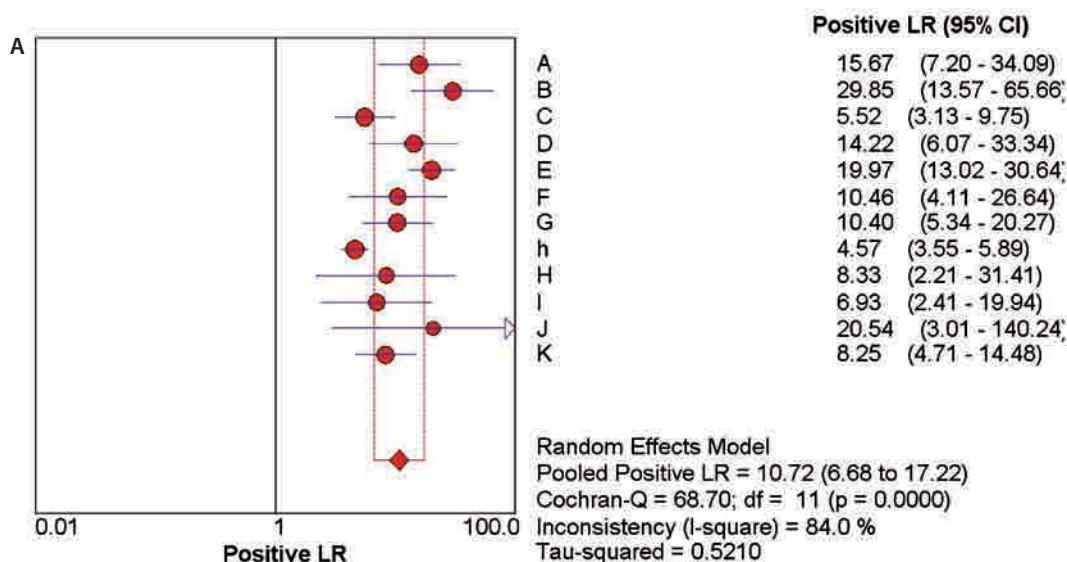

FIGURE 1-6 Paired forest plots of a simulated diagnostic test accuracy systematic review. (A) Positive likelihood ratio. (Continued)

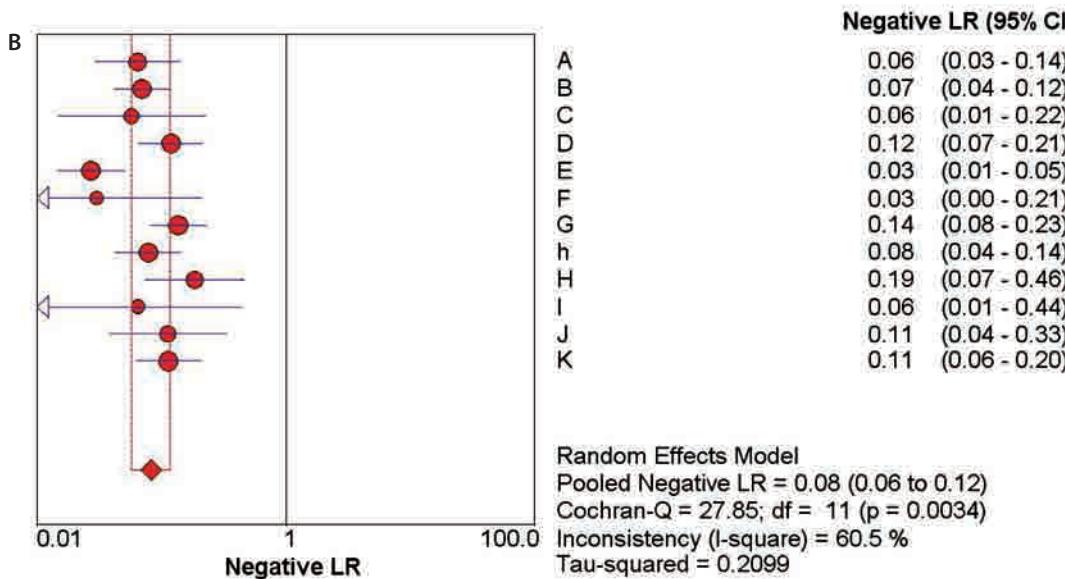

FIGURE 1-6 (Continued). (B) Negative likelihood ratio. Graphs have been drawn using Meta-DiSc software.^{47,48}

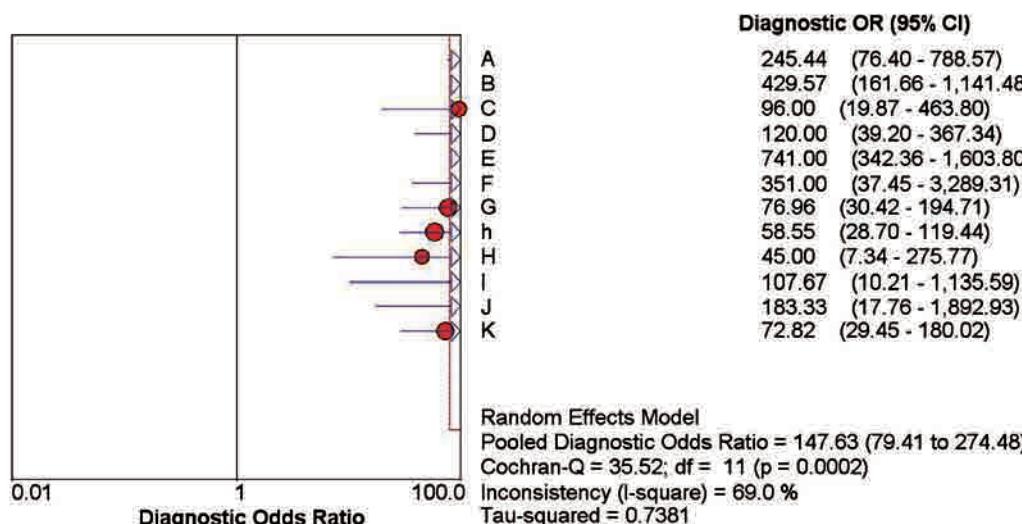

FIGURE 1-7 Summary diagnostic odds ratio (DOR) (forest plot) of 12 fictional diagnostic accuracy studies included in a simulated systematic review. Graph has been drawn using Meta-DiSc software.^{47,48}

Discussion

A detailed discussion of all findings of the review should be provided in this section. It means that findings of each individual included study as well as the findings of the whole systematic review should be discussed. For this purpose, the results of the conducted review should be compared to previous literature and any differences should be explained. The reasons for supporting the findings should be discussed as well. Limitations and shortcomings of the review as well as their influences on the review's validity should be stated. Comments should be helpful for clinical practice and designing future studies.

Conclusion

The bottom line of the review is expected to be found in this section of a systematic review. It should contain the paramount findings and very brief explanations for these findings. In addition, potential application of this new evidence in practice and research should be briefly stated. The conclusion section should be limited to a few paragraphs at most.

DIAGNOSTIC SYSTEMATIC REVIEWS IN DERMATOLOGY

It seems that diagnostic systematic reviews are still at their early stages in dermatology. Several chapters in this book

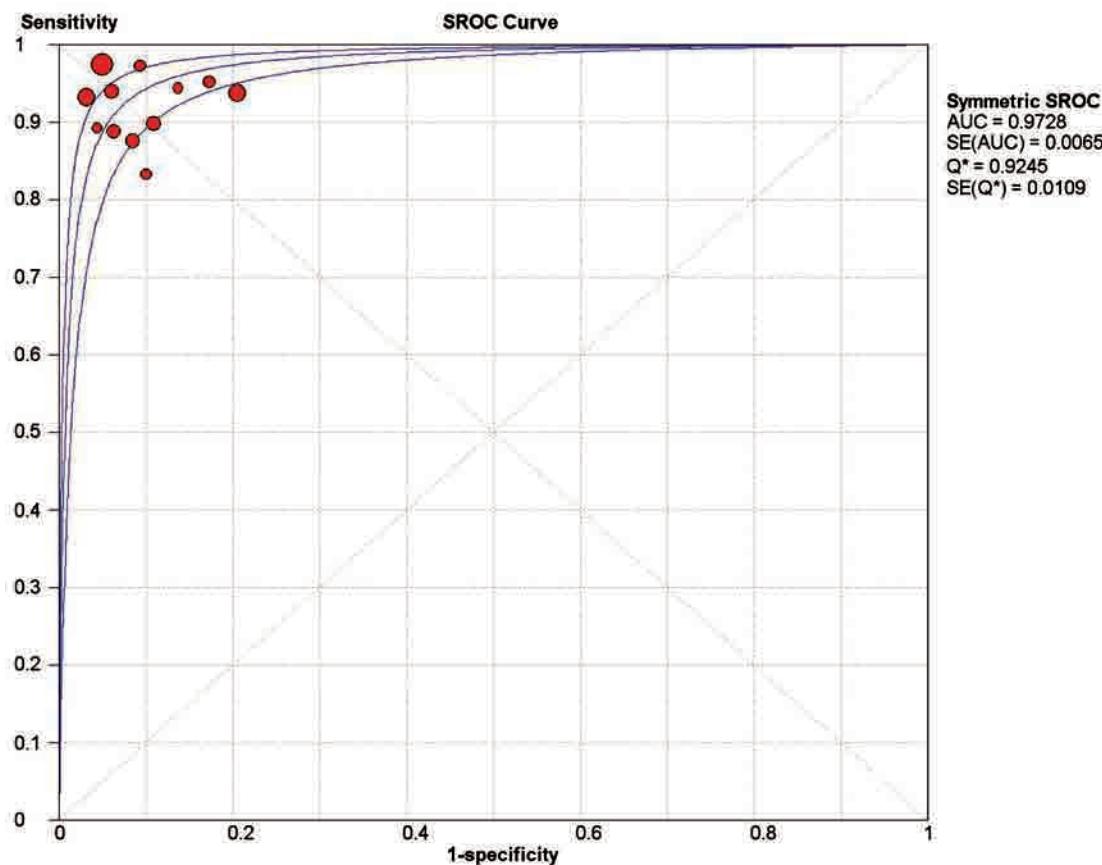

FIGURE 1-8 SROC curve of a simulated diagnostic test accuracy systematic review. This graph has been drawn using Meta-DiSc software.^{47,48}

(Chapters 2-9) provide evidence-based information on some diagnostic methods, which are used in dermatology for important diseases such as malignant melanoma, hirsutism, allergic contact dermatitis, and cutaneous T cell lymphoma. Evidence for useful diagnostic modalities

such as teledermatology and patch testing has been included as well.

In recent years, systematic reviews concerning diagnostic accuracy have been published in dermatology journals such as Rajpara et al. and Brenninkmeijer et al.^{11,54}

What We Know

- Physicians want to diagnose the disease as specifically as possible to (1) explain the details of condition to the patient, (2) be aware of risk factors and prognosis of the disease, (3) develop a proper treatment strategy based on all the details.
- The general principals of EBM approach to diagnostic test studies are similar to what exists for therapeutic, preventive, and prognostic studies, as they are interconnected.
- The hierarchy of evidence in diagnostic test studies is different from the widely accepted hierarchy for therapeutic interventions.
- Searching for the evidence on diagnostic tests is not widely utilized and is different from therapeutic interventions. *Cochrane Handbook of Systematic*

Reviews of Diagnostic Test Accuracy has provided useful resources in this regard.

- Acquaintance with outcomes such as sensitivity, specificity, positive and negative predictive values, likelihood ratios, and diagnostic odds ratio is crucial to properly understand a study on diagnostic test accuracy.
- Index test performance will depend on the spectrum of disease within a study population. The ability of a test to differentiate normal volunteers from severely ill patients may be misleading when the test is applied in clinical practice and not general population. On the other hand, index test accuracy is independent of disease “prevalence.”⁵⁵

What We Know (Continued)

- Similar to therapeutic studies, studies on diagnostic test accuracy are at risk of being affected by biases. Some instruments such as QUADAS and STARD have been developed to assess the quality of included studies. Dermatologists interested in diagnostic test accuracy studies are strongly encouraged to utilize and implement these tools.
- For certain reasons such as existence of “threshold effect”, studies on diagnostic test accuracy are usually more heterogeneous than their therapeutic counterparts. This fact makes pooling and summarizing the data more complicated in comparison with therapeutic studies.
- Several commonly used summary outcomes of diagnostic test accuracy studies such as sensitivity and specificity are paired. This characteristic necessitates the use of pair forest plots to display data summaries. Additionally, it results in using SROC curves as another graphic tool to demonstrate summary outcomes in relevant meta-analyses.
- Hence, the number of primary studies on diagnostic test accuracy, as well as systematic reviews and meta-analysis of these studies is increasing in all fields including dermatology. Dermatologists need to promote their knowledge and skills in critical appraisal and application of diagnostic tests and ultimately conduct quality diagnostic studies.

Diagnostic Accuracy of Teledermatology

Joseph C. Kvedar, M.D.

INTRODUCTION

Teledermatology is a growing field in dermatology which utilizes the innovations of communications technology to provide remote care to patients. It is a way of bridging the geographical gap between patients and providers and offers a potential solution to the problem of limited access to dermatologic care. In addition, teledermatology has the potential to increase the efficiency with which dermatologic care is delivered. Based on our review of the current literature, the evidence for the use of teledermatology in clinical practice is robust.

TELEDERMATOLOGY DELIVERY PLATFORMS

Store-and-Forward

Store-and-Forward (S&F) refers to asynchronous communications between parties (dermatologist to primary care or dermatologist to patient) involved in the care process in which clinical information (usually a medical history along with photographs of the dermatologic lesions) gathered by an individual at one location is sent to a dermatologist via communications technology, such as the internet and cellular phones, at a different location. Dermatologists receiving this information review it, at a time of their convenience, and later send back their assessment along with recommendations for treatment if indicated.

Features of S&F include: (1) dermatologists do not meet their patient in person, (2) the formation of a patient-dermatologist relationship is not typically established, and (3) dermatologists are limited by the clinical information gathered at the point of care including the quality of the photographs. The advantages to S&F include: (1) improved efficiency relative to live interactive and (2) work flow flexibility for the dermatologist. Physicians are able to view and respond to consultations at a time that is convenient for them. Also, total time spent on the S&F dermatologic consult is often less than a face-to-face dermatologic visit.¹⁻²

Live Interactive

The live interactive method of teledermatology refers to dermatologic consultation that is done where a physician

in one location can see and talk to a patient at another location via a live video conference. Dermatologists are able to take a complete history of the patient, and when it comes time for the skin examination a trained medical professional at the patient's location is able to maneuver the video camera for a proper examination. The dermatologist can interact with the health care professional during the skin examination, pointing out lesions that should be measured, photographed for archive, or biopsied. There is also an opportunity for thoughtful discussion about therapeutic options for the patient.

Features of live interactive include: (1) communication between the physician and the patient occurs in real-time, (2) tends to be less cost effective than S&F, (3) requires an interaction between clinician and participants at the point of care and therefore may be less convenient for dermatologists, and (4) typically requires more coordination between the physician and the patient to be at different places at the same time in order to meet on camera.

Both S&F and live interactive teledermatology are ways of delivering remote dermatologic care. Although each modality has unique features, neither one is considered superior to the other. A comparison of the features of S&F and live interactive teledermatology is provided in Table 2-1.

TABLE 2-1—Features of S & F And Live Interactive Teledermatology

S & F	Live Interactive
The dermatologist does not meet patient in person	Communication between the patient and the dermatologist occurs in real-time
The formation of patient-doctor relationship may not be established	It requires an interaction between the dermatologist and all participants at the point of care
The dermatologist is limited by the clinical information gathered at the point of care as well as the quality of the photographs	Typically it requires more coordination between the dermatologist and the patient in order to meet on camera at different places at the same time
It is cost-effective relative to live interactive	It tends to be less cost-effective than S & F
It allows for work flow flexibility and efficiency for the dermatologist	The length of the consult is similar to that of a regular face-to-face visit

Emerging Technologies

S&F and live interactive teledermatology mainly utilize the internet and computers as the medium for delivery of care. Although these are the primary modalities which have been clinically researched, it is important to realize that teledermatology encompasses the use of all forms of communications technology including cellular phones, personal assistant devices (PDAs), and satellite communication systems. The integration of these devices into providing dermatologic care and education is of increasing interest given the frequency with which they are used by the general public.

ANALYSIS OF THE EVIDENCE SUPPORTING TELEDERMATOLOGY AS A CARE DELIVERY PLATFORM

Comparisons of Teledermatology to Face-to-Face Care*

Following the first article on the subject of teledermatology in 1995, more than 250 publications have reported ongoing research in teledermatology around the world (PubMed search “teledermatology”). In general, individual studies in the field are variable with respect to quality of methodology, sample size, power, rigor, and analysis. In aggregate, there is a preponderance of evidence that teledermatology provides care of equivalent quality to face-to-face dermatology. Studies in this field have thus tended to focus more on the evaluation of process measures, which are vital in assessing the utility of teledermatology as a clinical tool. Whenever there is a change in the paradigm of the delivery of health care, there must be evidence to show that quality has not been sacrificed.

Studies Examining Process Measures

STUDIES ON DIAGNOSTIC RELIABILITY

Studies of diagnostic reliability evaluate the diagnostic agreement between clinic-based dermatologists and teledermatologists and explore both inter- and intraobserver reliability. Many of these studies report both complete agreement (agreement on a primary diagnosis) and partial agreement (agreement on a diagnosis within a differential). Overall, there are far more studies that evaluate S&F as a vehicle for teledermatology than live interactive (see above).

To date, studies evaluating the interobserver reliability between clinic based-dermatologists and teledermatologists using S&F technology have reported ranges from 0.41-0.97³⁻¹⁷ (Table 2-2). Studies exploring the interobserver reliability between clinic-based dermatologists and

teledermatologists using live interactive technology have found ranges from 0.54-0.99¹⁸⁻²⁴ (Table 2-3). One study by Edison et al. used three modalities (in-clinic consultation, live interactive, and S&F) to examine a single population of 110 patients and found that complete diagnostic agreement was reported 64% of the time in all three modalities.²⁵ Interobserver reliability was 80% between the clinic-based dermatologist and live interactive teledermatologists, 73% between the clinic-based dermatologist and S&F teledermatologists, and 70% between live interactive teledermatologists and S&F teledermatologists.

In order to explore whether the differences in diagnostic agreement between teledermatologists and clinic-based dermatologists are significant, some studies have assessed the interobserver reliability between clinic-based dermatologists alone. Overall, these studies have yielded comparable results to those studies evaluating the interobserver reliability between teledermatologists and clinic-based dermatologists^{7,15,18}. For example, one study by Whited et al. found comparable rates of interobserver diagnostic reliability between clinic-based dermatologists (0.54-0.92), between clinic-based dermatologists and teledermatologists (0.41-0.95), and between teledermatologists (0.49-0.92).⁷

The intraobserver reliability using S&F and in-person dermatology consultation has been reported in a handful of studies and ranges from 0.31-0.95^{8-9,16,26-27}. Only two studies have reported intraobserver reliability using live interactive teledermatology, compared to in-clinic dermatology consultation, and their results ranged from 0.59-0.87.^{19,21}

It is notable to mention one study that explored a combined live interactive and S&F model of teledermatology. In this study, both interobserver and intraobserver reliability illustrated significant increases with this combined model compared to S&F alone.²⁸

STUDIES ON DIAGNOSTIC ACCURACY

The results from research studies evaluating the diagnostic accuracy of teledermatology are difficult to interpret given

that there is no single gold standard in the field of dermatology. Although a biopsy can be helpful in the establishment of many dermatologic diagnoses, it is mainly considered a gold standard for establishing a diagnosis of dermatologic malignancy. Other reference standards (e.g., KOH prep), can also be helpful in making a diagnosis. Studies that have reported on the diagnostic accuracy of teledermatology have confirmed diagnoses via biopsy (usually for neoplasms) or other validated reference standards.

Diagnostic accuracy rates have been reported at rates ranging from 0.30-0.97^{7,27,29-34} (Table 2-4). These rates are based on studies comparing S&F teledermatologists to clinic-based dermatologists. To date, there have been no studies that evaluate the diagnostic accuracy of live interactive teledermatology.

There have been four studies that have found comparable accuracy rates between teledermatologists and clinic-based dermatologists, and one study that found higher accuracy rates among teledermatologists compared to clinic-based dermatologists.^{7,27,31-33} In this study by Lozzi et al. teledermatologists were allowed to consult with each other as well as request additional information from clinic-based dermatologists.³³ One could argue that this study is actually more representative of a real-life scenario where teledermatologists would be allowed to consult others. A recent study by Warshaw et al. however, found poorer diagnostic accuracy rates among teledermatologists (aggregated diagnoses 59.5%, primary diagnoses 42.9%) compared to clinic-based dermatologists (aggregated

diagnoses 76.1%, primary diagnoses 56.3%) in the diagnosis of nonpigmented neoplasms.³⁴ A randomized-controlled trial comparing store and forward teledermatology with store and forward combined with live and interactive found that both modalities performed well as measured by diagnostic confidence, diagnostic concordance, and need for conventional consultation³⁵

STUDIES ON MANAGEMENT RELIABILITY

Overall, research studies assessing the reliability of management decisions made by teledermatologists compared to clinic-based dermatologists have been shown to be encouraging with management agreement ranging from 0.36-1.0.^{4,7,13,15,16,19,23,30,32,36-40} In one of the biggest studies which evaluated 129 patients and compared management plans between teledermatologists (using S&F) and clinic-based dermatologists, comparable reliability for both medical therapy and clinic-based therapy recommendations were found.⁷ Diagnostic testing recommendations, however, were not reliable. With regard to diagnostic testing, similar results were found in another study by Mahendran et al. in which 163 S&F referrals of patients with one lesion suspicious for skin cancer were evaluated.¹² This study found management reliability between the teledermatologist and the two clinic-based dermatology consultants to range from 52-55%.

There have, however, been some studies that have assessed the reliability of biopsy and operative recommendations, which have yielded positive results (agreement ranging from 0.76-1.0).^{30,32,36-38} For example, a study by Shapiro et al. which evaluated the skin growths in 49 patients by digital photographs and in clinic consultations found that the teledermatologist and clinic-based dermatologist recommended a biopsy in the same 26/49 patients (agreement of 1.0).³⁷ There was also a recent study, which used the consensus opinion of an expert panel as a reference standard in the assessment of management decisions.³⁴ This study found management plans between teledermatologists (S&F) and clinic-based dermatologists to be equivalent (78.8% versus 83.4% respectively).

There have not been many studies evaluating management reliability of live-interactive teledermatology. One study found interobserver agreement between clinic-based evaluations and teledermatologists for biopsy recommendations to be 86%.²³ Another study that evaluated agreement by categories of management plans between a teledermatologist and a clinic-based dermatologist found an agreement rate of 72%. (44/61 cases).¹⁹ The study by Edison et al. which evaluated both S&F and live interactive teledermatology, found that clinic-based dermatologists agreed with the management plans of S&F teledermatologists 66% of the time.²⁵ Clinic-based dermatologists agreed with live-interactive teledermatologists 75% of the time, and live-interactive teledermatologists agreed with S&F teledermatologists 64% of the time.

STUDIES ON OTHER PROCESS MEASURES

Other process measures that have been evaluated in teledermatology research studies include intermediate outcomes such as clinic visits avoided, time to initial contact with a dermatologist, time to intervention, and length of consult. With regard to these process measures, teledermatology has been shown to be superior to conventional care.^{1-2,8,10,15-16,31,38-39,41-58} Several studies have evaluated the number of teledermatology consults that obviated the need for a dermatology outpatient clinic visit. For S&F teledermatology the percent of clinic visits avoided ranges from 13-59%, while visits avoid with live-interactive teledermatology have been shown to range from 44.4-82%.^{8,10,12,15-16,31,41-47,50-53}

Time to initial contact with a dermatologist as well as time to intervention, which are both closely related to a patient's clinical course, has been shown to decrease with the use of teledermatology when compared to the conventional process of patient referral. A randomized-controlled trial by Whited et al. found that patients utilizing S&F teledermatology consultations reached a point of intervention significantly sooner than those patients undergoing the typical referral process (median 41 days versus 127 days, respectively).⁴³ Another study found similar results, illustrating that teledermatology referral patients on average were evaluated sooner than conventional referral (12 days versus 88 days, respectively).⁴⁴ A study evaluating the wait times of patients with suspected skin cancers to see a clinic-based dermatologist found that median wait times and time to treatment were shorter for both melanoma and squamous cell cancer patients referred by teledermatology.⁴⁸

With regard to the actual length of a consult, when compared to clinic-based visits, S&F teledermatology consults have been shown to take less time.¹⁻² A study by Whited et al. illustrated this point when it found that S&F teledermatologists needed an average time of 7.2 minutes to review a consult versus a conventional consult, which required 24.4 minutes.² Although live-interactive teledermatology has been shown to be similar to outpatient dermatology clinic visits with regard to length of consult, studies have shown that compared to clinic visits, live-interactive teledermatology visits lead to a decrease in overall time for the visit (waiting time, consult time, and travel time).⁵⁵⁻⁵⁷

Studies Examining Clinical Outcomes

Research studies evaluating the clinical outcomes associated with teledermatology, such as patient clinical course, are rare given the reasons stated above. Studies to date that have assessed such clinical outcomes, however, have been promising.

A randomized controlled trial by Pak et al. compared to the clinical courses of patients undergoing a dermatology consultation in the clinic versus S&F teledermatology.⁵⁸

Based on evaluations before and after 4 months, subjects were rated as “improved”, “no change”, and “worse”. 65% of patients in the clinic-based group and 64% of patients in the teledermatology-based group were rated as “improved”, illustrating comparable clinical courses. Another randomized controlled trial that assessed an online asynchronous tool for the delivery of follow-up care in patients with acne, found that the degree of improvement seen in those subjects using this online tool was equivalent to those receiving conventional clinic-based treatment.⁵⁹

There is one study that attempted to evaluate clinical improvement among patients undergoing live-interactive teledermatology consultations by retrospective review.⁶⁰ This study found that of the 127 patients reviewed, 58.3% were rated as illustrating “clinical improvement”.

Studies Examining Doctor/Patient Satisfaction

Patient satisfaction for both S&F and live-interactive teledermatology has been shown to be generally neutral, with some studies illustrating overall satisfaction ranging from 42-93%.^{1,15,19,24,61-69} A study by Collins et al. found that 38% of patients preferred clinic-based dermatology consultations, 32% preferred S&F teledermatology, and 30% were unsure.⁶⁵ Similarly, a study by Whited et al. found that 41.5% of patients preferred S&F teledermatology consultation, 36.5% preferred clinic-based consultation, and 22% felt neutral about either option.⁶⁶ One study evaluating patient satisfaction with live-interactive teledermatology found that 66% of patients reported teledermatology was as good as clinic-based care, while another study reported 59% believed live-interactive teledermatology and clinic-based consultations were equivalent in quality.^{19,68} In both of these studies, however, some patients (13% and 18%, respectively) did report some discomfort with using the camera during their interaction.

Studies assessing referring clinician satisfaction with S&F teledermatology have found overall satisfaction rates ranging from 21-92%.^{1,15,61-63,66,70-71} In some studies, referring physicians have expressed that they feel teledermatology provides them with some educational benefit.^{1,62} In a study by Collins et al. physicians communicated that they believed teledermatology improved access to clinical specialists.⁷⁰ In studies where S&F teledermatology was utilized, the main complaint elicited by referring physicians was the time requirement that was needed to generate a consult.^{15,61,63,70} Feedback was similar for studies evaluating referring physician satisfaction with live-interactive teledermatology.^{19,72}

Studies have shown that satisfaction of teledermatologists themselves is good overall.^{1,15,20,24,62,66} 70% of teledermatologists utilizing S&F to evaluate patients in a study by Pak et al. reported that they believed their consult was of sufficient quality to make a diagnosis.⁶² In another study by Whited et al. 100% of teledermatologists stated that S&F made triaging patients easier.⁶⁶ With regard to

the evaluation of live-interactive teledermatologists, one study found that 98% of teledermatologists believed they were able to establish a good rapport with the patient, while another study found that 80% of teledermatologists believed their examination was as thorough as it would have been in a clinic-based setting.^{20,24} The most common negative comment made by teledermatologists in these studies was that they did not feel as confident in their diagnosis as they would have in clinic.

Studies Examining Cost Effectiveness

Although few studies that evaluate the cost-effectiveness of S&F teledermatology exist, research to date has shown that this modality of teledermatology has the potential to be cost-effective, especially from a societal perspective which takes into account all aspects of cost (for example, loss of work, productivity, etc.) associated with an intervention.^{2,4,73,74} A study by Moreno-Ramerie et al. performed a cost-effectiveness analysis on patients that were being referred for a suspected skin cancer via S&F teledermatology.⁷³ The study found teledermatology to be more cost-effective than conventional care, with teledermatology costing less per patient (79.78 Euros versus 129.37 Euros) and leading to patients being seen much earlier than those referred as usual (12.3 days versus 88.6 days). Another study found that, although direct costs of teledermatology were slightly higher than conventional care (\$294 per patient for teledermatology versus \$283 per patient for conventional care), when lost productivity costs were taken into account, teledermatology resulted in cost savings (\$340 per patient for teledermatology versus \$372 per patient for conventional care).⁷⁴

There are many more studies that focus on the economic analysis of live-interactive teledermatology compared to S&F. Currently, the consensus is that live-interactive teledermatology tends to be more costly than conventional care.^{50,52,56,75-80} However, studies have shown that this generalization may not apply in all healthcare settings. For example, a study by Armstrong et al. found that operating costs for live-interactive teledermatology were actually less than the operating costs of an outpatient dermatology clinic (\$274/hour for teledermatology versus \$346/hour for in-person clinic) in a remote rural setting.⁷⁹ In addition to this, it is important to consider the fact that, although the cost of technology is currently considered to be a significant portion of the cost of teledermatology, as the integration of communications technology continues to become commonplace, the cost of technology will likely decrease considerably.

Secondary Applications of Teledermatology

With the ongoing improvement of communications technology, as well as its continued integration into society, the applications of teledermatology as a clinical tool are vast.

Research is now beginning to focus more on the utility of these applications, as they have the potential to address many of the problems related to poor access to dermatologic care.

Triage

As briefly mentioned above, teledermatology has the potential to play a significant role in patient triage. This is especially true for those patients with lesions suspicious for skin cancer, as wait times associated with conventional patient referral are often prolonged. Many research studies have shown that using teledermatology to triage cancer patients can decrease both their wait time and time to intervention.^{37,44,48,50} A study by Hsiao and Oh performed a chart review of patients who were treated for skin cancer as a result of conventional or teledermatology referral and found that the mean time intervals for initial consult (48 day versus 4 days, $p < .0001$), biopsy (57 days versus 38 days, $p = .034$), and surgery (125 days versus 104 days, $p = .006$) were all less in patients referred via teledermatology.⁵⁰ Yung et al. reported on the use of teledermoscopy as a triage tool noting that agreement between teledermoscopy and face-to-face dermatologists was high (87.7%). They concluded that teledermoscopy is an effective tool to help manage triage in an environment with long wait times for an appointment.⁸¹

Management of Chronic Skin Disease/ Follow-up Care

Patients with chronic skin diseases, such as psoriasis and acne, often seen in dermatology clinics on a more regular basis than other patients. The amount of follow-up care that is required for these patients makes teledermatology an interesting option to consider because it allows for the preservation of patient contact without the inconvenience of having patients come into clinic as regularly. Although there have been few studies to date, the utility of using teledermatologic tools for follow-up care in those patients requiring frequent monitoring is currently being explored. In a study by Binder et al. teledermatologic follow-up care was done via home-care nurses after an initial outpatient visit for a leg ulcer. At the end of this study, 71% of leg ulcers were noted to improve.⁸² As mentioned above, a recent randomized-controlled trial of acne patients found that there is value in utilizing teledermatology for follow-up care.⁵⁹ Watson et al. examined the utility of a tool allowing patients with acne to submit self-captured images and relevant history over a secure website, in lieu of a follow up office visit. Subjects had either four online, asynchronous follow up visit or four in-office follow-up visits. Patients and Doctors were pleased with the application and there was no difference in quality of care as measured by lesion counts.⁸³ (see Studies Examining **Clinical Outcomes**, acne RCT)

Education and Support for Physicians and Patients

The use of communications technology as a bridge to sharing educational information between healthcare providers and patients is an important aspect of teledermatology, as providing education ultimately affects the delivery of healthcare. The use of such tools has been used to train residents. In a study by Williams et al. internal medicine residents in a hospital where there was no dermatologist, received 12 months of dermatology training via videoconferencing.⁸⁴ After the dermatology training, residents illustrated an increase in knowledge scores, and over 85% reported that the lectures improved their ability to provide patient care. Digital images along with a patient history gathered during dermatology consultations have also been used as a teaching tool during dermatology residency training.⁸⁵

Because primary care physicians often manage dermatology patients, having access to educational tools that can help support their decision-making. In a study by Gerbert et al. primary care physicians were randomly assigned to an internet-based skin cancer triage tool.⁸⁶ The physicians who utilized this tool scored significantly higher than the control group in 9 out of 14 outcome measures, which included diagnosis and evaluation planning for several skin cancers. The use of communications technology (email, online forums, etc.) can also help to facilitate knowledge exchange between general practitioners and dermatologists, aiding with management decisions as well.

Given the ease with which one can gain access to communications technology, future applications of teledermatologic educational tools will likely integrate direct communication between the dermatologist and patient. Hofbauer et al. evaluated an internet-based question-answering service at a university hospital in Switzerland and found that of those patients who asked dermatology-related questions, many of them reported high rates of satisfaction and changed whether or not they visited a clinic based on online recommendations.⁸⁷ The internet can also serve as a place of support and education for some dermatology patients with chronic diseases. For example, a recent study examined the role of online support communities in patients with psoriasis and found that of those patients participating in this community, 41% reported improvement in their psoriasis, half reported in improvement in their quality of life, and 60% reported having better availability of social support.⁸⁸

Mobile Teledermatology

Mobile teledermatology refers to the use of mobile devices such as cellular phones and personal digital assistants (PDAs), to send or receive dermatologic patient information. Integrating these devices into dermatologic care would be feasible given their increasing popularity with

consumers, as well as their ability to transmit and receive information without needing a direct Internet connection. Such technology has the potential to play a role in areas such as remote patient monitoring and follow-up, triage, treatment adherence, and patient education. This is especially true given the recent improvement in the quality of cameras that are embedded in these devices. Although few studies exist that have evaluated diagnostic agreement between clinic-based consultations and teledermatology images sent from mobile devices, results have been positive with one study reporting a κ value of 0.94 for diagnostic concordance, and another reporting a concordance rate of 71%.^{89,16} One of these studies also asked patients for their feedback on mobile teledermatology and found that 60% were not worried about its possible uncertainty, 69% were convinced of its usability, and 53% were willing to pay to use a similar service in the future.¹⁶

The ability of cellular phones to transmit and receive SMS text messages is currently being investigated as a simple and cost-efficient tool for providing patient support and education. An article by Schreier et al. describes a cellular phone-based compliance management system for psoriasis patients currently under implementation.⁹⁰ With this system, patients are able to send data (photographs, adverse event reports, etc) to an online monitoring center and if necessary, dermatologists are able to provide feedback to patients via SMS text messages or email. The role of SMS text messages in improving adherence to medical treatment is currently being examined as well. A recent randomized-controlled trial in Boston, MA found that patients who received daily reminders to wear sunscreen via SMS text message had nearly double the rates of sunscreen use versus a control group.⁹¹

Teledermoscopy

Clinical tools, such as dermoscopy, are now being integrated into the capture of digital images. In fact, dermoscopy attachments for cameras are now commonly sold (Figure 2-1). The utility of dermoscopy is that it allows for direct microscopic examination of pigmented skin lesions. Capturing these images could impart value on the diagnostic reliability of teledermatology. One study found 91% concordance in diagnostic agreement between teledermatologists and clinic-based dermatologists, while another study reported a κ value ranging from 0.681-0.703 with regard to management recommendations for pigmented lesions.⁹²⁻⁹³ A pilot study by Ferrara et al. examined the diagnostic accuracy of teledermoscopic images of melanocytic neoplasms via histopathologic diagnosis and reported a rate of 83%.⁹⁴

Teledermatopathology

The incorporation of digital cameras into microscopes has allowed for the transmission of both static and real-time

FIGURE 2-1 Example of dermoscopy attachment for digital camera. Third Generation DermLite FOTO Digital Epiluminescence Microscopy System. (Image courtesy of 3Gen, LLC.)

dermatologic images. As a result, dermatopathologists are now able to offer their expert opinion to those in a geographic area where such a specialist may not be available. Studies have found concordance rates from 78-100% between teledermatopathologists examining static images versus conventional histopathologic diagnosis.⁹⁵⁻¹⁰⁰ A study by Morgan et al. evaluated real-time teledermatopathologic diagnoses and reported good agreement as well ($\kappa = 0.76$).¹⁰¹ Progress has been made in this field with the introduction of the virtual slide system (VSS) in 2007, which enables the creation of a high-resolution digitized image of a slide that allows it to be viewed at different magnifications. Results from a study evaluating use of the VSS on the diagnosis of inflammatory skin lesions, found that only 3 out of 4 cases were correctly diagnosed, which authors felt was less than optimal.¹⁰² Authors of the study did state, however, that continued training on the VSS would most likely lead to future improvements in the diagnostic utility of this tool.

ADOPTION CHALLENGES

Although the technology needed for the integration of teledermatology into clinical practices is readily available, several barriers impeding widespread adoption persist. (Figure 2-2) Many healthcare providers continue to exhibit reluctance towards the adoption of teledermatology. This reluctance may stem from a lack of sufficient randomized-clinical studies, or from providers feeling satisfied with the current status of their clinical practices. As mentioned earlier, healthcare providers are concerned that integrating teledermatologic tools into their practice could lead to an increase in workload. It is important to consider, however, that new models of teledermatology are moving toward

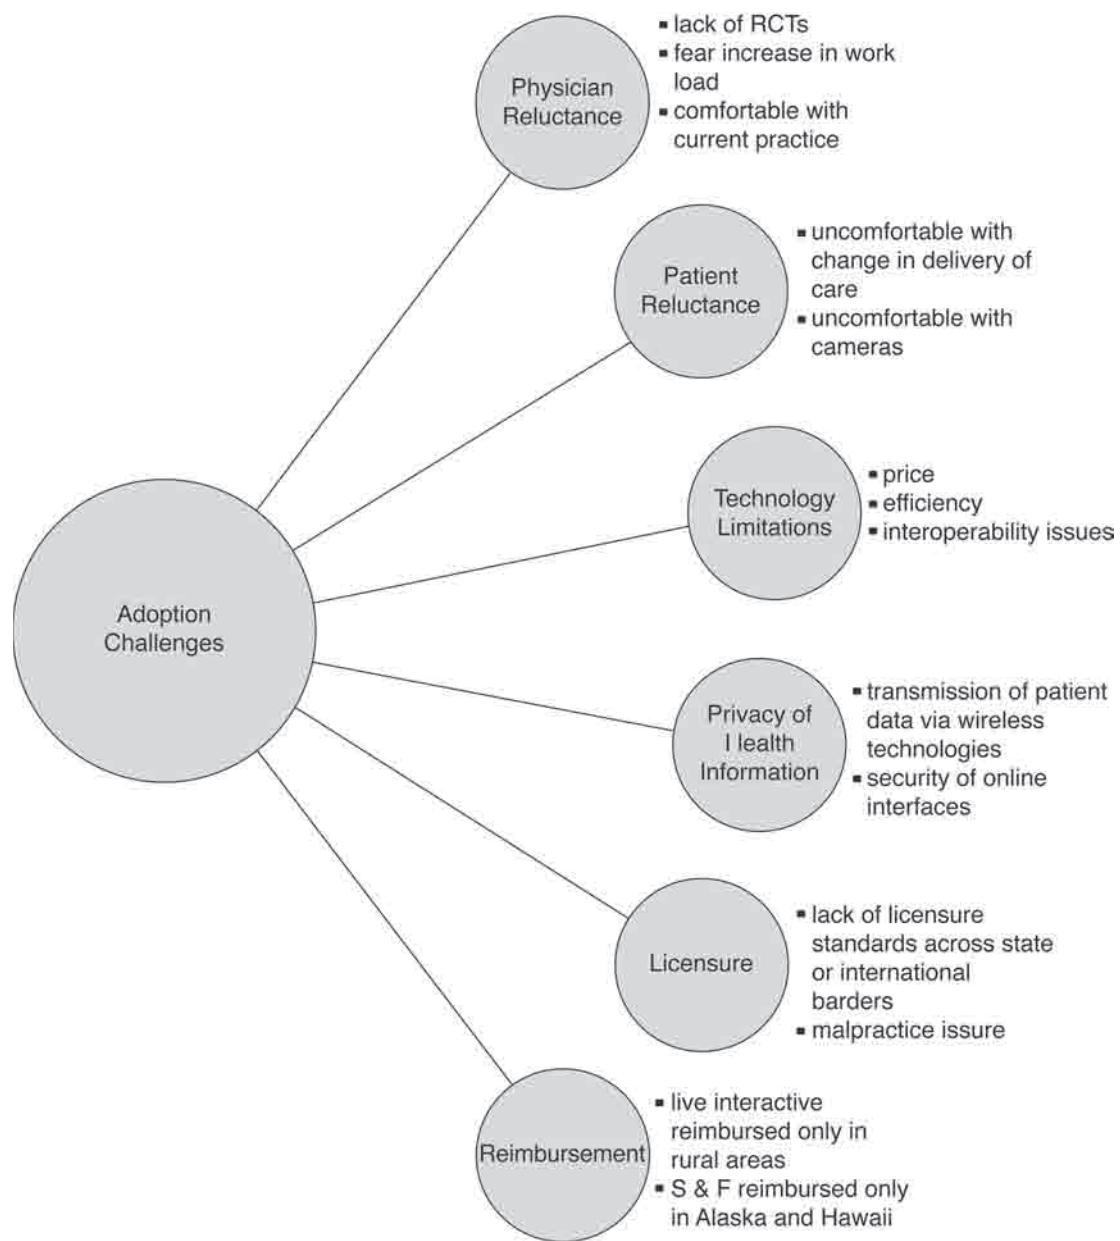

FIGURE 2-2 Challenges facing the adoption of teledermatology.

allowing for greater provider flexibility and versatility. Asynchronous models of teledermatology targeted at the most appropriate patients (e.g., those requiring frequent follow-up care) could allow for these patients to be seen more efficiently and at a time of convenience, allowing more time for dermatologists to see urgent patients in clinic.

Patients themselves may also feel reluctant to integrate teledermatology into their care. In previous studies, some patients have voiced feeling that “something was missing” during their teledermatology visit or that they were uncomfortable with the camera that was used.^{15,19,65,68} Emerging models of teledermatology, however, envision that teledermatologists will have some face-to-face contact with patients they are consulting (via live video

or previous clinic visit), making the experience more personal. As the integration of communications technology into clinical practices becomes more commonplace, we expect that teledermatology visits will feel more natural for patients. In addition, several studies have shown that there are a number of people who respond positively to teledermatology indicating that for some, adoption may be welcomed. (See section on *Studies Examining Doctor/Patient Satisfaction*)

Another challenge to the adoption of teledermatology lies in the technology itself. The price of utilized equipment is still considered significant in many situations, especially when high quality products are sought out. As previously mentioned, however, the rate at which technologic development is progressing is leading to greater affordability and

availability. The efficiency of current technology along with issues of interoperability between different devices remains a problem in some cases, but it is thought this will improve much over time.

Given the widespread use of wireless technologies to transmit patient data, especially with recent consumer-grade products that allow for patients to transmit their own clinical information, there have been growing concerns over the issues of privacy and security. Currently, several secure online interfaces are being created to help ensure that such healthcare information remain protected. The Health Information Portability and Accountability in the United States has set standards for the security of patient information.¹⁰² In addition, the Joint Commission on Accreditation of Healthcare Organizations also requires that high standards for the protection of patient information are met before granting accreditation to organizations.¹⁰³

Teledermatology allows a platform for the delivery of healthcare regardless of geographic boundaries. However, no licensure standards that have been created for the delivery of telemedical healthcare across state or international borders, creating a dilemma. Licensure in this scenario will be important to address in the future, given the issues that could arise with regard to malpractice. Clearly defining the responsibility of all parties involved with teledermatology consultations (referring physician, teledermatologists, etc.) is the key to avoiding future conflict.

Of all the challenges facing the adoption of teledermatology, reimbursement remains one of the biggest to be tackled. Currently Medicare and Medicaid reimburse physicians for live-interactive teledermatology consultations in only state-defined nonmetropolitan areas of the United States. S&F teledermatology consultations, however, are generally not reimbursed. This is true except in the states of Alaska and Hawaii, where Medicaid is currently funding S&F consultations on a trial basis because of the poor access to specialized care in these states.¹⁰⁵ The lack of randomized-controlled trials is a likely contributor to the reluctance of insurance companies to reimburse for teledermatology visits, which is a call to researchers in the field to continue with their efforts.

CONCLUSION

Research to date has illustrated the utility of teledermatology as a clinical tool and suggests that it is equivalent to face-to-face dermatologic care. Its applications, which include providing remote dermatologic care, aiding in patient triage, and providing a platform in which to educate patients and providers, are vast and valuable. Although there continue to be challenges facing the adoption of teledermatology into clinical practice, its integration is slowly becoming apparent. In 2003, American Telemedicine Association reported that more than 70 dermatology training programs were incorporating teledermatology into their practice,¹⁰⁶ and this number is likely rising.

The American Dermatology Association has released a statement with their position on the use of teledermatology, including guidelines for technology requirements, confidentiality standards, and licensure,¹⁰⁷ which is a sign that the value of teledermatology is recognized. With this in mind, however, it is acknowledged that much teledermatology research remains to be done. It is not until equivalence to conventional care is better elucidated that teledermatology will gain better acceptance in the medical community.

Evidence-Based Patch Testing

S. Iris Ale, M.D., and Howard I. Maibach, M.D.

INTRODUCTION

Evidence-based medicine can be applied both to therapeutic interventions and diagnostic procedures. When applying evidence-based medicine to diagnosis, we referred to evidence-based diagnosis (EBD). EBD can contribute to the assessment of the validity, and accuracy, as well as possible adverse effects of any diagnostic procedure in relation to its costs. Therefore, practitioners could better serve those who are under their care by using evidence to determine best practices in diagnosing.

EVIDENCE-BASED DIAGNOSIS APPLIED TO PATCH TESTING

Patch testing is currently used in clinical practice as the most important investigative and diagnostic method available for studying delayed contact hypersensitivity. It is a relatively inexpensive and safe procedure designed to establish a causal link between sensitization to a specific agent and allergic contact dermatitis (ACD). Patch testing constitutes—together with a detailed clinical history and a complete physical examination—a crucial step in the diagnostic work-up of ACD. Properly interpreted, patch test reactions are acceptable as “scientific proof” of the cause of dermatitis and are of medicolegal importance. The procedure involves the epicutaneous application of a specific substance (allergen) that should induce a cutaneous inflammatory reaction in the susceptible (sensitized) person; whilst causing no reaction in a nonsensitized person. The local reaction, reproducing the dermatitis “in miniature”, provides a visible representation of the subject’s general ability to react to the substance. Patch testing may be considered as one the most direct of all methods of medical testing, because it employs the agent that causes the disease; it applies that agent to the target organ, and it reproduces locally the pathogenic and immunologic mechanisms and morphologic changes of the disease itself.

However, as a bioassay, patch testing still confronts several inherent methodologic problems and requires strict observation of the technical aspects and critical assessment of the results.

In this article, we will discuss the validity of patch testing in the context of the principles of EBD. We will also

address the considerations pertinent to the decision to perform patch testing in the individual specific patient.

WHEN AND WHY PATCH TESTING?

Patch testing is indicated when an allergic component of the dermatitis is suspected. It has been shown to be significant both, in confirming contact sensitivities suspected from the clinical history and in unveiling unsuspected sensitivities. A number of studies have shown that history and physical examination alone are insufficient to consistently evaluate a patient with ACD.^{1–3} Cronin¹ studied 1000 patients by thorough clinical investigation and patch testing and demonstrated that the accuracy of the clinical prediction varied, depending on the characteristics of the clinical dermatitis and the causative allergen. For nickel, the most frequent sensitizer in women, the allergy was anticipated in 64% of the subjects, whilst chromate, the most common sensitizer in men, was suspected only in 40% of the cases. For other common allergens such as lanolin and neomycin sensitization was predicted in only 16% and 8% of the cases respectively. Similarly, Fleming et al.² demonstrated that clinical questions were accurate to predict the causative allergen in only 29–54% of ACD cases, depending on the involved allergen. Reliable identification of causative allergens by history alone represents an overwhelming task in which we are usually unsuccessful. Podmore et al.³ patch tested 100 consecutive patients, 41 of them were tested for screening purposes (e.g. eczema without an obvious allergic contact factor or clinical contact dermatitis without an obvious allergen). In 59 patients, a contact allergen was strongly suspected. Diagnosis was confirmed in 32 patients. In addition, 17 patients had 23 unexpected positive reactions. At least 50% of the unexpected reactions were considered relevant to the patient’s skin condition. If only the clinically suspected substances are tested, then all other possible sensitivities—which are not immediately evident from the history—would be neglected. For this reason, a standard series of allergens should be applied in all patients with suspected contact dermatitis. In addition to the investigation of a probable ACD, patch testing should also be done to uncover unsuspected (“occult”) contact allergies in patients with chronic or nonresponsive eczematous dermatitis, especially those

with hand or hand-and-foot dermatitis (dyshidrotic, hyperkeratotic and even pustulosis palmaris et plantaris), stasis dermatitis, atopic dermatitis, nummular eczema, and unclassified eczema. Patch testing may also be considered in patients with eczematous psoriasis,⁴ essential pruritus and suspected drug eruptions.⁵ Finally, it may be indicated when dealing with any dermatitis that persists for more than 3 months, is resistant to an appropriate therapy, or worsens during topical treatment. When these patients are assessed clinically but without patch testing, they may not be suspected of having an allergic component. Moreover, in many cases, the offending agent is present in the topical products prescribed or self-administered for the treatment of the primary disease. However, when testing these patients, bear in mind that, as the prevalence of allergic contact dermatitis is deemed to be lower than in patients meeting the case definition of allergic contact dermatitis,⁶ the predictive value of patch testing will decline (see the following).

Although patch-testing is primarily conducted according to the clinical history and physical examination, the diagnostic process is bi-directional and test results will guide further questioning and investigation. Reconsidering the history in the light of the test results can lead to recognition of many concealed sources of causative exposure. Even when uncovering unsuspected contact allergies are important, the significance of these sensitivities to the clinical dermatitis varies substantially. Many times, no clinical relevance is found, whilst other times, avoiding exposure to the sensitizer may constitute the only measure that can be adopted to control the flares in a chronic, recalcitrant dermatitis. The correct diagnosis and characterization of the causative agent(s) of the patient's dermatitis constitute essential prerequisites for adequate therapeutic and preventive measures to be established. Conversely, without the use of diagnostic patch testing, the patient may be given needless prohibitions in a vain attempt to improve the dermatitis.

WHAT IS THE VALIDITY OF PATCH TESTING RESULTS?

The validity (credibility, believability) of any test system is its intrinsic ability to detect or measure the aimed biologic phenomenon, (i.e., to determine which individuals have the target disease and which do not), relying on the test capability to detect both true-positive and true-negative reactions, while minimizing the number of false-positive and false-negative reactions. In the case of patch testing; does a positive patch test reaction predict contact sensitization with certainty or it can be elicited by a different biologic phenomenon like contact irritancy? A single patch test is a 'snapshot' of the tempo of an evolving immunologic process, and the issue of whether a positive patch test reaction is causally linked to the disease being studied involves several pitfalls including the inherent risk of

false-positive responses, mostly because of irritancy, and the difficulties in assessing clinical relevance. Besides, the magnitude of the problem of false-negative results is largely unknown.

The Problem of False-Positive and False-Negative Patch Test Reactions

The ideal patch test should correctly diagnose contact sensitization while producing no false-positive or false-negative reactions. However, even when an appropriate testing technique is applied, false-negative and false-positive reactions may occur. The frequency of false-negative reactions is difficult to evaluate. A false-negative reaction can occur for a number of reasons: (1) failure to perform delayed readings after allergen removal and evaluation at 48 hours, which is especially important for allergens known to elicit delayed reactions, and when testing elderly patients, who may present a protracted immunologic response; (2) the test concentration and/or the amount of the substance applied may have been insufficient; (3) the vehicle may not have released a sufficient amount of the allergen (the biologic availability was too low); (4) the patient skin is unresponsive by prior sun exposure, local application of corticosteroids, systemic administration of corticosteroids or immunosuppressors or other causes of skin hyporeactivity (5) the test site might have been inappropriate; (6) the occlusion might have been insufficient; (7) there was an inadequate replication by the test of the real exposure conditions, namely irritation, occlusion, heat, mechanical trauma, etc, that might enhance the percutaneous penetration of the allergens and cannot be reproduced in patch testing.

When patch testing with a particular substance is negative in a patient who has an evident dermatitis from contact with that substance, the putative allergen should be retested—perhaps in a different concentration, with a different vehicle, or with a different testing method, such as open or semi-open tests and use tests and/or repeated open application test (ROAT). Likewise, the investigator must be aware of the pitfalls of false-positive reactions. A false-positive reaction may be attributed to several causes, such as: (1) testing with allergens that are marginally irritants, (e.g., metals, formaldehyde, epoxy resin, etc.); (2) testing with allergens at concentrations that exceed their irritancy thresholds; (3) spill over reaction from a nearby true-positive reaction; (4) multiple simultaneous positive reactions; (5) testing patients with active dermatitis or otherwise sensible or irritable skin. Certainly, these lists are not exhaustive. The issues of skin hyper and/or hyporeactivity would be better assessed if appropriate negative and positive controls were routinely applied in clinical patch testing. The negative control would be a chamber containing only petrolatum, whilst the positive control should be a mild irritant such as 75% aqueous propylene glycol, 20% nonanoic acid, or 0.25%

sodium lauryl sulphate. To discriminate between false-positive reactions and true allergic reactions, we can repeat patch testing of the individual allergen with lower concentrations or serial dilutions, repeat patch testing with 24 hours occlusion, or perform additional tests such as the ROAT.^{7,8} Irritation reactions in ROAT are very limited compared to patch tests.

Even if the allergic nature of a positive reaction as read by international guidelines cannot be taken for granted, for most common allergens a positive patch-test reaction is predictive for contact sensitization.⁹ The validity of patch testing may, therefore, be considered as good for many allergens, if tested under controlled conditions and in the proper concentration, and patch testing is performed and evaluated according to the international guidelines.¹⁰

WHAT ARE THE INDICATORS FOR EVALUATING THE VALIDITY OF A DIAGNOSTIC TEST?

The statistical principles that underlie the evaluation of diagnostic tests are frequently overlooked by clinicians. These principles are substantial in recognizing the inherent limitations that are present when applying diagnostic tests. The classic indicators for evaluating the accuracy of diagnostic tests are the sensitivity, the specificity, the predictive value (PV) and the likelihood ratios (LR). These indicators compare the diagnostic discrimination of the test to the reference criterion or gold standard, which, by definition, has a sensitivity and a specificity of 100%. The concept can be delineated using a 2×2 contingency table that takes into account the test result (i.e., interpreted as positive or negative) and the presence or absence of the disease being studied (Table 3-1).

CONTACT ALLERGY			
Patch Test Result	Present	Absent	Predictive Value
Positive	True Positive (TP)	False Positive (FP)	Positive (TP / TP + FP)
Negative	False Negative (FN)	True Negative (TN)	Negative (TN / TN + FN)
SENSITIVITY (TP / TP + FN)		SPECIFICITY (TN / TN + FP)	

Sensitivity = $TP / (TP + FN)$, specificity = $TN / (FP + TN)$

Positive predictive value = $TP / (TP + FP)$, negative predictive value = $TN / (FN + TN)$

Positive likelihood ratio (LHR+) = sensitivity / (1 - specificity)

Negative likelihood ratio (LHR-) = $(1 - \text{sensitivity}) / \text{specificity}$

Prevalence = $(TP + FN) / (TP + FP + FN + TN)$

Pretest odds = prevalence / (1 - prevalence), post-test odds = pretest odds \times likelihood ratio;

Post-test probability = post-test odds / (post-test odds + 1)

Sensitivity and Specificity

The key to patch testing is to allocate the tested subjects into either those who are allergic to the test chemical and should have a positive result or those who are not allergic, who should have a negative result. As has been stated before, those instances in which the test result is positive, but no disease is present, are called false-positive results. The negative test results found when disease was actually present are called false-negative results. The proportion of subjects with a positive test result, out of all those with disease is known as the sensitivity of the test. In our scenario, it measures the proportion of allergic individuals that are correctly identified by the test; ergo, it measures how sensitive the test is to detect contact allergy. Specificity is the proportion of subjects with an appropriate negative test result out of all those without disease. In other words, sensitivity and specificity indicate the proportion of individuals that have been correctly identified as allergic or not allergic.

These indices are the most commonly reported measures of test efficacy, provide stable estimates of the test's diagnostic discrimination and can be applied to any diagnostic test irrespective of the characteristics of the population on which the test is used.^{8,9,11–13}

Predictive Values

Although the concepts of sensitivity and specificity are required to determine the validity and accuracy of a diagnostic test, from a clinical point of view it is more important to determine to what extent the test can help estimate the probability of presence or absence of disease after testing. In other words, in clinical practice it is essential to know how a particular test result predicts the risk of disease. Sensitivities and specificities do not do this: they describe how abnormality (or normality) predicts particular test results. Physicians need to make inferences about the presence or absence of disease from an obtained test result. There are two ways to quantify this inference: predictive values and likelihood ratios.¹⁴ The traditional concept of predictive values (Table 3-1) presents the absolute probability that the disease is present (positive predictive value) or absent (negative predictive value). The positive predictive value of the test (PV+) is measured as the percentage of true-positive results out of all the positive test results. It is an estimate of the probability that a patient with a positive test result actually has the disease. Similarly, the percentage of true-negative results out of all the negative test results is referred to as the negative predictive value of the test (PV-). The positive and negative predictive values are of great importance for clinicians, who interpret the test results in a case by case basis and may be applied in clinical decision-making. However, these values are influenced not only by the sensitivity and specificity of the test, but also by the

prevalence of the disease in the population upon which the test is applied.^{14,15} If the rate of disease in the population tested is low, then the PV- increases and the PV+ decreases. In general, when the prevalence of the specified disease is low, even a test with high specificity will produce a large number of false positives, thereby reducing the PV+ of the test.¹⁶ Thus, the PV will vary depending not only on the test's properties but also on the prevalence of the disease in the population upon which the test is applied. Therefore, they do not offer a single measure to describe the test's inherent accuracy.

Likelihood Ratios

As PVs depend on the prevalence of the disease, they can rarely be generalized beyond the study (except when the study is based on a suitable random sample, as is sometimes the case for population screening studies). To overcome the difficulty arising from interpretation of PVs, decision analysts have proposed an alternative method to assess the predictive properties of a test: the likelihood ratio (LHR).^{14,17,18} LHRs are alternative statistics for summarizing diagnostic accuracy, which have several particularly powerful properties that make them more useful clinically than other statistics. Conceptually the LHR is the ratio of two probabilities, namely the probability that a specific test result is obtained in patients with the disease, divided by the probability of obtaining the same test result in patients without the disease. In the case of dichotomous test measures, the likelihood ratios have a direct relationship to sensitivity and specificity that can be summarized as follows: Positive likelihood ratio (LHR+) = sensitivity/(1 – specificity); Negative likelihood ratio (LHR-) = (1 – sensitivity)/specificity. However, unlike sensitivity and specificity, computation of the LHR does not require dichotomization of test results. Forcing dichotomization on multicategory test results may discard useful diagnostic information.¹⁹ An LHR greater than 1 indicates that the test result is associated with the presence of the disease, whereas an LHR less than 1 indicates that the test result is associated with the absence of disease. An LHR of 1 implies that the test result is equally likely to occur among patients with the disease as in patients without the disease. The further LHR are from 1 the stronger the evidence for the presence or absence of disease. LHR above 10 and below 0.1 are considered to provide strong evidence to rule in or rule out diagnoses respectively in most circumstances. LHR+ from 5 to 10 and LHR- from 0.1 to 0.2 provide moderate evidence for the presence or absence of disease. Tests with LHRs ranging from 0.33 to 3 rarely alter clinical decisions. LHR are ratios of probabilities, and can be treated in the same way as risk ratios for the purposes of calculating confidence intervals.^{12,19} Theoretically, LHRs (unlike predictive values) are independent from the prevalence of the disease. Actually, LHRs may differ across various clinical settings and may be affected by the same limitations discussed above.

Diagnostic Odds Ratio, Pre-test and Post-test Odds, Pre-test and Post-test Probabilities

An alternative way to compare tests is by means of the diagnostic odds ratio. The diagnostic odds ratio is calculated as $(\text{sensitivity} \times \text{specificity}) / [(1 - \text{sensitivity}) \times (1 - \text{specificity})]$ or as LHR+ divided by LHR-.²⁰ Potentially useful tests tend to have diagnostic odds ratios well above 20 (e.g., a LHR+ of 7 and a LHR- of less than 0.3). Other indicators that can help estimate the probability of disease after testing are the pretest and post-test odds and pre-test and post-test probability (Table 3-1). The sensitivity and specificity of a diagnostic test and the pre-test probability of disease can be used to estimate the post-test probability in an individual patient. Without any additional information, pre-test probability equals the prevalence of a disorder. If more information becomes available from clinical history, physical examination, clinical investigations, and diagnostic tests, then the probability of having or not having a disease will increase and even come close to 100%. The post-test odds are defined as the pre-test odds multiplied by the LHR+ of a test. The resulting post-test odds can be converted to a post-test probability of disease that is identical to the predictive value of the test. An estimate of the post-test probability of disease that is more relevant for an individual patient can be obtained by adjusting the pretest probability, taking into account patient characteristics and clinical experience.

WHAT ARE THE PROBLEMS WITH THE INDICATORS OF TEST VALIDITY WHEN APPLIED TO CLINICAL PATCH TESTING?

When we want to determine the accuracy of a diagnostic test using measures such as sensitivity, specificity, or PV, we should know in advance which subjects have the disease and are being studied based on some gold standard criterion. The optimal design for assessing the accuracy of a diagnostic test is considered to be a prospective blind comparison of the test, and a reference test or gold standard in a consecutive series of patients from a relevant clinical population.²⁰ As patch testing constitutes the only reliable and readily available test for diagnosis of contact allergy, the gold standard for comparison must be a confident clinical diagnosis made through the exhaustive study of each case and fulfillment of a precise case definition, in terms of the clinical findings, history of exposure to the tested substance, and reproducibility of the response with an appropriate time course after exposure.⁶ Alternatively, a repeated open application test (ROAT) or a controlled exposure to the tested substance can be envisaged as a reference for comparison. However, these tests also have a certain degree of ambiguity and need further standardization.²¹ Available data concerning validity and accuracy of

patch testing as a diagnostic tool are quite limited because, in clinical grounds, we usually do not apply diagnostic tests to groups of subjects who are known to have the disease we are trying to diagnose, (i.e., with incontrovertible contact sensitivity to the substances being tested). Similarly, data regarding testing in subjects without contact dermatitis are scarce.

To assess the validity of patch test screening trays in the evaluation of patients with allergic contact dermatitis, Nethercott and Holness²² tested 1032 patients, 639 of them with the International Contact Dermatitis Research Group (ICDRG) standard series and 393 with the North American Contact Dermatitis Group (NACDG) standard series, with the use of Al-Test patches or Finn Chambers. They found that sensitivity, specificity, positive accuracy, negative accuracy and validity index for the ICDRG and NACDG screening series were 0.68, 0.77, 0.66, 0.79, 0.72 and 0.77, 0.71, 0.66, 0.79, 0.74, respectively. Applying Nethercott's estimates for sensitivity and specificity, we can calculate the LHR+: sensitivity/(1 - specificity) = 0.68/(1 - 0.77) = 2.95, and the LHR:(1 - sensitivity)/specificity = (1 - 0.68)/0.77 = 0.43. These values are far from being ideal as nearly 30% of all patch test results were considered inaccurate. Note, however, that the authors considered those patients with positive test results in which investigation did not provide evidence to support clinical relevance (either present or past) as having false-positive tests. Similarly, patients with negative test results to the screening series in which further testing revealed positive responses to other allergens were taken to have false-negative screening tests.

Other important consideration concerning the validity of clinical patch testing is that patch testing does not represent a particular test –such as serum glucose-, but rather a technique of testing. Thus, sensitivity, specificity, PV or LHR data may be allergen specific and will vary depending on the allergens tested and also according to the degree of severity of the patch-test reaction. Thus, we have to keep in mind that the accuracy of clinical patch testing may be higher for one allergen than for another, and also, higher in ++ and +++ reactions versus + reactions. In addition, not only the allergen but also the allergen concentration has to be considered when assessing patch test validity. Delayed sensitivity is a dose-related phenomenon and the outcome of an individual patch test not only depends on the existence of delayed hypersensitivity to the tested allergen but also on the allergen concentration and the delivered dose. Therefore, the test concentration has an essential role in determining the amount of positive test results to be obtained. The allergen dose should be kept sufficiently high to detect allergy in weakly sensitized individuals but low enough to minimize irritant reactions and the risk of sensitizing the patient. When a test substance has low irritant properties, it is possible to use a relatively high test concentration, hence allergic reactions will be more likely elicited. Conversely, if the substance has a fairly high irritant potential, then a lower test concentration will have to be used

to avoid the induction of false-positive irritant reactions. In the latter circumstance, allergic reactions are less likely elicited, especially in weakly sensitized persons. Variations in the cutoff concentrations will determine changes in the balance between positive and negative results. If the allergen concentration is raised, both true-positive and false-positive test results will increase and the number of false-negatives will decrease; the sensitivity increases and specificity decreases. Conversely, if the allergen concentration is reduced, we will have less false-positive test results, but also more false-negative responses. The specificity increases but sensitivity will decline. Therefore, the sensitivity and specificity of the test, as well as the predictive values are related to the elicitation concentration of the allergen. The choice of allergen dose is a compromise; it should maximize the chance of obtaining true-positive results, while minimizing the number of false-positive irritant results in nonallergic subjects. Patch test concentrations for most allergens, even for allergens in the recommended standard screening series, have been established testing groups of patients supposed to have allergic contact dermatitis. In this context, a concentration is considered appropriate when capable of eliciting a reasonable proportion of true-positive tests results, (i.e., positive results that were considered relevant on clinical grounds), whilst eliciting a reasonably low proportion of irritant results according to morphologic criteria. However, the threshold for irritancy shows huge variance among individuals, and there are large interindividual variations in the minimal amount of allergen required to elicit an allergic reaction. So, allergen concentrations would be better estimated employing serial dilution test technique on patients proved to be sensitive to the tested allergen through controlled exposure, and also, on nonsensitive controls. Using this technique it would be possible to establish the concentrations eliciting strong, optimal, and minimal reactions. Thus, the mean, standard error and ranges of reactivity for the different allergens could be calculated. This procedure has been used to standardize some patch testing materials such as TRUE TestTM.²³ The cutoff concentration for TRUE Test allergens was determined as the minimum concentration that caused a 2+ reaction in at least 90% of sensitive patients.²³ On the other hand, comparative multicenter studies with TRUE Test and Finn chamber technique indicate proximity in limits of weak sensitization and irritancy for several standard allergens, such as nickel, dichromate, cobalt, balsam of Peru, fragrance mix, carba mix and thimerosal.²⁴

Finally, in clinical patch testing, positive reactions are at least ten times less frequent than negative ones. Therefore, even assuming that the test has high specificity, false-positive reactions will have great impact on the proportion of true positives out of all positives elicited (i.e., the PV+ of the test). This substantiates the importance of achieving a high prevalence rate of truly sensitized patients through a careful clinical assessment before patch testing. When the rate of allergic persons tested increases (i.e., patch testing is

used mostly to confirm a clinical diagnosis of ACD), then the PV+ will increase at the same test sensitivity.¹³

WHAT ARE THE ADDITIONAL PROBLEMS THAT MAY AFFECT THE VALIDITY OF CLINICAL PATCH TESTING?

There are several sources of unreliability that are inherent to clinical patch testing and that may interfere with the reliability of the results. Recognizing the benefits of patch testing, as well as all its possible pitfalls is of utmost importance to the physician using this method for clinical diagnosis.

Problems associated with the Patch Test Methodology

Standardization of the patch test technique is essential for reproducible results. Significant research on chemical and toxicologic aspects of test allergens, appropriate vehicles, and skin penetration, all contributed to the development of reliable and consistent patch test techniques. Yet, systematic studies for several important aspects are still lacking, and patch testing still confronts inherent methodologic problems. Several factors may influence patch test reactions and many sources of unreliability still exist, including variations in patch test materials, technique and methodology, as well as inherent biologic variability of patch test responses. Technical inconsistencies, such as variations in the amount of material applied can lead to erroneous results. The ideal test situation is a test area completely covered with the test preparation without any spreading outside that area. Excessive amounts can provoke spillover and irritant reactions, whilst inadequate dosing may, conversely, result in false-negative and doubtful reactions. The amount of allergen applied with the Finn Chamber technique should approximate to 20 mg, but, as a manually dispensed system, the amount of allergen applied is potentially variable depending on technique.²⁵ Other factors, such as the patch test system used may induce variability. The degree of occlusion and the conformity to the skin surface are different with the different systems and could be responsible for differences on the kinetics of allergen penetration. Also, the use of an appropriate vehicle is crucial as it influences the bioavailability and subsequent percutaneous penetration of the allergen. Petrolatum remains the standard vehicle for most allergens, with the exception of the TRUE Test. Earlier studies demonstrated that patch test suspensions in petrolatum contained undispersed allergen particles, and both the particle size and number differed significantly between different test substances and different manufacturers.^{26,27} This was frequently seen with metal salts, such as nickel sulphate,²⁸ but other test substances, such as disperse dyes²⁹ also produced a number of problems. The nonhomogeneous release of allergen from the vehicle may result in false-positive reactions.²⁸

Furthermore, many studies have found poor stability for some allergens.³⁰ Allergenic degradation products can be formed during storage, mostly by oxidation, as in the case of terpenes, such as limonene and linalool. In these circumstances, it may be difficult to determine the real allergenic fraction. In addition, much research is needed to define the chemical structure and to characterize the allergenic fractions of some complex allergenic substances such as balsam of Peru, colophony, or wool alcohols.

Problems associated with the applied amount of allergen, the stability and the vehicle seems to be solved with the “ready to use” delivery systems, such as TRUE Test, which has been pharmaceutically optimized concerning stability, solubility, and bioavailability of the allergens. However, only the standard series and a few additional allergens are available with TRUE Test.

The methodologic inconsistencies in patch testing may have several implications, including inappropriate diagnosis and incorrect counseling for the individual patient, as well as unfeasibility in the comparison of patch test results from different departments. Advances are being made in the optimization of patch test preparations and the dispersion of allergens and the quality of these materials has significantly improved in the last 15 years, but much work is still needed.

Validity of Testing with the Standard Series of Allergens

Most clinical cases of ACD are caused by a relatively small number of chemicals. Because of this, patients are tested with a group of 20 to 25 relevant test preparations consisting of chemically defined compounds, mixes of allergens, and natural and synthetic compounds found in the industrial and domestic settings grouped in a “standard series” as a primary screening procedure for suspected ACD patients. These series have been recommended by research groups such as the ICDRG³¹ the European and Environmental Contact Dermatitis Research Group (EECDRG),³² and the NACDG,³³ with minor changes in the different countries because of regional differences in exposure to sensitizing compounds. Their constitution is based on statistic of allergens and they are periodically revised to adapt to changes in exposure, introduction of new environmental allergens onto the market, and information regarding irritation, active sensitization, etc. Requirements to include a chemical in a standard series have been formulated by Bruze et al.³⁴ Demands on a sensitizer in the standard series are: being common in the environment; contact allergy rate above 0.5-1.0% in routinely tested CD patients; reliable patch test results, high degree of clinical relevance and minimal adverse effects, particularly patch test sensitization. When testing with these substances, it is reasonable to assume that most of the obtained positive reactions can be ascribed to contact allergy. The usefulness of this screening series has been confirmed, even when the percentage

of sensitivities detected by the standard series is variable in the different studies.^{33,35-38} In a multicenter study in 4824 consecutive patients from five European contact dermatitis departments, the sensitivities detected by the standard series alone ranged from 37 to 73% depending on the testing institution.³⁵ Patients with positive reactions only to additional allergens and negative to the standard series varied in frequency from 5 to 23% between the different centers. Sherertz and Swartz³⁶ found that 76% (499) of their patients had positive patch tests; 36% (179) of positive reactions occurred to allergens in the standard series exclusively; 24% (122) were positive only to additional allergens and negative to the standard series, and 40% (198) reacted both to the standard series and additional allergens. The authors concluded that the standard series is a useful screening tool, since of all patients who had positive reactions, 75% would have been diagnosed as having contact allergy if the standard series alone had been used. However, testing with additional allergens is also important given that more than half of these patients had at least one additional contact sensitivity that would not have been detected if supplemental allergens had not been used. Cohen et al.³³ tested 732 consecutive patients with the NACDG standard 20 allergens, the NACDG extended series and other allergens if estimated necessary. Overall, 363 patients (50%) had positive patch test reactions. Of these; 23% had positive reactions to the standard series of 20 allergens alone, 40% had positive reactions only to allergens in the supplementary group and 37% had a positive reaction to a standard series allergen and an additional supplementary allergen. Of the total cohort of 363 reactors, 221 patients (61%) were considered to have clinically relevant positive patch test reactions. Only patients with current clinical relevance were included in this group. Those patients reacting only to a standard series allergen had a high rate of clinical relevance (69%). However, they accounted for only 15.7% of patients with current clinically relevant reactions. The remaining 74% of clinically relevant reactions were detected only with the use of supplementary allergens alone or in conjunction with the standard series. The authors concluded that the screening patch testing should be done with an extended series of allergens including many from the supplementary series. Therefore, the NACDG developed an extended screening series containing more than twice the number of allergens than the original standard series.³⁷ In a multicenter study from the Informational Network of Dermatological Clinics (IVDK) in Germany,³⁸ 4140 patients were tested with the German Standard Series. Contact sensitization was diagnosed in 47% of patients tested, varying between 30 to 64% in the different centers. Forty percent of all patients proven to have contact allergy, were diagnosed using the standard series alone, whilst 20% of cases were diagnosed solely with additional allergens (occupation-specific or material brought in by the patient). Veien et al.³⁹ tested 6759 patients with the European standard series over a 5-year

period. Additional allergens were tested in 1450 of these patients. Positive reactions to the allergens in the standard series were seen in 1941 patients (29%), whilst 236 of the 1450 patients (16%) also tested with substances not included in the standard series had one or more positive reactions. Of the 1941 patients with positive patch tests, 1705 (88%) reacted only to substances in the standard series, 98 patients (5%) reacted both to substances in the standard series and to additional non-standard substances, while 138 (7%) reacted only to nonstandard substances. Therefore, most studies underline the importance of testing with the standard series, adding when necessary supplementary allergens from the complementary "aimed" trays, according to the clinical circumstance. The variations observed by the different authors may be attributed to differences in the population tested, (i.e. differences in exposure, in the number of additional substances tested, etc.) The absolute frequency of contact allergy in any population will never be known, but the more substances and products are tested, the greater will be the observed percentage of sensitization.

Validity of testing with other Nonstandardized Allergens

Most patients should be tested to a standard series, additional series or individual allergens will be selected depending on the history and the distribution of the dermatitis, the occupation and the geographic area. The characterization of a patch test allergen requires an adequate knowledge of its sensitizing capacity, its occurrence in the environment and, if possible, the results of testing of a large number of subjects. Most allergens from the standard tray and the most commonly used additional "aimed" trays are chemically defined materials of high purity and a large amount of clinical data has been accumulated concerning patch testing concentrations. When testing with these substances, it is reasonable to assume that most of the obtained positive reactions have significance and that investigation to assess relevance is warranted. In contrast, testing with nonstandard allergens, should be undertaken with caution. These may be chemically pure substances, but often they are compound products and may contain unknown components. Moreover, some components can be irritants; such is the case for many industrial products. Specialized textbooks regarding test's concentrations for many nonstandardized materials are currently available.⁴⁰ This information is of practical value as a starting point when testing with these materials. However, remember that for several of these substances, there has been little research concerning test concentrations and suitable vehicles. When testing chemicals for which there are limited data, we have to determine the appropriate strategy of testing and the valid test concentration, as we lack the information to categorically substantiate any conclusion. Therefore, patch testing with those materials may have little to contribute

diagnostically unless there is a definite clinical suggestion of their responsibility in the causation of the dermatitis. Finally, there are substances for which no information exists, except the chemical composition provided through the Material Safety Data Sheets for industrial products or the list of ingredients for household, cosmetic and toiletry products. Usually these products are technical grade chemicals; therefore, it should always be considered that they may contain unknown components. Should any substance be considered potentially irritant, an open use test may be envisaged. It should be performed with diluted substances, whose concentration can be progressively increased as far as no response either allergic or irritant appears. It is often helpful to patch test an uncommon substance at two or three tenfold serial dilution, such as 0.01% 0.1% and 1.0%. This procedure will prevent serious irritant reactions and may help to distinguish between irritant and allergic reactions.⁴¹ If an allergen is serially diluted, we usually observe a gradual reduction in the intensity of an allergic reaction, whilst an irritant reaction will tend to disappear abruptly. A gradually declining reaction, still distinctly positive at 0.01% or even 0.001%, constitutes highly suggestive evidence of contact allergy to the tested substance. It has been the usual practice to determine the "safe" or "nonirritating" test concentration for new materials, by testing in control groups. However, before any human test is performed, complete toxicologic information of the material must be procured. In addition, the control subjects should be followed up for 1 month to rule out active sensitization. It is recommended to test at least 20 control subjects based on the premise that if none reacts at the selected concentration, then, the testing is above the 95% one-tailed confidence limit. Usually, the test is performed with several concentrations, selecting the highest nonirritant concentration as the elicitation (cutoff) concentration. The highest nonirritant concentration is then applied to the subject with suspect ACD to the substance. The development of a positive patch test response with the morphologic attributes of an allergic reaction will constitute evidence of contact sensitization because of the substance.

The validity of patch testing may, therefore, be considered as good for standard allergens and allergens from many of the additional series, if tested under controlled conditions and in the proper concentration, but may be considered as poor for poorly standardized substances or for substances with unknown skin irritant potential.

Problems Derived From Testing With Allergen Series (multi-testing)

When testing with allergen series, we are, in fact, performing several individual tests with different allergens. If the cutoff concentration for each individual allergen in the series were settled at a 95% upper confidence limit, then, from a statistical viewpoint, each time we test 20 substances

in a nonsensitized person, there would be a 100% chance of eliciting a false-positive result from one of the substances tested. If we set the upper confidence interval at 99%, (i.e., assuming a false-positive response rate of 1% for each substance), we still have a 20% possibility of eliciting a false-positive result each time we test 20 substances.^{11,13} As we consider the tray of substances as a single screening test, rather than an assemblage of individual substances, we are dealing with a confidence interval of 80%, well below the conventional 95% confidence interval used in other diagnostic tests. If we wish to use a 95% confidence interval for patch-test screening and reduce the number of false positive reactions, it would be necessary to lower the cutoff concentration of the individual test substances, which will simultaneously reduce the true-positive response rate. Alternatively, we can consider reducing the number of test substances in the standard screening series to the indispensable minimum to diminish the risk of false-positive reactions. The above-mentioned concepts stress the significance of carefully assessing the clinical relevance of all positive reactions. Diepgen and Coenraads¹³ delineated another problem associated with testing multiple substances. When estimating differences in sensitization rates between two groups of subjects (e.g., between males and females or between atopics and nonatopics), we frequently perform pairwise comparisons using chi-square tests, one for each allergen tested, setting a *p*-value of 0.05 as statistically significant. In this circumstance, and for a series of only ten allergens, there is a random possibility of over 40% of finding by chance a statistically significant difference for at least one allergen between the two groups.

Problems Derived From the Reading and the Interpretation of Patch Test Reactions

Even when the proposals of the ICDRG in 1970¹⁰ standardizing the patch test readings were generally accepted and represented a substantial advance, reading of patch test responses needs to be considered eminently subjective and constitute one of the limitations of the method. Patch testing is a perceptual test, based on inspection and palpation of the test area. As any test that involves human perception and judgment, patch testing is bedeviled by variability of reporting on results. Especially, the reader's background knowledge and experience have great importance in the validity of the reported patch results. In epidemiologic studies, this variability is recognized as an inevitable consequence of the use of perceptual tests.

The classification and score grading of patch test reactions depend on descriptive morphology. The significant point in assessing a positive patch test is ascertaining whether it represents an allergic reaction or a false-positive reaction. Typical morphologic features of a positive allergic patch test reaction are erythema, edema, papules, and vesicles (or bullae). At least an erythematous infiltration and/or

papules should be present for a reaction to be considered allergic, whilst reactions that show only erythema without infiltration, called doubtful reactions, are frequently nonspecific or correspond to irritancy. Allergic patch test reactions are traditionally scored in terms of intensity, and a grading scale from 1+ to 3+ is currently accepted for ranking these allergic reactions.¹⁰ However, even when all reading systems are based on the same morphologic features, it remains some variation in the exact definition of the different grades of this scale between the different working groups. For instance, there are discrepancies in the reading of the 1+ reaction. Some groups define the 1+ reaction as homogeneous redness in the whole test area with scattered papules, whilst others only require redness and homogeneous infiltration in the whole test area. No real consensus has been reached in this matter so far.

Such minor differences of categorization may determine variations in interpretation of the responses. Bruze et al.⁴² studied the accordance in patch test readings according to the different reading systems and showed that there was good accordance among various readers, except with the NACDG system. The morphologic feature that seemed most difficult to evaluate was the papule, so, perhaps it would be convenient not to demand the existence of this feature as essential for the categorization of a patch-test reaction as allergic.

The time of patch test readings has been standardized but it has variations between different patch-test centers. Usually, the first reading is performed on day two (48 hrs) after patch test application, approximately 30 minutes after taking off the patches, and the second reading is performed at 72 or 96 hours. A delayed reading (1 week) is also recommendable because certain allergens, (e.g., neomycin, or corticosteroids, among others) may determine late positive reactions. Patch testing should be read at least in two successive opportunities, without which, their accuracy is seriously impaired. A single reading on day two (48 hrs) may determine that approximately 30% of the contact allergies detected by the standard series are missed, as compared with the number of allergies found when the test are read repeatedly up until 1 week from patch test application.⁴³ In addition, multiple readings are crucial in distinguishing false-positive irritant reactions, since the timing of these reactions is different from the allergic ones.

Problems Derived From the Assessment of Clinical Relevance of Patch Test Reactions

For clinical patch testing, validity alone is not an adequate measure of the test's utility. The confirmation of the diagnosis of contact sensitization without information regarding the relevance of the allergic reactions, fall short of its intended use. The fact that contact allergy to certain allergen(s) has been reliably demonstrated by careful patch testing does not prove that such allergen(s) is responsible

for the patient's ACD. A true positive patch test reaction only indicates that the patient has been previously exposed and sensitized to the substance. Patients may suffer major changes in their lifestyle on the basis of patch-testing results, therefore it is crucial to establish that the positive reaction is actually linked to the clinical dermatitis, either as a primary cause or as an aggravating factor. Based on the presence of a putative allergen in materials which come into contact with the skin either occupationally or during leisure activities, the pattern of distribution of the skin lesions, and the effect of elicitation by exposure and healing of the dermatitis by avoidance, positive patch-test results are judged as possible, probable or certainly relevant. According to the ICDRG criteria,^{10,44} we consider that a positive patch test reaction is "relevant" if the allergen is traced. If the source of a positive patch test is not traced, we consider it as an "unexplained positive". We refer to as "current" or "present" relevance, if the positive patch test putatively explains the patient's present dermatitis. Likewise, when the positive patch test explains a past clinical disease, not directly related to the current symptoms, we refer to this as past relevance. From a practical perspective, establishing that a positive reaction has past relevance or possible relevance does not direct the clinician to intervene directly for the very problem for which past testing was performed. Reporting data not presently relevant serves an important epidemiologic role and may be useful in preventing further outbreaks of ACD in a patient. Yet, it does not provide the information that it is essential in the management of the present problem for which the patient is being evaluated.

The determination of relevance depends primarily on the expertise of the investigator and the possibility of detecting the allergen in the environment of the patient. Many times a positive reaction is judged nonrelevant because of insufficient environmental information. We must perform a rigorous environmental evaluation, investigating the existence of allergenic exposures, characteristics of this exposure and possible concurrent factors. Relevance scores and accuracy of the assessment are significantly improved by a comprehensive knowledge of the patient's chemical environment.

If the results of the patch tests are negative for a patient for whom a diagnosis of ACD has been proposed, one has to go back to the beginning, that is, to a thoroughgoing anamnesis and physical examination. The assumed allergens should be retested (perhaps in another concentration, with another vehicle, or with another testing method) and additional allergens should be tested.^{41,45}

Besides patch testing, other types of skin tests such as open and semi-open tests, tests with product's extracts, repeated open application tests (ROAT), provocative use tests (PUT), may be required to establish a definite causative relationship between the positive patch test result and the clinical dermatitis.^{11,21,45} Use testing, such as ROAT has

significant potential in refinement of the evidence-based diagnosis of clinical relevance. This test is not standardized to the same extent and it is time-consuming, but mimics some real-life exposure situations. However, for general validation, a standardized measurement of the results of use testing like the ICDRG scoring system for patch testing is required.²¹ It has been observed to be a significant relationship between the patch test threshold and the ROAT threshold,⁴⁶ but the amount of allergen required to elicit a reaction for these two study methods is not the same. Fischer et al.⁴⁶ demonstrated that the dose per application eliciting a reaction in the ROAT is substantially lower than the dose required, eliciting a reaction in the patch test. This could be explained by the accumulation of allergen in the skin from repeated exposure and/or to the repeated stimulation of the immune system. The stronger response in the ROAT compared with the patch test threshold is relevant for risk evaluation of the elicitation potential of allergens in final products, because the same dose per unit area, eliciting a negative patch test result, might elicit a reaction when applied repeatedly in an open test.

CAN I APPLY THE TEST IN THIS SPECIFIC SITUATION? IS PATCH TESTING COST-EFFECTIVE AND SAFE IN THIS SPECIFIC PATIENT?

Whereas some studies indicate that the prognosis of ACD is poor; if the responsible allergen is identified, patient education and allergen avoidance can lead to significant improvement and even cure of the dermatitis. Accurate identification of the culprit agent and implementation of effective avoidance measures is the only significant approach in ACD treatment. Patch testing is, undeniably, the gold standard in diagnosing contact allergy, and provides a valuable mean of diagnosis that allows the physician to identify a specific chemical responsible for the dermatitis and initiate appropriate management alleviating patients' suffering without losing valuable time.⁴⁷

However, as we have discussed, the validity of diagnostic patch testing depends on the clinical circumstances, especially on a good pretest probability based on careful patients' selection. The first step in the diagnostic work out is to perform a comprehensive and standardized clinical history that covers the clinical evolution of the dermatitis and all possible etiologic factors, a complete clinical examination, and an assessment of exposure, including hazard identification, estimation of dermal exposure and risk characterization. Patch testing will be more cost-effective if we were able to fulfill a precise case definition for ACD before the test. Performing patch test as a last recourse in

patients failing to meet the case definition for ACD will hardly be cost-effective. If patch testing is performed in these patients, the practitioner should thoroughly assess the clinical relevance of all positive reactions.

The overall benefits of patch testing have been scarcely studied. Rajagopalan et al.⁴⁸ evaluated retrospectively the value of patch testing in 260 ACD patients using a standardized questionnaire and revising medical records. In this preliminary evaluation, they concluded that when patch testing is performed on patients with a prediagnosis duration of 2 months to 1 year, the postdiagnosis duration of the dermatitis was considerably decreased when comparing with the nontested patients. They suggested that patch testing should not be delayed to the extent that prognosis becomes worse in terms of chronicity of symptoms. In a subsequent multicenter observational prospective study⁴⁹, the quality-of-life outcome between patch-tested and nonpatch-tested patients was assessed using a previously validated dermatology-specific quality-of-life (DSQL) instrument. Five hundred sixty seven patients from ten centers were studied. Centers were selected to obtain a mix of stratified degrees of usage of patch testing. Data on 431 patients at the 6-month follow-up showed a significantly higher improvement in each of the DSQL domains in patch-tested patients (43% of the total group) compared with nonpatch tested subjects. In addition, a significant difference was observed in the time required to confirm the diagnosis and the proportion of subjects with confirmed diagnosis between the patch-tested and the nonpatch-tested groups.

Another important aspect to consider is patch test safety and the possibility of inducing changes in the patients' immune status. Patch testing may reactivate earlier dermatitis, boost up previous hypersensitivities, clinically silent because of a high activation threshold, elicit severe test reactions, or, what is worst, and it may actively sensitize the patients to the applied haptens. Even if active sensitization for the testing is rare, at least when testing standard allergens, we should be aware of this possibility.

Patch testing is safe and cost-effective if it is performed appropriately, patients are selected properly and a meticulous and rigorous assessment of clinical relevance of the patch test reactions is applied.

An evidence-based approach in patch testing requires an exhaustive knowledge of both clinical and diagnostic aspects of contact allergy, including the patch-test procedure and its pitfalls, as well as the potential allergens, and cross-reacting substances in domestic and occupational environments. This approach must guarantee a safe and cost-effective policy of patch testing.

What We Know

- Patch testing is currently used in clinical practice as the most important investigative and diagnostic method available for studying delayed contact hypersensitivity. It constitutes, together with a detailed clinical history and a complete physical examination, a fundamental step in the diagnostic work up of ACD.
- Several studies have shown that history and physical examination alone are not adequate to consistently and fully evaluate a patient's contact allergens. Patch testing has been shown to be significant both, in confirming contact sensitivities suspected from the clinical history and in unveiling unsuspected sensitivities.
- The outlined evidence suggests that, even if patch testing has limitations from the standpoint of its validity, it can be effectively used as a diagnostic test to establish the presence of contact sensitization to the test chemicals.
- The validity and reliability of patch testing is greater when testing allergens from the standard series, in the proper concentration and the methodology and evaluation is made according to the international guidelines such as those recommended by the ICDRG.
- If we want to maximize validity and accuracy, several aspects of the patch test procedure should be improved, including the adoption of strict criteria for the selection of patients, further standardization of the patch materials and methodology, improved use of dose response assessments, and implementation of rigorous procedures for the assessment of clinical relevance of the patch test reactions.
- Patch testing is cost-effective only if there is high pretest probability of contact sensitization. Therefore, we should always start with a careful and comprehensive clinical history, physical examination, and exposure assessment in order to produce clear-cut pretest probabilities of fulfilling the case definition for ACD, as well as better identifying the chemicals most probably relevant to the clinical dermatitis before performing the patch test.
- Patch testing results require biologic and clinical interpretation. A true positive patch test reaction only indicates that the patient has been previously exposed and sensitized to the substance and cannot be considered as a scientific proof of the patient's dermatitis unless relevance is established.
- It is indispensable to determine the relevance of the patch test reaction to the clinical situation. Patients may suffer major changes in their lifestyle on the basis of patch-testing results, therefore it is crucial to establish that the positive reaction is actually linked to the clinical dermatitis.
- When performing clinical patch testing we will always face a dilemma. Although it is true that increasing the number of tested substances will also increase the number of positive allergic reactions, it will also, because of multiple testing, give rise either to false-positives or to reactions not relevant to the specific situation. On the other hand if only small panels of chemicals are tested, selected on the basis of history of exposure, relevant allergies may be missed. This stresses the importance of always performing a meticulous assessment of the clinical relevance of the patch test reactions.
- The validity of the results will increase through the judicious use of serial dilution testing. Using a range of concentrations rather than a single concentration would be more discriminating, allowing us to better rule out false-positive reactions because of irritancy as well as establishing the elicitation threshold in allergic reactions. Ascertaining the patient's degree of sensitization may have important practical implications *vis a vis* the implementation of rational avoidance measures.
- Providing an objective proof of the allergic condition, and identifying the responsible allergen (s) patch testing is essential for a rational management of ACD patients.

METHODS

One author (GW) used PubMed to search the MEDLINE database of abstracts and full-text articles using the following key words: "melanoma," "melanoma diagnosis," "melanoma epidemiology," "melanoma risk factors," and "melanoma screening." Two authors (GW, JD) reviewed the listed articles and selected only those epidemiologic and randomized control studies from 1985 to present time that were cited in at least five other publications to be used as references in this chapter.

INTRODUCTION

Melanoma arises from the malignant transformation of melanocytes. Embryologically, melanocytes are neural crest cell derivatives that migrate to the basal layer of the epidermis during development. Melanoma most commonly occurs in the skin, although it can also arise in other locations such as the eyes, ears, gastrointestinal tract, leptomeninges, and mucous membranes.

EPIDEMIOLOGY

Melanoma is the sixth most common cancer in the United States, and the incidence has more than tripled in the Caucasian population over the last 20 years.¹ Approximately 68,720 new cases of melanoma was diagnosed in the United States in 2009² The current lifetime risk for developing melanoma is 1 in 60 Americans, a 2000% increase since 1930.

While the incidence of melanoma is increasing worldwide, the highest incidence is found in Australia and New Zealand.³ According to a recent analysis of global cancer statistics from 2002, 37.7 cases per 100,000 men, and 29.4 cases per 100,000 women were reported in Australia and New Zealand, compared to 6.4 cases per 100,000 men and 11.7 cases per 100,000 women in North America.⁴

Melanoma is uncommon in children and adolescents, and approximately 90% of these cases are in those ≥ 10 years of age.⁵ An analysis of the Surveillance, Epidemiology and End Results (SEER) database showed that the incidence in those less than 20 years of age is increasing by 2.9% per year.⁶ Melanomas in children can be more advanced lesions

with a worse prognosis, perhaps a result of a delay in diagnosis or a lack of awareness.⁷

Although melanoma accounts for 4% of all skin cancers, it causes more than 74% of skin cancer deaths. In 2009, 8,650 people are expected to die from melanoma—5,550 men and 3,100 women.² Despite screening and early detection programs, the overall mortality rate from melanoma has remained stable or continues to rise.⁸ From 1969 through 1999, mortality decreased among men and women between ages of 20 to 44 years.^{8,9} However, the mortality rate among men >65 years, who make up 20% of all cases, rose by 157% during the same period.

RISK FACTORS

Numerous studies have identified risk factors for the development of melanoma. The risk factors are both genetic and environmental, likely with some interplay between the two. The major factors include excessive sun exposure, number of melanocytic nevi, cutaneous phenotype, and family and personal history of melanoma (Table 4-1).

Sun Exposure and Skin Type

Ultraviolet radiation is the main environmental factor responsible for melanoma in individuals with lightly pigmented skin. This has been supported by studies which have demonstrated an inverse relationship between latitude and melanoma incidence.¹⁰ Green or blue eyes, blond, fair, or red hair, tendency to freckle, and inability to tan are all documented risk factors.¹¹

Several case-control studies that examined the relationship between sun exposure, sunburn, and melanoma were analyzed in a systematic review.¹² Intermittent exposure and sunburn in childhood and adolescence were strongly associated with an increased risk of melanoma, while occupational exposure did not confer an increased risk.

Number and Type of Melanocytic Nevi

Epidemiologic studies have consistently shown a higher risk of melanoma with greater numbers of melanocytic nevi. In one study, the risk of melanoma was doubled in individuals

TABLE 4-1—Risk Factors for Developing Cutaneous Melanoma

Risk	Relative risk
Greatly increased risk	
Personal history of atypical moles, family history melanoma, and greater than 75–100 moles	35
Previous nonmelanoma skin cancer	17
Congenital nevus (giant, >20cm)	15-5
History of melanoma	9-10
Family history of melanoma in parent, sibling, or children	8
Immunosuppression	8-6
Moderately increased risk	
Clinically atypical nevi (2–9)	7.3-4.9
Large number of nevi (51–100)	5.0-3.0
(26–50)	4.4-1.8
Chronic tanning with UVA (PUVA treatments [>250] for psoriasis)	5.4
Modestly increased risk	
Repeated blistering sunburns	
Thrice	3.8
Twice	1.7
Freckling	3.0
Fair skin, inability to tan	2.6
Red or blond hair	2.2
Clinically atypical nevus (1)	2.3

with 50 to 99 small nevi compared with those with less.¹³ In addition, individuals with atypical nevi are at an increased risk for developing melanoma. An atypical nevus is usually larger than common nevi and also displays some degree of color variability, such as having a tan or pink shade. It also has poorly defined or “fuzzy” outer edges. In the same study cited above, the presence of a solitary atypical nevus doubled the risk of melanoma, while having >10 atypical nevi was associated with a twelve-fold elevation in risk.

Personal History of Melanoma

A personal history of melanoma is associated with an increased risk of developing a second cutaneous melanoma.^{14,15} The risk is even higher in patients who have had two primary cutaneous melanomas, as up to 30% may have a third melanoma within 5 years.¹⁶ For patients with a history of both atypical nevi and a prior cutaneous melanoma, the risk of a second primary is higher than in those with a sporadic cutaneous melanoma.¹⁷

Family History of Melanoma

Roughly 10% of melanomas are hereditary, defined as kindreds in which melanoma occurred in two or more blood relatives.¹⁸ Genetic linkage studies have identified a familial melanoma gene, CDKN2, on chromosome 9p21 which encodes the tumor suppressor protein p16.¹⁹ Mutations in this gene have been found in approximately 50% of familial melanoma patients that link to chromosome 9p.

DIAGNOSIS

Benign pigmented lesions must be distinguished from early melanoma. The ABCDs (*asymmetry, border, color, diameter*) of melanoma provide a guide for making this diagnosis.²⁰ In general, benign lesions are symmetric, have well-defined borders, are uniform in color, and are usually <6 mm in diameter. In contrast, melanomas are asymmetric, have poorly defined borders, and are more heterogeneous, with colors ranging from tan to black, often with areas

of red, white, or blue. Melanomas are often larger than 6 mm at the time of diagnosis. The ABCD checklist is diagnostic test with good sensitivity (90 to 100%, depending on whether a positive test is defined as the presence of one, two, or three of the ABCDs).²¹

Since the origin of the ABCD acronym nearly 20 years ago, evidence has accumulated that the addition of “E” for “Evolving” will significantly improve the ability of physicians and patients to recognize melanomas at earlier stages. Evolving lesions are those noted to have changed with respect to size, shape, symptoms (e.g., itching, tenderness), surface (e.g., bleeding), or shades of color.

“E” for Evolving recognizes the dynamic nature of this skin malignancy. This is especially important for the diagnosis of nodular melanomas, which frequently present at more advanced stages (i.e., thicker tumors), thus making a significant contribution to melanoma mortality rates. Nodular melanomas frequently lack asymmetry, border irregularity, color variation, and diameter greater than 6 mm. However, in one series of 125 patients, change of the lesion (i.e., evolution) was noted in 78% of nodular melanomas.²² A study by Cassileth et al. of presenting symptoms in malignant melanoma found that changes in “size, elevation and color” were the most frequent cluster of symptoms reported by patients as catalysts precipitating medical evaluation.²³

MAJOR SUBTYPES

There are four histologic subtypes of cutaneous melanoma. These include superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. Distinction among the subtypes is based on histologic growth pattern, anatomic site, and degree of sun damage. Table 4-2 describes the epidemiologic and clinical features associated with each type.

Superficial Spreading Melanoma

Superficial spreading melanoma is the most common subtype, comprising 75% of all malignant melanomas. It is most commonly seen in individuals aged 30-50 years,

and is usually found on the trunk in men and the legs in women. Clinically, the superficial spreading type appears as a flat or slightly elevated brown plaque with variegate pigmentation. It is usually >6 mm in diameter, and may have a nodular appearance when the diameter is >2.5cm. In more advanced lesions, multiple shades of red, tan, brown, blue, black, gray, and white can be appreciated.

Nodular Melanoma

By definition, nodular melanomas are vertical growth phase melanomas.²⁴ They comprise 15 to 30% of all melanomas. They occur most often in the fifth and sixth decades of life, and are usually found on the legs and trunk. Clinically, a nodular melanoma appears as a darkly pigmented papule or dome-shaped nodule, although amelanotic variants are infrequently seen.²⁵ Rapid growth occurs over weeks to months, and this subtype is responsible for most thick melanomas.^{26,27}

Lentigo Maligna Melanoma (LMM)

LMM usually presents in the sixth or seventh decade, and is typically located on the head, neck, and arms. Most lesions begin as a freckle-like brown macule that gradually enlarges and develops darker, asymmetric foci (Figure 4-1). The radial growth phase is called lentigo maligna (LM) or Hutchinson’s freckle. The radial growth phase may last for years and never develop a vertical growth phase. Approximately 5 percent of intraepidermal lesions progress to become clinically palpable, indicating dermal invasion and transformation into lentigo maligna melanoma.²⁸ The risk of progression of LM to LMM varies with age. For a patient 45 years of age with LM, the estimated risk of developing LMM by age 75 is 3.3. For a patient 65 years of age with LM, the risk of developing LMM is 1.2%.²⁹

Acral Lentiginous Melanoma

Acral lentiginous is the least common subtype of melanoma, comprising 2-8% of all melanomas. They most commonly arise on palmar, plantar, subungual, and occasionally,

TABLE 4-2—Histologic Types of Cutaneous Melanoma

Type	Frequency(%)	Common age at diagnosis	Common Site	Clinical features
Superficial spreading	70	Mid 40s	Any	Raised border; brown lesion with pinks, whites, grays, and blues
Nodular	15	Mid to late 40s	Any	Arises from normal skin or nevus; brown to black lesion
Acral lentiginous	10	60s	Hands and feet	Flat, irregular; dark brown to black lesion
Lentigo maligna	5	70s	Face	Very irregular border; tan to brown lesion

FIGURE 4-1 Lentigo maligna melanoma. (Photo Courtesy of Ryan Ramagosa, M.D.).

mucosal surfaces. This subtype is also the most common type of malignant melanoma among Asians and dark-skinned individuals, with the sole of the foot being the most frequent site involved. Clinically, an acral lentiginous melanoma appears as a dark brown or black, unevenly pigmented patch. The sudden appearance of a pigmented band originating at the proximal nail fold (Hutchinson's sign) is suggestive of acral-lentiginous melanoma.

SCREENING

The U.S. Preventive Services Task Force reviewed the evidence in 2001, and concluded that there is insufficient evidence to recommend routine screening for skin cancer in asymptomatic patients in the primary care clinical setting.³⁰ Selective screening is ultimately the most effective in individuals with risk factors for melanoma. Compared to the general population, individuals with one or two risk factors (e.g., freckling, red or blonde hair, history of three or more blistering sunburns before 20 years of age), have 3.5 times the risk of developing melanoma, and in people with three or more risk factors, the risk is multiplied twenty-fold.³¹

In addition, detection of melanoma at an early stage saves lives; 5-year survival rates steadily decrease as the tumor thickness and stage increase. Most people with stage I lesions can expect prolonged disease-free survival and even cure, while those with thicker, advanced stage lesions (e.g., >4.0 mm) are at a higher risk to die from metastatic disease.³²

Screening examination of the entire body surface can increase the likelihood of detecting melanoma six-fold compared with partial examination. Men have more lesions on the back, and women on their lower legs, possibly because these are common areas of sunburn; screening of those sites could particularly aid early detection.³³

Skin Self Examination

A minority of individuals practice regular skin self examination (SSE), with estimates of 20%-25% in the United States.³⁴ The ability of SSE to detect melanoma and reduce morbidity and mortality has not been extensively studied. A study done by Berwick et al. reported that SSE could reduce melanoma mortality by as much as 63%.³⁵ A study in 2003 reported that regular performance of SSE was associated with a significantly reduced likelihood of having tumors >1 mm thick at diagnosis (odds ratio (OR), 0.65; 95% confidence interval (95% CI), 0.45-0.93).³⁶ The limitation of these studies is how they differ widely in their definitions of SSE and typically do not define overall practice of SSE, as specific behaviors that can be more reliably measured.

In a recent study by Swetter et al. the association between SSE practices and tumor thickness in patients with recently diagnosed melanoma was examined.³⁷ Three hundred and twenty one melanoma patients completed questionnaires on demographics and SSE practices. Patient-reported SSE was measured by routine examination of 13 specific body areas, frequency of mole examination, and use of a melanoma picture aid to assist with SSE. Patients routinely examining at least some of their skin had thinner melanomas [adjusted geometric mean tumor ratio, 0.73; 95% confidence interval (95% CI), 0.50-0.94]. Frequency of mole examination did not predict tumor thickness. Using a melanoma picture as a SSE aid was strongly associated with reduced tumor thickness (adjusted ratio, 0.75; 95% CI, 0.66-0.85 forever versus never use). A composite measure of thoroughness of SSE was the best predictor of thickness (adjusted ratio, 0.58; 95% CI, 0.36-0.75) for high versus low thoroughness.

Dermoscopy

While the ABCD rule of melanoma recognition is valuable for patient education and for all clinicians, further evaluation with dermoscopy improves the detection of melanoma. Dermoscopy refers to the use of a hand-held lens in combination with oil immersion to better view a pigmented lesion. In one report, the addition of dermoscopy for evaluation of a subgroup of clinically equivocal lesions resulted in the same high rate of specificity (99.6 versus 98.4% compared with visual examination alone), but a significant increase in positive predictive value (23 versus 6.9%).³⁸

A meta-analysis of thirteen studies³⁹ involving primarily specialist clinicians, showed that the diagnostic accuracy was significantly higher with dermoscopy than with gross visual examination (odds ratio (OR) 4.0 (95% confidence interval (95% CI), 3.0-5.1) and 2.7 (1.9-3.4), respectively). Although these studies suggested that dermoscopy had greater sensitivity for the diagnosis of MM, a randomized trial showed a 42% reduction in the number of

patients referred for biopsy in the dermoscopy arm.⁴⁰ This was consistent with the finding of a significant reduction in the benign to malignant ratio of excised melanocytic lesions from 18:1 to 4:1 (pre- and postdermoscopy eras, respectively).

Confocal Microscopy

Confocal laser scanning microscopy (CLSM) is a relatively new and advanced technique for examining pigmented lesions of the skin. CLSM obtains optical sections within intact cutaneous tissue that makes it ideally suited to the study of skin. Because melanin is refractile at near infrared wavelengths, melanocytic-derived cells are easily visualized. Preliminary studies have shown specific CLSM features of malignant melanomas and nevi that improve the diagnostic accuracy for melanocytic lesions that are difficult to diagnose.⁴¹

Langley et al. conducted a study evaluating the diagnostic accuracy of CLSM compared to dermoscopy in a prospective examination of melanocytic skin tumors.⁴² Overall, 37 melanomas and 88 nevi were studied. Morphologic CLSM criteria that were used to establish a confocal diagnosis were based on well-known criteria. Examination was performed by a single observer with

experience in CLSM. Sensitivity and specificity of dermoscopy for the diagnosis of melanoma were 89.2% and 84.1% (PPV 70.2%, NPV 94.9%), respectively. Sensitivity and specificity of CLSM were 97.3% and 83% (PPV 70.6%, NPV 98.6%), respectively. CLSM had a higher sensitivity with similar specificity compared to dermoscopy;

Early confocal microscopes were overly time consuming to use and, because of their bulky and complex configuration, could not be conveniently placed on certain anatomic areas. As a consequence, great efforts have been made to design compact instruments for use in routine clinical application. Recently, the first hand-held confocal microscope was introduced providing a small and easy to use configuration for acquisition and storage of CLSM images.

Biopsy

Suspicious lesions should undergo full-thickness biopsy. Excisional biopsy with narrow margins of 1-2 mm borders is preferred. A punch or incisional biopsy approach is appropriate when there is a low suspicion for melanoma, the lesion is large, or when it is impractical to perform an excision.⁴³ Incisional or punch biopsies should include the area of the lesion that appears most suspicious.

What We Know: Cutaneous Melanoma Diagnosis

- Incidence of cutaneous melanoma (CM) has tripled in the Caucasian population worldwide over the last two decades.
- Major risk factors for CM are:
 - Green or blue eyes; blond, red, or light hair; those with a tendency to freckle or are unable to tan.
 - Excessive ultraviolet radiation exposure in high risk individuals especially if the individual has had three or more blistering sunburns before 20 years of age
 - Greater number of melanocytic nevi or individuals with atypical nevi. Atypical nevi are usually larger than common nevi, have poorly defined or fuzzy outer edges, and display some degree of color variability including tan and pink. The presence of a solitary atypical nevi doubled the risk of CM while having 10 or more is associated with a twelve-fold increase in risk.
 - Personal history of CM. Those diagnosed with a single CM are at increased risk of developing a second and up to 30% of patients who have had two primary CM diagnoses will develop a third CM within 5 years.
 - Individuals with two or more blood relatives who have been diagnosed with CM are at increased risk.

Genetic linkage studies have identified a mutation in the gene CDKN2 in approximately 50% of familiar melanoma patients.

- The ABCDE's (Asymmetry, Border, Color, Diameter, Evolving) can be used to help identify CM. CMs are generally asymmetric, have poorly defined borders, are multicolored including tan, black, red, white, or blue, are larger than 6mm, and change size.
- Early diagnosis and prevention key to survival. Melanoma is curable if detected and surgically excised early. CM in-situ has a 99% cure rate while patients with lesions >4 mm have a 5-year survival rate of less than 50%.

Detection in those with a stage 1 lesion can expect prolonged disease-free survival or be cured while those diagnosed with thicker, more advanced stage lesions are at higher risk of mortality.

- Suspicious lesions should undergo full-thickness biopsy and an excisional biopsy with narrow margins (1-2 mm borders) is preferred. A punch or incisional biopsy can be used when there is low suspicion of melanoma, the lesion is large, or it is impractical, but should include the area that appears most suspicious.

The prognosis of melanoma is related to tumor thickness. Depth for depth, all melanomas have the same metastatic potential, regardless of subtype. Melanoma is curable if detected early and surgically excised. Melanoma in-situ has a 99% curability rate, and patients with thin lesions (< 0.75 mm) have a 5-year survival rate of > 98%. This is in contrast to patients with thicker lesions (> 4 mm) who have 5-year survival rate of less than 50%.

Diagnosis of Cutaneous T-Cell Lymphoma

Derek V. Chan, M.D., Ph.D., Sara B. Olack, Ph.D., Jennifer D. Bahner, M.D., Sean W. Carlson, D.O., and Eliot N. Mostow, M.D., M.P.H.

INTRODUCTION

Cutaneous T cell lymphomas (CTCLs) are extranodal non-Hodgkin's lymphomas arising primarily in the skin.¹ Mycosis fungoides (MF) and the more aggressive Sézary Syndrome (SS) constitute the majority of clinically encountered forms of CTCL.² Thus, the emphasis of this chapter will be on these two forms of CTCL, although other forms of CTCL will also be briefly touched upon.

The initial diagnosis of early MF is sometimes difficult, especially in early stages, as plaque and patch lesions often resemble benign dermatoses.³ Hence, from 1999 through 2004, the International Society for Cutaneous Lymphoma (ISCL) conducted a series of five meetings to review criteria and develop a method for diagnosing early MF. A report was issued in 2005, summarizing the conclusions of the meetings, and in this chapter, we utilize the findings as a foundation upon which we delve into a discussion of the evidence-based diagnosis of CTCL.³ Compared to other diseases, and certainly for those utilizing clearly defined lab values as criteria for the inclusion/exclusion of disease, the diagnosis of CTCL is more subjective, but an understanding of the evidence behind each set of criteria will hopefully benefit both the clinicians and patients.

The ISCL algorithm for the diagnosis of early mycosis fungoides includes clinical, histopathologic, molecular,

and immunopathologic criteria. A scoring system was proposed in which a score of or greater out of a total possible score of 6 was "consistent with" a diagnosis of mycosis fungoides. Each of these criteria will be reviewed separately in the sections that follow.

With respect to clinical criteria, patients received a score of 2 if they had persistent and/or progressive patches or thin plaques as well as at least 2 of the following additional criteria: lesions located in a nonphotoexposed area, variation in lesion size or shape, or poikiloderma. If patients had only 1 of these additional criteria, in addition to persistent or progressive plaques, they only received a score of 1. Histologically, if patients had superficial lymphoid infiltrates along with epidermotropism in the absence of spongiosis, as well as atypical lymphocytes, they received a histological score of 2. If patients had only atypical lymphocytes or epidermotropism in the absence of spongiosis, they received a histologic score of 1. With respect to molecular studies, if patients had a T cell receptor (TCR) gene rearrangement, they received 1 point. Flow cytometry/phenotypic analyses resulted in patients receiving 1 point if they had any of the following: > 50% loss of CD2, CD3, and/or CD5 on T cells, < 90% loss of CD7 on T cells, or discordance of epidermal and/or dermal expression of CD2, CD3, CD5, or CD7. These criteria are summarized in Table 5-1.

TABLE 5-1—Proposed Criteria for Diagnosis of Early Mycosis Fungoides

Maximum # Points	Required Finding	Additional Findings	# Points
Clinical: 2	Persistent and/or progressive patches or thin plaques	Lesions located in a non-photo-exposed area	1
	Persistent and/or progressive patches or thin plaques	Variation in lesion size or shape	1
	Persistent and/or progressive patches or thin plaques	Poikiloderma	1
Histologic: 2	Superficial lymphoid infiltrate with epidermotropism	Absence of spongiosis	1
	Superficial lymphoid infiltrate with epidermotropism	Atypical lymphocytes	1
Molecular: 1	Positive T cell receptor gene rearrangement	N/A	1

	Existence of mycosis prior to presentation	Presence of leukemic cells in blood	B Stage (T4 N0-3 M0-1)
Sézary syndrome	Rarely	Yes	2
Erythrodermic mycosis fungoides	Yes	None or very little	0-1
Erythrodermic mycosis fungoides, not otherwise specified	No	None or very little	0-1

(Adapted from a 2002 report of the International Society of Cutaneous Lymphomas.⁴)

For the diagnosis of advanced MF and SS, the ISCL issued a report in 2002 after meeting twice to discuss criteria for diagnosing erythrodermic cutaneous T cell lymphomas (E-CTCL).⁴ The proposed definitions of the various forms of E-CTCL are depicted in Table 5-2.⁴ Blood involvement grading (B1 vs. B2) is depicted in Table 5-3, with B0 signifying no blood involvement. In the following sections of this chapter, we will review some of the evidence supporting the recommendations outlined by the ISCL.

TABLE 5-3—Summary of Proposed Criteria for Evaluating B1 vs. B2 Designation in Staging of Erythrodermic CTCL. (Adapted from a 2002 Report of the International Society of Cutaneous Lymphomas⁴)

	Blood Involvement	Criteria
B1	Minimal	<ul style="list-style-type: none"> • At least 5% Sézary cells (blood smear) and positive T cell receptor gene rearrangement or other evidence of a clonal population • At least 20% Sézary cells (blood smear)
B2	Leukemic	<ul style="list-style-type: none"> • Absolute count of at least 1000/mm³ • CD4:CD8 ratio of at least 10:1 due to an increase in CD3+ or CD4+ cells via phenotypic analysis (flow cytometry) • Positive T cell receptor gene rearrangement (PCR or Southern blot) • Abnormal T cell clone by cytogenetic analysis (FISH) • Phenotypic aberrations (CD2, CD3, CD4, CD5), CD7 loss on T cells, or greater than 40% CD4⁺CD7⁻ cells

CTCL, cutaneous T cell lymphomas.

CLINICAL CRITERIA

Although research has shown that the majority of patients with CTCL do not die from their disease, the survival of patients with MF and SS has been shown to decrease with increasing skin stage.⁵ Earlier diagnosis could, therefore potentially increase survival because the risk of progressing to extracutaneous disease in MF patients increases with skin stage, although roughly 9% of early stage MF patients progress to higher stages even with treatment.^{6,7} Because recognition of early stage CTCL can be difficult, given that it may mimic other dermatoses clinically and histologically, a higher index of suspicion may be needed to initiate a more extensive work-up.^{8–10} Many of the recommendations made by the National Comprehensive Cancer Network (NCCN) regarding the essential diagnostic work-up of MF and SS are based on lower-level evidence and clinical experience.¹¹ However, there are research-based, key elements in taking a history, performing a physical examination, and ordering laboratory studies, which may facilitate the physician in making a more timely diagnosis of CTCL.

History

The index of suspicion for CTCL will vary depending on the experience of the clinician, the history of present illness and the clinical presentation. For patients suspected of having CTCL, an accurate list of medications including commencement dates should be elicited, as certain medications can produce a pseudolymphoma (Table 5-4), as well as other drug-induced reactions which may mimic CTCL.¹² Discussion of whether a trial off the medication(s) has been attempted and the response should be recorded.³ A history of prior tick bites may also be pertinent, especially in a patient with unilesional lesions, as tick bites may stimulate lymphoproliferative disorders such as a CD30+ lymphoproliferative disorder.¹³

When eliciting a history in a patient suspected of having MF, it is important to note the persistent nature of the lesions or an increase in the size or number of lesions.³ The presence of B-symptoms should also be recorded. Fever, fatigue, and weight loss may accompany certain CTCL subtypes,

TABLE 5-4—Medications which may Simulate MF or Cause or Predispose Patient to Pseudolymphoma

Fluoxetine ³⁹
Antihistamines ⁴⁰
Atenolol ⁴¹

MF, mycosis fungoides.

such as subcutaneous panniculitis-like T-cell lymphoma,¹⁵ or may suggest a systemic lymphoma with secondary cutaneous involvement. Patients with SS will also typically complain of an intense pruritus. In general, however, pruritus is nonspecific and may or may not accompany CTCL.

Physical Examination

The presentation of the patient to the physician's office will obviously dictate the work-up. The evaluation of an erythrodermic patient suspected of having Sézary syndrome will differ from the referred patient with an "atypical lymphoid infiltrate" suspicious for CTCL. This is the reasoning for presenting the typical clinical features of the CTCL

subtypes separately (Table 5-5). However, in general a complete skin examination is recommended for anyone suspected of having CTCL. Common sense mandates an examination of lymph node regions, because detection of lymphadenopathy may provide clues to an alternative diagnosis or may be used in staging purposes if a diagnosis of CTCL is confirmed. An abdominal examination should also be performed to evaluate for organomegaly, as visceral involvement may occur in later stages of disease or may be concurrent in other lymphomas with cutaneous involvement (secondary cutaneous lymphomas). Examination of the oral and nasal cavities may also be appropriate depending on the patient's presentation as CTCL sub-types may affect these areas.

TABLE 5-5—Physical Examination Findings

CTCL subtype	Typical morphology of lesions, associated skin findings	Common Distribution	Extracutaneous spread
Mycosis fungoides	Patches, infiltrated plaques, and tumors; poikiloderma and variation in size and shape are common. ³	Tendency to appear initially on non-sun exposed areas ³	Lymph node and visceral involvement may be present in later stages ¹⁴ ; can involve the oral cavity ⁴²
Folliculotropic MF	Typically patches, plaques, follicular papules, nodules/tumors, acneiform lesions ^{14,43} ; alopecic eyebrows with plaques noted to be common ⁴³	Thicker plaques and tumors may favor the head and neck region; thinner plaques and patches may be occur on the trunk and extremities ⁴³	Concurrent lymph node involvement and visceral involvement reported ⁴³
Pagetoid reticulosis	Typically presents with one 'psoriasiform' patch or plaque ¹⁴	Classically on the extremities ¹⁴	Not reported ¹⁴
Granulomatous slack skin	Patches, plaques, and skin laxity/bulky skin folds in intertriginous areas ^{14,44}	Skin laxity typically in intertriginous areas ⁴⁴ , with preferential involvement of the axillary regions ¹⁴	No evidence of definitive extracutaneous spread found in a review of the literature; reference reviewed herein reported 4 cases with no extracutaneous disease ⁴⁴
Primary cutaneous anaplastic large cell lymphoma	Single or multiple nodules, tumors, and sometimes papules, which may show ulceration; may spontaneously regress ¹⁴	No preferential anatomic site ⁴⁵	Extracutaneous spread in roughly 10% of patients, mostly with lymph node involvement ¹⁴
Lymphomatoid papulosis	Papular, papulonecrotic, and nodular skin lesions in multiple growth phases characteristic; lesions may show spontaneous regression but typically recur and are chronic ¹⁴	Mainly on trunk and limbs ¹⁴ , but may not preferentially involve any site ⁴⁶	LyP is not classically thought to spread extracutaneously; although in a small minority of patients a systemic lymphoma may be associated with a history of LyP ^{14,46}
Subcutaneous panniculitis-like T-cell lymphoma	One to several nodules and plaques ¹⁴	Preferential involvement of the lower extremities, although disseminated disease can occur ¹⁴	Extracutaneous spread rare ¹⁴
Primary cutaneous CD4+ small/medium pleomorphic T-cell lymphoma	Solitary plaque or tumor ¹⁴	Superior trunk, face, or neck ¹⁴	Lymph node involvement rare if ever as studies have shown no lymph node or bone marrow involvement ⁴⁷
Sézary syndrome	Erythroderma; frequently marked exfoliation, eyelid ectropion, marked pruritus, alopecia, edema, keratoderma, and fissuring on palms and soles; dystrophic nails common. ^{14,34}	Generalized (for erythroderma); fissuring on palms and soles ¹⁴	Lymph node involvement ¹⁴ ; bone marrow involvement rare ³⁶ ; blood involvement by definition

(Continued)

TABLE 5-5—Physical Examination Findings (Continued)

CTCL subtype	Morphology of lesions, associated skin findings	Common Distribution	Extracutaneous spread
Extranodal NK/T-cell lymphoma, nasal-type	Multiple plaques or tumors ¹⁴	Trunk and extremities; facial distribution in nasal-type ¹⁴	Cases with skin involvement may also involve the liver, spleen, bone marrow, and testes ⁴⁸
Primary cutaneous aggressive CD8+ T-cell lymphoma	Papules, nodules, and tumors with ulceration or necrosis, or with patches and plaques ¹⁴	No preferential site found in a review of the literature	Lymph nodes may be unininvolved; spread to testis, lung, and CNS reported ⁴⁹
Primary cutaneous γ/δ T-cell lymphoma	Ulcerated plaques and tumors ¹⁴	Preferential involvement of the extremities; may be disseminated ¹⁴	Lung, liver, and spleen involvement have been reported ⁵⁰ , but lymph node involvement rare ¹⁴
Primary cutaneous peripheral T-cell lymphoma, unspecified	Nodules or tumors are typically present in patients who carry this diagnosis; lesions may be solitary, localized, or generalized ¹⁴	No preferential site ¹⁴	Systemic disease may develop in patients diagnosed as having an unspecified primary cutaneous T-cell lymphoma ⁵¹
Adult T-cell leukemia/lymphoma smoldering variant or cutaneous-type	Nodules or tumors, generalized papules, or plaques ¹⁴ ; may rarely present as solitary nodule ⁵²	No preferential site found in a review of the literature.	Cases classified as a cutaneous-type of ATLL have been described with only cutaneous involvement (i.e. lack of lymph node or blood involvement) ⁵² ; however, skin lesions in ATLL are generally associated with disseminated disease ¹⁴

MF, mycosis fungoides; LyP, lymphomatoid papulosis; ATLL, adult T-cell leukemia/lymphoma

Laboratory and Ancillary Testing

A complete blood count (CBC) with differential and comprehensive metabolic panel (CMP) is indicated in the evaluation of patients with suspected CTCL. These tests may be beneficial in detecting other diseases (e.g., hepatitis or renal disease), or in distinguishing CTCL subtypes. For example, ATLL, which may resemble MF, may present with hypercalcemia and leukocytosis.¹⁴ In order to diagnose SS based on the proposed criteria formulated by the International Society for Cutaneous Lymphomas (ISCL), erythroderma accompanied by at least one of the following must be present: (1) an absolute Sézary count of ≥ 1000 cells/mm³; (2) a CD4/CD8 ratio ≥ 10 because of an increase in CD3+ or CD4+ cells by flow cytometry; (3) abnormal expression of T-cell markers by flow cytometry; (4) elevated lymphocyte count with a hematologic-based T-cell clone; (5) or a “chromosomally abnormal T-cell clone”.⁴ Based on the proposed ISCL criteria alone, erythrodermic patients suspected of having SS will require a CBC with differential, flow cytometry, a possible blood smear, and/or a Southern blot or PCR to detect a T-cell clone. The NCCN guidelines support the acquisition of the aforementioned studies in nondiagnostic skin-biopsies of patients with suspected MF and SS, especially in those patients who present with erythema covering greater than 80% of the body surface area.¹¹

A lymph node biopsy may also be performed when a definitive diagnosis is lacking.¹¹ Before a biopsy of a suspected skin lesion is performed, it may be important to

discontinue topical steroids for a short period of time prior to the biopsy (i.e. anecdotally for approximately two weeks prior to the biopsy). Skin scrapings may also be performed in select cases as tinea corporis may mimic MF.³

HISTOLOGIC

The initial evaluation of MF represents a diagnostic challenge for dermatopathologists. The classic histopathologic appearance of MF in its advanced plaque stages demonstrates: (1) lymphocytes with marked cellular atypia and cerebriform nuclei (“Sézary cells”), and (2) a band-like lymphocytic infiltrate in the upper dermis, the dermal-epidermal junction, and epidermis (“epidermotropism”).¹⁵ While histologic evaluation of advanced MF is relatively straightforward, in its early stages, the histologic features of MF are notoriously difficult to differentiate from benign inflammatory dermatoses and lymphoid hyperplasias.^{3,16} Moreover, MF evolves slowly, and patients often carry a long-standing diagnosis of eczema or parapsoriasis.¹⁶ For these reasons, the reproducibility and concordance rates among pathologists in the diagnosis of early MF are low.^{17,18}

In an effort to standardize reporting of MF lesions, The International Society for Cutaneous Lymphoma has advocated an integrated grading system developed by Guitart et al. in 2001 for the histologic evaluation of biopsies suspicious for MF.³ This grading system, summarized in Table 5-6, is based on the sequential evaluation of major and minor histologic criteria reflecting the pathologist’s degree

TABLE 5-6—Criteria for the Diagnosis of Mycosis Fungoides¹⁶

I. Major Criteria	
Low Power	Density
0 = Scant infiltrate	
1 = Mild perivascular superficial infiltrate	
2 = Moderately dense perivascular or band-like infiltrate without thickening of papillary dermis	
3 = Dense, confluent infiltrate with thickening of the papillary dermis and involvement of the reticular dermis	
Medium Power	Epidermotropism
0= None	
1 = Focal basal epidermotropism and/or single Pautier microabscess or a few couplets/triplets or scattered lymphocytes without spongiosis	
2 = Extensive basal epidermotropism and/or two or more Pautier microabscesses	
3 = Extensive epidermotropism with more lymphocytes than keratinocytes	
High Power	Atypia
0 = No atypia	
1 = Mild atypia (small and intermediate cells)	
2 = Moderate atypia (small, intermediate, <i>plus</i> large atypical cells)	
3 = Uniformly atypical or pleomorphic cells, many mitotic figures, few small round reactive lymphocytes. Lymphocytes are mostly intermediate or large in size.	
Minor Criteria	
1=Reticular fibroplasia of the papillary dermis around single lymphocytes (wiry collagen)	
1 = Primarily low-grade intraepidermal atypical lymphocytes	
2 = Primarily high-grade intraepidermal atypical lymphocytes	
1 = Lymphocytic infiltrate <i>without</i> inflammatory features:	
— edema of the papillary dermis	
— mixed inflammatory infiltrate (eosinophils, PMNs)	
— spongiosis	
— margination of neutrophils without prominent endothelial cells	

of diagnostic certainty. Diagnosis is obtained by adding the component scores. Based on the total score, lesions are evaluated as: (1) perivascular/interface lymphocytic dermatitis (total score = 0-2 points); (2) atypical lymphocytic infiltrate (MF cannot be excluded) (total score = 3-4 points); (3) atypical lymphocytic infiltrate suggestive of MF (total score = 5-6 points); or (4) MF (total score = 7-13 points).¹⁶

Guitart et al. showed improvement in the agreement rate among pathologists trained to use this grading system (precision rated kappa = 0.854), as compared to independent assessment alone (precision weighted kappa = 0.630).¹⁶ However, as is true of all of the histopathologic studies to date, the Guitart grading system has not yet seen widespread use or been validated by others.³

Only three studies since 2000 have examined the efficacy of histologic criteria visible on hematoxylin and eosin staining in diagnosing early MF.¹⁸⁻²⁰ These retrospective case series used univariate analyses to determine significant criteria distinguishing early-MF from non-MF lesions. The sensitivity, specificity, and results of univariate analysis in these studies are summarized in Table 5-7. Histologic features that were specific for early MF in at least two of the three studies included Pautrier's microabscesses and haloed lymphocytes. Features that were sensitive for early MF in at least two of the three studies included monomorphic lymphocytic infiltrates and disproportionate epidermotropism. Two studies examined whether histologic criteria that were shown to be significant on univariate

analysis had additional discriminating power on multivariate analysis. Naraghi et al. found that no criteria had additional discriminating power, while Santucci et al. found that five criteria were independently associated with early MF cases ($p < 0.001$): epidermal medium-large cerebriform cells, dermal medium-large cerebriform cells in clusters, absence of papillary dermis fibrosis, epidermotropism with lined single cells, and absence of dermal blast-like cells.^{18,19}

The efficacy of immunohistochemical staining in diagnosing early MF is an emerging area of interest. In a retrospective study of T cell markers on paraffin-embedded sections of MF lesions and benign inflammatory dermatoses, Cotta et al. showed that CD7 immunolabeling was

significantly lower in the MF group compared to the benign dermatoses group ($p = 0.04$). In the MF lesions, the difference between the number of CD3- and CD7-positive cells was significant (86.45% for CD3 and 53.87% for CD7; $p < 0.001$), while in the benign inflammatory lesions, there was no significant difference (79.09% for CD3 and 73.63% for CD7; $p = 0.669$).²¹

Finally, subsequent to the International Society for Cutaneous Lymphoma report, a study by Ismail et al. reviewed a group of 92 patients with suspected MF to definitive MF, graded on a scale from 1 (not MF) to 7 (definitive MF), on the basis of clinical and histologic data.²² They then correlated surface CD7 expression or loss by flow

MF, mycosis fungoides; NR, not reported.

cytometry, the presence, or absence of a TCR gene rearrangement, and CD45RB⁺/CD45RO⁻ staining pattern in formalin-fixed paraffin embedded biopsy samples with the numerical score for each of the 92 patients.²² They found that in cases of definitive MF, > 90% CD7 loss (100.0% of patients) correlated well with high CD45RB expression but marked CD45RO loss in the epidermotropic atypical lymphocytic cells in biopsied lesions (85.5% of patients) and less so with a positive TCR gene rearrangement

(57.1% of patients).²² In cases of probable MF, such as in patients with a score of 4, > 90% CD7 loss (83.3% of patients) again correlated well with CD45RB positivity but CD45RO loss in epidermotropic cells (83.3% of patients) and less so with positive TCR gene rearrangement studies (58.3% of patients).²² These results (Figure 5-1) suggest that CD45RB and CD45RO immunostaining in formalin fixed paraffin embedded sections could be proposed as a future criterion to aid in the diagnosis of MF.

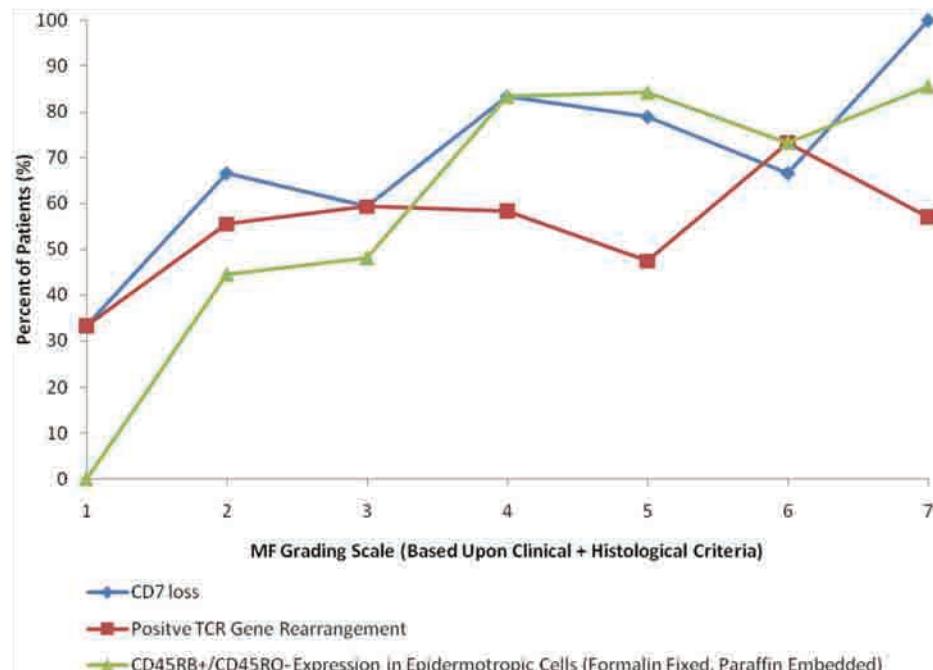

FIGURE 5-1 Summary of data comparing MF grade with the percentage of patients with > 90% CD7 loss by flow cytometric analysis of cells from frozen biopsies of lesions, positive TCR gene rearrangements, and a specific pattern of marked CD45RO loss but CD45RB positivity in epidermotropic cells.²²

MOLECULAR

As noted in the introduction, in the early stages of cutaneous T-cell lymphoma, clinical diagnosis is difficult. The lesions in early CTCL can be difficult to distinguish from benign inflammatory dermatoses, and histopathologic distinction between CTCL and benign lymphocytic infiltrates can be challenging. Hence, the use of validated diagnostic tools to aid in distinction of these diseases. While immunophenotypic findings (discussed in following

section) can help distinguish benign from malignant processes, they are frequently insufficient for definitive diagnosis. Demonstration of clonality via T cell receptor gene rearrangements further supports a diagnosis of malignancy.

There are several polymerase chain reactions (PCR)-based clonality assays available for detection of T-cell clonality. Each method has unique advantages and drawbacks.²³ A Medline search of “TCR gene rearrangement CTCL” revealed 52 results. Table 5-8 summarizes the applicable studies.

CYTogenetic studies

Conventional cytogenetic studies are of limited use in primary cutaneous T-cell lymphomas, because of the low mitotic index of CTCL clones and poor morphology of their mitoses. Furthermore, in early stage mycosis fungoïdes, peripheral blood is often not involved; karyotyping of skin samples is difficult because the tumor cells are terminally differentiated and contaminated by large numbers of reactive cells. However, in patients with advanced CTCL, chromosomal abnormalities have been reported in peripheral blood lymphocytes.²⁴ Such karyotypic changes have been reported to be associated with a worse prognosis.²⁴ Table 5-9 summarizes the applicable studies.

PHENOTYPIC STUDIES

Flow cytometry may be used in cases that are difficult to interpret. A PubMed search was conducted on flow cytometry in the context of CTCLs. Table 5-10 summarizes the findings from some of the studies that have examined surface marker expression in mycosis fungoïdes and

TABLE 5-11—CD3^{dim} Expression in Mycosis Fungoïdes and Sézary Syndrome²⁵

	# of Patients	Source
MF/SS	4 of 4	Blood ± bone marrow or lymph node
MF/SS	2 of 2	Lymph node ± bone marrow
No evidence of MF/SS	0 of 14	Blood ± lymph node

MF, mycosis fungoïdes; Sézary syndrome.

anaplastic large cell lymphoma. The remainder of this section will focus on specific markers.

CD3

CD3 is a marker primarily restricted to T lymphocytes. Reduced expression of CD3 is often seen in T lymphocyte populations from blood, bone marrow, or lymph nodes in CTCL, MF-type or SS, and the use of the term “CD3^{dim}” to refer to T cell populations with reduced (but not absent) expression of CD3 has been proposed.²⁵ Table 5-11 summarizes the findings by Edelman and Meyerson. The use of CD3^{dim} versus CD3⁺CD7⁻ lymphocyte populations for the detection of MF/SS has also been studied. Patients without evidence of MF/SS averaged 5.5% CD3⁺CD7⁻ cells, suggesting that the use of CD3^{dim} may more accurately estimate the true number of circulating abnormal lymphocytes, in cases where there are not a lot of truly abnormal lymphocytes, as CD3⁺CD7⁻ lymphocytes may also be present in benign dermatoses^{25–27}.

CD4 & CD8

Altered expression of CD4 relative to CD8 can also occur in CTCL.²⁸ As noted in the introduction, the ISCL has proposed a CD4:CD8 ratio of greater than 10:1 as a criteria for SS.⁴ It has been suggested that a CD4:CD8 ratio greater than 10:1 occurs in between 60% to 80% of patients with SS.²⁹ One study has shown that SS patients do indeed have elevated CD4:CD8 ratios compared to those with MF, benign dermatoses, and unaffected individuals.³⁰ Table 5-12 summarizes these findings. In contrast, an earlier study investigated the CD4 and CD8 surface markers in the peripheral blood of patients with CTCL and found elevated CD4:CD8 ratios in patients with SS as well as MF (Table 5-13).³¹ Compared to normal controls and individuals with psoriasis, atopic dermatitis, or chronic dermatitis, the SS patients had CD4:CD8 ratios averaging 31.4, followed by the MF patients with ratios of 9.4.³¹ In contrast, patients with psoriasis,

TABLE 5-10—Summary of Phenotypic Findings by Flow^{30,32,77}

	CD2	CD3	CD4	CD5	CD7	CD8	CD26	CD30
MF	+	dim/+	+	+	-	-	-	-
ALCL	+++	++	-/++	+	++	+/-	—	+

TABLE 5-12—CD4:CD8 Ratios in Peripheral Blood are Elevated in Patients with Sézary Syndrome Compared to Patients with Mycosis Fungoides and Benign Dermatoses³⁰

	Mean CD4:CD8 Ratio	# of Patients
SS	21.5	28
MF	2.4	9
Benign Dermatosis	1.3	7
Control	3.3	12

MF, mycosis fungoides; SS, Sézary syndrome.

atopic dermatitis, or chronic dermatitis had CD4:CD8 ratios less than or equal to 3.1.³¹ These data suggest that individuals with CTCL have elevated CD4:CD8 ratios compared to other inflammatory diseases. The proposed criterion of a ratio of 10:1 is hence, in line with these findings.

CD7

CD7 loss has also been reported in patients with SS. One study noted a partial or complete loss of CD7 in 86 of 112 (76.8%) SS patients as the only aberration.³⁰ In another study, CD4⁺CD7⁻ cells were elevated in many SS/MF patients compared to normal controls.³² This study noted, however, that about a quarter of the patients with elevated CD4:CD8 ratios had CD7⁺ abnormal cells, suggesting that up to a quarter of such patients could be missed by relying on CD7 loss only.³² The authors also concluded that the lack of a large population of CD4⁺CD7⁻ cells in the context of a normal CD4:CD8 ratio is not diagnostically useful.³² A CD4⁺CD7⁻ cell population in the context of an elevated CD4:CD8 ratio would, therefore presumably be more useful in the diagnosis of MF/SS.³²

CD26

CD26 (dipeptidyl peptidase IV (DPP IV)) loss has also been proposed as a marker of MF/SS cells^{29,33}. In a recent study with 179 individuals, CD26 loss on peripheral blood

TABLE 5-14—CD26 Loss in Peripheral Blood in Patients with SS, MF, and Benign Dermatoses³⁰

	Percent CD26 negativity based on flow cytometry
SS	59.30%
MF	33.30%
Benign Dermatosis	14.20%

MF, mycosis fungoides; SS, Sézary syndrome.

lymphocytes was greater in SS versus MF versus benign dermatoses (Table 5-14).³⁰ Furthermore, another study looked at CD4⁺CD26⁻ cells in patients with MF, SS, erythrodermic inflammatory skin disorders, and normal controls.²⁹ In this study, the percent of CD4⁺CD26⁻ lymphocytes was higher than 30% in 13/14 of B1-MF patients.²⁹ The percent of CD4⁺CD26⁻ lymphocytes was higher than 40% in all SS cases.²⁹ However, all normal controls, individuals with erythrodermic inflammatory skin disorders, and individuals with B0-MF disease always had percentages lower than 30%.²⁹ Taken together, these two studies appear to support a cutoff around 30% for disease involving the blood. Of note, the first study discussed did not delineate between B0-MF and B1-MF, and hence, it is possible that any differences between the two subgroups of patients without MF with respect to CD26 were not appreciated, as was the case with the second study.

CLOSING

As depicted above, an accurate diagnosis of CTCL may be challenging. Multiple diagnostic modalities may be necessary to arrive at a definitive diagnosis. Although the diagnosis may be made, determining the full extent of disease and correct staging involves additional tests. Rosen et al. suggested the following tests in the initial evaluation of suspected CTCL: “CBC with differential, chemistry panel, LDH, skin biopsy for histopathology, immunophenotyping, and TCR gene analysis, blood smear for Sézary cell count, flow cytometry: T-cell subsets, CD4/CD8 ratio, TCR gene analysis (skin, blood, lymph node), lymph node biopsy of palpable nodes, imaging: CT/PET scans (chest, abdomen, pelvis), bone marrow biopsy, and serologic tests: HTLV-1, HIV”³⁴.

Keehn, et al. noted, “further clinical evaluation of CTCL patients includes a complete history and physical examination, emphasizing the types of skin lesions, body surface area, lymph node, liver, and spleen involvement. Baseline tests should include a complete blood cell count; additional tests that may be useful in staging patients with clinically advanced MF include peripheral blood flow cytometry for T-cell subsets, serum chemistries (liver and renal function tests, calcium, phosphorus, uric acid, and lactate dehydrogenase), chest radiograph, and biopsy of palpable lymph nodes. Staging procedures for patients with advanced disease would also include computed tomography (CT) scan of the neck, abdomen, and pelvis, and also

TABLE 5-13—CD4:CD8 Ratios in the Peripheral Blood of Patients with SS, MF, or Benign Dermatoses³¹

	CD4:CD8 Ratio (mean)	s.d.	# Patients
SS	31.4	24.1	8
MF	9.4	5.9	4
Atopic or Chronic Dermatitis	3.1	1.4	14
Psoriasis	2.2	0.5	6
Normal Controls	2.1	0.4	10

MF, mycosis fungoides; SS, Sézary syndrome.

What We Know

- Cutaneous T-cell lymphoma (CTCL) often presents with a spectrum of clinical signs and symptoms and can be difficult to diagnose because of similarities to more common inflammatory skin conditions.
- Evidence exists to improve the sensitivity and specificity of the diagnosis of CTCL, including scoring systems that are referenced and reviewed in this chapter.
- Clinically, persistent and/or progressive patches or thin plaques as well as at least two additional criteria are required. Lesions located in a non-photoexposed area, variation in lesion size or shape, or poikiloderma can be important.
- Histologically, a superficial lymphoid infiltrate along with epidermotropism in the absence of spongiosis, as well as atypical lymphocytes, are significant.
- T-cell receptor gene rearrangement studies, if positive, offer additional support for the diagnosis
- Flow cytometry/phenotypic analyses can be used, using specified criteria, to assist in the diagnosis.
- A total body skin exam with attention to subtle areas of dermatitis and/or pigment change, as well as an assessment of lymph nodes, is important for any patient with potential CTCL
- The biopsy specimens used for the diagnosis should be sent to a pathologist/lab that you trust to have experience and interest in the diagnosis, and clinical-pathologic correlation can be very important.
- Counseling patients and other caregivers about the somewhat complicated diagnostic criteria for CTCL can be helpful in helping them understand the need for getting appropriate studies as well as anticipating potential ambiguities or delays in the initial diagnosis.

possibly bone marrow biopsy.”³⁵ Data from Sibaud et al. argue against the need for bone marrow examination in MF and SS patients.³⁶

In the end, the evidence-based diagnosis of CTCL is complicated because there is no one “gold standard” for diagnosis, and there are multiple data points that have some level of subjectivity. Still, consensus groups have come up with criteria to assist the clinician and patient and we believe this chapter may provide additional material to help the interested reader further understand this topic.

Diagnostic Criteria for Cutaneous Lupus Erythematosus

Christopher B. Hansen, M.D., and Richard D. Sontheimer, M.D., Ph.D.

INTRODUCTION

Lupus erythematosus (LE) is a systemic autoimmune disorder associated with polyclonal B cell activation that has heterogeneous clinical expression. The skin is a frequent target organ. The term “LE related skin disease” is generally used in a broad fashion to represent the many different types of cutaneous lesions that occur in LE patients. Cutaneous LE refers specifically to the forms of skin disease that are unique to lupus patients and share common histologic features.

Patients that present with cutaneous manifestations of lupus are best understood as existing along a spectrum of disease from no apparent systemic involvement (skin only lupus) to severe life-threatening systemic disease. Recent epidemiologic evidence suggests that patients with cutaneous LE that fail to meet criteria for systemic LE are at least as prevalent as those designated as having systemic LE.¹

Historically, cutaneous findings were the hallmark of LE and presently they remain a key component for several reasons. Skin changes may be the initial, or most easily recognized, feature of a disease that can target vital internal organs. In addition, untreated or undertreated skin disease may lead to erythema, dyspigmentation, and scarring in cosmetically sensitive areas.² The ability to make a correct and timely diagnosis of cutaneous LE, therefore, is crucial in terms of the ongoing evaluation and treatment.

The diagnosis of cutaneous LE is not always straightforward. Clinicians and specifically dermatologists are at times confronted with patients that seemingly have nonspecific skin lesions that may be photo-exacerbated along with nonspecific systemic complaints. Complicating this is the fact that many rheumatic diseases like LE can evolve over time and may not initially present in “full bloom.” Because of the heterogeneity of cutaneous LE the diagnosis of lupus is frequently entertained when creating a complete differential diagnosis. While clinical gestalt may be helpful, clinicians increasingly recognize the preference for a more evidence-based approach in making the diagnosis. In this scenario, the following research questions among others could be asked:

Research Questions

1. Are there established diagnostic criteria for cutaneous LE?
2. What clinical features or diagnostic tests are most helpful to establish a diagnosis of cutaneous LE?
3. What evidence, if any, is published about the predictive value of these tests?
4. How specific are certain histologic features for cutaneous lupus?
5. Is there reliable testing to distinguish different subtypes of cutaneous LE?

For a variety of reasons, evidence-based trials in all aspects of cutaneous LE have been at best sparse. The level of evidence for the majority of what will be discussed in this chapter comes from combined clinical experience from “experts” in the field. While there has been much discussion, and some attempt, to create evidence-based diagnostic criteria for cutaneous LE³, none have been validated in larger studies. Therefore, there is no single clinical feature or test that absolutely “clinches” the diagnosis of cutaneous LE. In the absence of validated criteria, cutaneous LE remains a clinical diagnosis correlated with the presence of characteristic histologic features seen in affected skin. For example, serologic (such as an ANA test) or immunofluorescence testing are often employed to strengthen, but are not strictly required for diagnosis.

The purpose of this chapter will be to review the published evidence regarding the diagnostic evaluation of cutaneous LE from a clinical, histologic, and laboratory standpoint. This should allow the clinician an understanding of the level of evidence available for different diagnostic methods. This chapter will focus on the diagnosis of cutaneous LE and not the relationship between cutaneous LE and systemic disease, nor any predictive testing in that regard.

CLINICAL FEATURES OF CUTANEOUS LE

The ability to make a diagnosis of cutaneous LE by definition requires the presence at some point in time of an

active skin lesion created by local autoimmune activation. While this statement seems obvious, the reader must remember that LE can and does manifest without cutaneous involvement. In addition, patients with LE can develop skin disease that may not be directly related to their underlying disease process.

As mentioned, the clinical features of cutaneous LE are variable and different presentations have been identified with an increased risk of scarring or with an increased likelihood of internal disease.⁴ The idea of a classification system for LE-related skin disease was recognized. The method and terms used have been debated over the years. For the purposes of the remainder of this chapter we will use the well recognized Gilliam classification to discuss the diagnostic approach to each subtype.⁵ (Table 6-1) As part of this classification, LE-related skin disease is divided into two broad categories: lupus-specific and lupus nonspecific skin disease. Lupus erythematosus (LE)-specific skin disease refers to those lesions that have the characteristic histologic changes of LE, which will be discussed later in this chapter. LE nonspecific skin disease refers to those cutaneous lesions that are related to the patient's underlying autoimmune disease but do not share the characteristic histologic features of LE (e.g., cutaneous vasculitis).

Urticaria
LE-non specific bullous lesions
Others

(Adapted from Costner MI.⁴)

Lupus erythematosus-specific skin disease is further divided into three broad categories based on clinical and histologic features. Acute cutaneous lupus (ACLE), subacute cutaneous lupus (SCLE) and chronic cutaneous lupus (CCLE).⁶ These subtypes are associated with different patterns of risk for systemic LE disease activity. There is considerable variability in terms of cutaneous presentation within each of these groups. Some cutaneous LE patients may manifest more than one type of cutaneous LE or have skin lesions that are indeterminate (don't fit well into any category).

ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS (ACLE)

The localized form of ACLE has classically been termed a "malar rash" or "butterfly rash". This refers to the confluent symmetric erythema that occurs over the malar eminences and bridge of the nose and sparing the nasolabial folds. It carries a strong association with systemic disease and if present qualifies as one of the 11 American College of Rheumatology (ACR) classification criteria for systemic LE.⁷ (It is important to understand that these ACR criteria were developed for the classification of SLE for the purposes of clinical research studies. They were not intended to serve as diagnostic criteria in clinical settings.) In large cohorts, it is a feature in 20–60% of patient with systemic LE.⁸ Rather than confluent erythema, the eruption may begin as erythematous papules in a similar distribution. There is also a more generalized variety that may occur as a morbilliform or exanthematous eruption on the trunk and extremities.

The diagnosis of ACLE based on the above features is often made without a biopsy. However, there are many other causes of malar erythema that have been reported as clinical mimics of ACLE including rosacea, tinea facie, dermatomyositis, photodrug reaction, polymorphous light eruption, acute graft-versus-host disease, cutaneous tuberculosis, and leishmaniasis. There are currently no evidence-based systematic studies that clinically differentiate among these differential diagnosis entities.

Rosacea deserves special mention as a clinical mimicker of ACLE. In a study of patients referred to a dermatology clinic for treatment with a presumptive diagnosis of LE, there were 21 (6.7%) who were in fact diagnosed as having a different dermatologic condition. Of these, 16/21 (76%) had rosacea based on biopsy and/or clinical features. Many of these patients did have at some point, low positive ANA titers. This would suggest that at times rosacea can be difficult to clinically differentiate from ACLE and clinicians may give too much weight to serologic testing.⁹

SUB-ACUTE CUTANEOUS LUPUS ERYTHEMATOSUS (SCLE)

SCLE consists of nonscarring papulosquamous or annular skin lesions that occur in a characteristic photo-distribution.

These two morphologies can appear together in the same patient and appear to have a similar prevalence in case series. Interestingly SCLE usually spares the central face. The individual annular lesions often have an active border that can demonstrate vesiculation and crusting. While SCLE does not scar it can result in marked “vitiligo-like” hypopigmentation. Photosensitivity is a common feature of SCLE, occurring in 85% of patients.^{10–11}

The clinical differential diagnosis for SCLE includes psoriasis, drug eruptions, actinic granuloma annulare, erythema multiforme, and other forms of cutaneous lupus. There are again few studies that have attempted to differentiate SCLE from other dermatologic conditions based on clinical features. However, there are a few comparisons of the clinical features of SCLE compared to CCLE. In one study, a comparison of the clinical, histologic, and immunofluorescent distinctions between SCLE and CCLE in 27 patients was performed.¹² Clinical features most characteristic of SCLE rather than DLE included superficial, nonindurated, nonscarring lesions, and photosensitivity. The lack of induration of an active lesion was the single most helpful finding to clinically distinguish SCLE from CCLE.

When evaluating a patient with suspected SCLE, approximately half of patients will meet four ACR criteria for SLE but only 10–15% of SCLE patients will develop severe manifestations of SLE (i.e., lupus nephritis).¹¹ The presence of double-stranded DNA antibodies and overlapping cutaneous features of ACLE could also indicate a higher risk for clinically significant systemic LE disease activity and damage in a SCLE patient. SCLE can also overlap with other autoimmune disorders, particularly Sjögren's syndrome.¹³

In 1985, Reed and coworkers reported five patients who had not previously experienced features of SLE or cutaneous LE who developed clinically, histopathologically, and immunopathologically typical SCLE skin lesions while taking hydrochlorothiazide.¹⁴ Since that time over 100 cases of suspected drug-induced SCLE have been published.¹⁵ The list of associated medications continues to grow but common culprits include antihypertensive agents and oral terbinafine.¹⁶ At this time, there are no biologic markers to reliably distinguish drug- induced from idiopathic SCLE. The diagnosis is made with clinical suspicion and resolution of the condition upon withdrawal of the medication. In the appropriate clinical setting drug-induced SCLE should be considered, particularly in patients with onset over 50 years of age.

CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS (CCLE)

Chronic cutaneous lupus erythematosus refers to cutaneous LE lesions that differ clinically from SCLE and ACLE in their propensity to be chronic and scarring. In the spectrum of CCLE are entities such as discoid LE, chilblain LE, and LE panniculitis/LE profundus. For the purposes of this chapter, only discoid LE lesions will be discussed.

The most common form of CCLE is termed “classic” discoid LE. “Classic” discoid LE lesions typically begin as red-purple macules that over time usually evolve into larger, coin shaped plaques with prominent, adherent scale extending into hair follicles. Eventually the lesions tend to develop central scarring and depigmentation. In more darkly pigmented individuals, characteristic postinflammatory disturbances are seen—hyperpigmentation at the active borders and hypopigmentation at the inactive centers. The most typical areas of involvement include the face, scalp, and ears. Some patients will develop more disseminated lesions on the upper trunk, extensor arms, and even legs. It has been verified in larger cohorts that discoid lesions rarely occur solely below the neck. There are less common clinical variations of discoid lesions that include hypertrophic discoid LE, mucosal discoid LE, and discoid LE/lichen planus overlap.

The differential diagnosis for discoid LE lesions is large and depends on the stage of development and location. Early lesions may be clinically similar to tinea, sarcoid, contact dermatitis, seborrheic dermatitis, lichen planus, or psoriasis. More advanced lesions may resemble nonmelanoma skin cancers, hypertrophic lichen planus, scarring infectious processes such as tuberculosis or leishmaniasis, or even depigmenting conditions such as vitiligo or morphea. One useful clinical feature that is often present in more advanced discoid lesions is follicle-sized keratotic spikes sometimes referred to as “carpet tacks.” Whether this is a true pathognomonic feature of discoid lesions has not been studied.

IMMUNOHISTOLOGIC FEATURES OF CUTANEOUS LE

Histologic examination is critical in establishing a diagnosis of cutaneous LE. Like most inflammatory conditions in the skin, there is no single histologic feature that is diagnostic for LE. “LE specific histology”, as previously discussed, does not imply that the characteristic histologic changes seen in LE-specific skin disease may absolutely not be seen in any other cutaneous disease process. It is a term that allows clinicians to classify types of cutaneous lesions commonly seen in LE patients. LE-specific skin disease is characterized by a lymphocytic vacuolar interface dermatitis.¹⁷ The intensity of the infiltrate and additional histologic features can vary. The capacity to distinguish among the different types of LE specific skin disease based on histologic features is more controversial. Attempts have been made to determine to what degree specific histologic features associate with specific subtypes of cutaneous LE. Features such as: epidermal atrophy, hyperkeratosis, follicular plugging, and mucin deposition have been examined. The ability of a blinded dermatopathologist in two different studies to correctly identify the correct clinical subtype of cutaneous LE based on histologic features alone is quantified in Table 6-2.^{18–19} These data would suggest that histologic differentiation of

TABLE 6-2—Clinical/Histopathologic Correlation of Subsets of Cutaneous Lupus

	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value
CCLE (n=66)	64%	67%	72%	57%
SCLE (n=48)	54%	74%	60%	69%

N=114, CCLE- Chronic cutaneous lupus erythematosus, SCLE- Subacute cutaneous lupus erythematosus.

clinical subtypes of cutaneous LE is not reliable based on the features examined in these studies.

In addition to routine histology, immunopathology has been employed for several decades for the diagnosis of cutaneous LE. The test has been used both to aid in the diagnoses of cutaneous LE by sampling lesional skin and at times to assess risk for systemic LE disease activity by seeking to identify immunoreactants (IgG, IgM, IgA, and/or C3) displayed in a band-like fashion at the dermal-epidermal junction of nonlesional skin (i.e., “lupus band test”). This chapter will focus on immunopathology in lesional skin to assist the diagnosis of cutaneous LE and not systemic disease.

The usefulness of direct immunofluorescence microscopy in the diagnosis of cutaneous LE has been debated. The chief problem being that similar patterns of immunoreactants have been reported in lesional skin from many conditions including dermatomyositis, porphyrias, granuloma annulare, necrobiosis lipoidica diabetorum, amyloidosis, graft versus host disease, psoriasis, pyoderma gangrenosum, sarcoidosis, leprosy, erythema multiforme, scabies, facial telangiectasias, and pemphigoid.²⁰ In addition, actinically damaged skin can also produce false positive findings that can be confusing. This calls into question the clinical utility of the test.

In order to gain a sense for the diagnostic utility of direct IF testing to diagnose cutaneous lupus, Table 6-3 characterizes the sensitivity of immunofluorescent (IF) testing in different dermatologic conditions based on a portion of a larger study from the Warsaw Academy of Medicine.²⁰ It has been argued that while false positives are common, the density and pattern of the immunodeposits and the presence of multiple immunoreactants can increase the positive predictive value.²¹ This claim has not been objectively quantified and what constitutes a dense immunodeposit is still somewhat subjective.

Histology of Acute Cutaneous Lupus Erythematosus

The histology from the common macular form of ACLE is often subtle and nonspecific. Along the dermal-epidermal junction, vaculopathic degeneration of keratinocytes can be seen.¹⁷ In severe pronounced cases, there may be frank epidermal necrosis resembling toxic epidermal necrolysis.²² More commonly, there is typically a sparse dermal cellular

infiltrate with variable edema. The presence of increased dermal mucin has long been recognized as a key histologic feature in cutaneous lupus. These mucin deposits can be stained with colloidal iron or Alcian blue preparations. Some experts feel this is the most useful morphologic finding to favor a diagnosis of LE over other causes of a lichenoid interface dermatitis.¹⁷ However, there have not been quantitative studies published to determine if increased mucin is seen in all biopsies or to what degree.

The major histologic differential diagnosis for ACLE is dermatomyositis (DM). A blinded study looked at the cutaneous pathologic changes of DM versus ACLE in 20 biopsy specimens from lesions matched for anatomic site and lesion morphology.²³ When given those two options, investigators were only able to make the correct histopathologic diagnosis of DM or ACLE in 11 of the 20 cases, suggesting that ACLE cannot be distinguished from DM based solely on histology.

There are few published data on the direct immunofluorescence findings in ACLE. Most of the published studies deal either with nonlesional skin or with lesional skin in CCLE or SCLE. There are also little data on specific patterns in these lesions. The age and location of the skin lesion as related to sun exposure influence the prevalence of such deposits.

Histology of Subacute Cutaneous Erythematosus

Histology of SCLE also shows interface dermatitis with variable degrees of hyperkeratosis, basal cell degeneration,

TABLE 6-3—Diagnostic Testing for Cutaneous LE- Immunofluorescence

dermal edema, and mononuclear cell infiltration around the dermal-epidermal junction extending into the dermis. The mononuclear infiltrate is usually limited to perivascular and adnexal structures in the upper third of the dermis, and the epidermis may be mildly atrophic. There is considerable overlap in the features of SCLE versus “classic” discoid lesions, as mentioned. The data to this point would indicate that while there are histologic features that would favor a diagnosis of discoid LE over SCLE, there is enough overlap to state that the two subtypes cannot be completely differentiated from the histology.²⁴ No attempts have been made to take into account the age of the lesion biopsied with the hypothesis being that an advanced discoid lesion is more likely to appear considerably different from SCLE.

In the original cohort of patients with SCLE, approximately 60% were found to have deposits consisting of immunoglobulin and complement components arranged in a granular bandlike pattern along the dermal-epidermal junction in lesional skin.²⁵ Later studies have confirmed this number or found greater frequencies.²⁶ Some investigators have reported the presence of a dust-like pattern of IgG deposition over the dermal-epidermal junction and epidermal basal layer to be enriched in SCLE lesions compared to other forms of LE-specific skin disease.²⁷ This immunofluorescence pattern appears to correlate with the presence of Ro/SS-A autoantibodies in the circulation. The presence of immune deposits in lesional skin from a patient suspected of having SCLE can help confirm the diagnosis, but its absence does not necessarily rule it out. It is worth remembering that these deposits are not specific for LE as they can be seen in normal and particularly sun-exposed skin, and may be present in other non-LE dermatologic conditions and therefore must be correlated to the routine histopathology.

LABORATORY FINDINGS

Chronic Cutaneous Lupus Erythematosus

Discoid lesions are characterized by an interface dermatitis that involves the hair follicles and epidermis. Such lesions typically have a more intense superficial and deep perivascular and periappendageal lymphocytic infiltrate. There is often marked hyperkeratosis with keratotic follicular plugging. Acanthosis and dermal fibroplasia can be seen in older lesions.

As in other subtypes, direct immunofluorescence microscopy is frequently positive at the dermal-epidermal junction in discoid LE lesions. The exact percentage varies in different reports but may be as high as 90%.²⁸ One study took 28 patients with CCLE and compared them to 15 controls with lesions that clinically simulated CCLE in some fashion. Histopathologic examinations and direct immunofluorescence was performed on lesional skin from all sets of patients. The immunofluorescent testing revealed

a sensitivity of 58% and specificity was 87% with a positive predictive value of 95% and a negative predictive value of 32%.²⁹ This study suggests that in patients presenting with discoid LE appearing skin lesions, a negative immunofluorescence would be useful in excluding discoid LE mimics. However, the study did not examine whether there was any added negative predictive value in comparison to routine histology alone.

There is no direct comparison of the type and morphology of the immunoreactant in chronic cutaneous LE in comparison to other forms of cutaneous LE. Expert opinion indicates that CCLE is unique in that the band of immunoreactants is generally thicker and extends along the basement membrane of the hair follicle. Additional studies have suggested that the frequency of immunoreactants can vary with anatomic location with the head, neck and arms often positive and the trunk often negative.³⁰ These locations correlate with increased exposure to UV light. The frequency may also be related to the age of the lesion with lesions older than 3 months being more often positive than newer lesions. A discussion of the histologic and immunologic features of other forms of CCLE such as lupus panniculitis is beyond the scope of this chapter.

LABORATORY FEATURES OF CUTANEOUS LE

As previously mentioned, the diagnosis of cutaneous LE is made on clinical grounds supported by characteristic histologic findings. Therefore, the purpose of any additional laboratory testing is two-fold:

1. To support the clinical and histologic diagnosis of cutaneous lupus
2. To establish the likelihood of systemic LE

This section will discuss the value of laboratory tests to support the diagnosis of the different subsets of cutaneous LE. Many of the laboratory tests used in the diagnosis of LE revolve around autoantibody testing. The interpretation of antibody testing, including the anti-nuclear antibody (ANA) test, can be complicated. The clinician interpreting the test must consider differences in techniques, patient age, comorbidities, and medications. One must also consider what result or level constitutes a significantly abnormal test. The astute clinician will therefore consider all these factors when applying the results of a specific autoantibody test result to a particular patient suspected of having cutaneous LE. The prevalence of particular serologies in subsets of cutaneous LE has generally been obtained through case series with variable results.

Acute Cutaneous Lupus Erythematosus

As ACLE is usually associated with systemic LE, laboratory profiles are similar. Antinuclear antibody testing remains

a very sensitive test for systemic LE with 99% prevalence.³¹ The 1% of “ANA-negative” systemic LE patients can typically be found to have Ro/SS-A autoantibodies upon investigation. The prevalence of ANA in patients presented with ACLE has not been directly measured but would one would expect it to closely parallel systemic LE. More specific but less sensitive tests include dsDNA, Sm, and rRNP autoantibodies. Hematologic abnormalities and proteinuria are frequently seen in systemic LE but are not necessarily related to the presence or diagnosis of ACLE.

Subacute Cutaneous Lupus Erythematosus

Antinuclear antibodies are detected in approximately 50% of patients with SCLE. Ro/SS-A antibodies are present in frequencies ranging from 40–100% of such patients. La/SS-B antibodies are present in 12–42% of patients with SCLE. Higher percentages are obtained for Ro/SS-A and La/SS-B antibodies, using the more sensitive enzyme-linked immunosorbent assay (ELISA).⁴ Ro/SS-A and La/SS-B antibodies have been repeatedly found to be more common in SCLE than in other forms of cutaneous LE. Sm, dsDNA, and U1RNP antibodies have been reported to occur in approximately 10% of patients with SCLE and can be indicators of clinically-significant underlying systemic LE.¹¹

Approximately 50% of patients with SCLE skin lesions will meet at least four criteria for systemic lupus.²⁵ Multiple laboratory abnormalities can again be seen including depressed complement levels, particularly in patients with systemic disease. These abnormalities are not specific to making a diagnosis of SCLE.

What We Know

- There are no validated diagnostic criteria for cutaneous LE.
- The diagnosis is made based on clinical findings supported by characteristic histopathologic features from an active skin lesion.
- Specific histopathologic features are variably present depending on the stage of the lesion biopsied.

Chronic Cutaneous Lupus Erythematosus

Laboratory findings in patients with CCLE, other than histopathology, are often of minimal use from a diagnostic standpoint. Patients with CCLE without systemic disease frequently have no detectable laboratory abnormalities.³² ANAs are detected in approximately 30% of these patients but are typically low titer.³³ Ro antibodies are found in approximately a quarter of patients with CCLE and U1RNP in perhaps 10%. Sm, La antibodies appear to be very uncommon in CCLE patients.⁴

Up to 25% of patients with SLE will develop discoid LE lesions at some point during the course of the disease.^{34–35} This group will clearly have different laboratory findings than those presenting with isolated CCLE.

CONCLUSION

The diagnosis of cutaneous LE is currently made by the presence of characteristic clinical features supported by the histopathology. There are currently no defined diagnostic criteria using clinical or histologic features that are supported by evidence-based medicine. One would anticipate that the development of reliable criteria could be very difficult for such a heterogeneous condition but if available, could be helpful in difficult cases.

Dermatologists frequently encounter patients with skin lesions in which they consider cutaneous LE to be in the differential diagnosis. If the clinical and histologic features still leave doubt, then there are tests that can be performed that may provide additional diagnostic information. These include direct immunofluorescence and autoantibody testing. The predictive value of these tests has been established in relatively small randomized studies.

- There is considerable histologic overlap between different clinical subsets of cutaneous LE.
- There are relatively few studies evaluating the predictive value of additional testing including immunofluorescence.

Diagnosis of Parasitic Skin Diseases

7

Hermann Feldmeier, M.D.

SEARCH METHODOLOGY

Data for this chapter were found through searches of Medline and Lilacs databases using the keywords “pediculosis capitis”, “scabies”, “tungiasis”, and “cutaneous larva migrans” in combination with “diagnosis”. Additionally, reference lists of retrieved articles were searched. No date restrictions were set in these searches. Articles in English, French, German, Spanish, and Portuguese were analyzed. References found in text books on parasitic skin diseases, and tropical medicine were also used.

INTRODUCTION

In the past, the diagnosis of the four major parasitic skin diseases – scabies, pediculosis capitis, cutaneous larva migrans and tungiasis – essentially was based on clinical findings together with a history of exposure. However, clinical findings are seldomly specific and are subject to considerable inter-patient variation. Signs and symptoms depend on the duration of the infestation and its intensity, vary according to the developmental stage of the parasite, may be influenced by the age of the patient, and are modulated by a concurrent skin disease of non-infectious origin. This underlines the importance of diagnostic tools to identify the parasite in question, either directly on/in the skin or in ex vivo specimens.

Obviously, the suitability of diagnostic methods depends on the setting in which the patient lives. For instance, in areas where scabies is endemic – resource-poor communities and marginalized population groups - cost-intensive diagnostics requiring skilled personnel, such as videodermatoscopy, are not at hand and simple procedures have to be used instead. Therefore this chapter summarizes evidence on the validity of diagnostic approaches suitable in affluent or in resource-poor settings.

PEDICULOSIS CAPITIS

Parasite and life cycle/Epidemiology

Pediculus humanus capitis can only propagate on human scalp. From hatching of juvenile head lice to the next generation of eggs glued to hair shafts it takes 9 to 11 days. Head lice undergo only an incomplete metamorphosis, i. e.

juvenile lice are smaller than adult lice but have the same morphology. Transmission of head lice requires intimate head-to-head contact. Transmission through fomites is theoretically possible, but has little relevance in practice.

Clinical findings

Itching of the scalp is the most common symptom of head lice infestation. The degree of itching increases with the duration of infestation and the number of lice present on the scalp. However, whether this symptom is perceived or not seems to depend on the socio-cultural setting in which the patient lives. Whereas in Israel 30% of children infested with head lice complained about prurigo, in Venezuelan children only 14% reported this symptom^{1,2}.

Primary signs are reddish, intensively itching papules of 2-3 mm diameter. They are often surrounded by an erythema. Immediately after a bite wheals may occur, with the subsequent development of papules and itching. In the case of a primary infestation, signs develop with a delay of 4-6 weeks. This means that in the early phase of head lice infestation (when the patient is already infectious) the diagnosis cannot be made on clinical grounds. In the case of re-infestation, signs appear within 24-48 hours - an indicator for an immune-mediated reaction against components of lice saliva.

Secondary signs are the result of extensive scratching. Repeated scratching leads to **excoriations**. If the patient is not treated and continues scratching, an **ulcer** may develop. Excoriations reduce the natural barrier function of the epidermis and are an entry port for pathogenic microorganisms, typically *Staphylococcus aureus* and streptococci, leading to impetiginization of the scalp. The frequency of superinfection depends on the setting. In two resource-poor communities in Brazil, bacterial superinfection was observed in about 3% of infested individuals, while in France, only 1.2% of children with pediculosis capitis showed signs of superinfection^{3,4}.

Persistent superinfection leads to the development of regional lymphadenopathy. In two populations in Brazil with more than 10 episodes of head lice infestation per year and a restricted access to health care, cervical lymphadenopathy was observed in 12% and 15% of the infested individuals⁴. In children infested only temporarily, the

frequency of regional lymphadenopathy was similar to that of non-infested individuals⁵. Chronic infestations and persistent scratching may lead to eczema of the scalp (“lice eczema”). In homeless children or children refugees in low income countries, chronic impetiginization of the scalp associated with massive exsudation results in hair shafts intricately glued to each other (similar to the Polish plait observed in the 19th century).

Case history/Travel history

In western Europe the incidence of head lice infestation varies considerably during the year with a peak between calendar week 30 and 40, i. e. after the summer holidays⁶. Hence, in a child recent holidays support a presumptive diagnosis of pediculosis capitis.

Detection of parasites

Active pediculosis capitis – defined as the presence of nymphs, adults and/or viable ova – requires treatment. Presence of **only** egg shells (nits) or apparently dead ova is no indication for treatment. In praxis, though, it is not easy to make the differentiation between an active infestation and an infestation experienced in the recent past.

There are two methods to confirm the presence of *Pediculus humanus capitis* on human scalp: visual inspection and diagnostic combing (Table 7-1). In clinical practice the diagnosis of an active infestation is usually made by visual inspection, i.e. the direct observation of juvenile or adult head lice on the scalp. After parting the hair (e.g. with an applicator stick), the scalp is examined systematically, preferably with an illuminated magnifying glass (Figure 7-1).

Detection combing can be performed on dry or wet hair. Combs must have parallel-sided teeth and a distance

FIGURE 7-1 Visual inspection of the scalp and the hair using an applicator stick.

of ≤ 0.3 mm between teeth, so that the even juvenile lice are caught between the teeth. In wet combing a conditioner is applied onto the hair first. When coated by the conditioner, lice cannot crawl away, stick to the comb and are easily detected in the conditioner liquid. After each strike, the conditioner is wiped on sanitary paper and objects stuck between the teeth of the comb are inspected (Figure 7-2 A,B,C). Combing has to be done systematically from one side of the head to the other until the first louse is detected. If the entire hair is combed, diagnostic combing has the additional benefit of treatment.

Several authors have tried to determine the accuracy of visual inspection and wet combing. In one study, in only 6% of children head lice were found on the scalp by visual inspection, as compared to 25% after detection combing, resulting in a sensitivity of visual inspection of 22%. More recent data from a study in Turkey revealed a sensitivity of

TABLE 7-1—Diagnostic Value of Visual Inspection Versus Wet Combing

A) Presence of eggs/nits Diagnostic parameter	Visual inspection % (95% CI)	Wet combing % (95% CI)
Sensitivity	86.1 (82.2 – 90.0)	68.4 (63.1 – 73.7)
Positive predictive value	100	100
Negative predictive value	95.3 (92.9 – 97.7)	89.8 (86.5 – 93.1)
Accuracy	96.3 (94.1 – 98.5)	92.0 (88.9 – 95.1)
B) Presence mobile stages		
Sensitivity	28.6 (23.5 – 33.7)	90.5 (87.2 – 93.8)
Positive predictive value	100	100
Negative predictive value	94.9 (92.4 – 97.4)	99.3 (98.3 – 100.0)
Accuracy	95.0 (92.5 – 97.5)	99.3 (98.3 – 100.0)

FIGURE 7-2 Wet combing for detection of active pediculosis capitis. The hair is extensively wetted with conditioner (A) and then systematically combed with a high quality lice comb (B). After each strike the comb is wiped on a piece of white sanitary paper (C).

31%. In an observer-blinded, prospective diagnostic trial Jahnke et al.⁹ differentiated the diagnostic value of visual inspection and wet combing with regard to the detection of immobile and mobile stages. The authors showed that the sensitivity of visual inspection in detecting eggs/nits was significantly better than wet combing (86% versus 68%; P<0.001). The negative predictive value of visual inspection was also better (95.3% versus 89.8%; p<0.01). In contrast, wet combing largely outperformed visual inspection in the diagnosis of trophic stages: sensitivity 90.5% versus 28.6%, respectively (p<0.001); negative predictive value 99.3% versus 94.9%, respectively; (P<0.01). If only visual inspection was used, the true prevalence of active infestation would have been underestimated by a factor of 3.5.

In industrialized countries children have rarely more than 10 head lice¹⁰. This is important, because the sensitivity of any diagnostic method for parasitic skin diseases depends on the intensity of infestation. For instance, in patients with ≤10 trophic stages the sensitivity of wet combing is in the order of 90%, in patients with 20 head lice or more it is considered to be 100%⁵.

If in a scientific investigation the intensity of infestation needs to be determined, the number of head lice detected during the first three (or five) minutes of wet combing is a good proxy¹¹.

As head lice cannot be confounded with artefacts, theoretically the specificity of visual inspection and of detection combing should be very high. However, diagnosis of head lice infestations is often done by people who are not familiar with the size and the shape of head lice and their eggs and misinterpret what they see. In the USA, only 59% of 614 samples sent to a reference centre contained trophic forms or eggs¹². Surprisingly, only 17% of samples forwarded by physicians contained louse-derived material, as compared to 70% from nurses and 86% from teachers¹². Debris such as dandruff, and other epidermal material was found in 35% of all samples, other arthropods (book lice, beetles mites, bed bugs etc.) in 5%. In addition, only 53% of the specimens thought to contain a trophic stage or a viable egg actually showed the corresponding life stages of the parasite. Hence, reports by lay people and physicians on the presence of head lice should be interpreted with caution.

Resource-poor setting

In resource-poor settings a very simple approach to diagnose head lice infestation is asking individuals about their infestation status. Caretakers in poor communities in Brazil and Nigeria, after being asked about the presence of head lice on the head of their children, were aware of the infestation status with a sensitivity of 74% - 81% for active infestation^{13,14}. In the case of severe infestation, the sensitivity of self-diagnosis was as high as 92%.

Laboratory investigations

Head lice and their eggs are easily identified in a dissecting microscope. Haematological examinations are not helpful.

SCABIES

Parasite and life-cycle/Epidemiology

Sarcoptes scabiei is an arachnid of the genus *Acarus*. Humans are the only host of *Sarcoptes scabiei var. hominis*. Sarcoptes mites from companion animals only temporarily infest human skin. The female mite is responsible for symptoms and signs. Fertile females burrow into the stratum corneum of the epidermis, where they feed and produce ova. They live four to six weeks, producing two to four eggs per day which are deposited in the burrow. After two to four days larvae hatch from the eggs, and the next generation of adults develops within 10 to 14 days.

During a few months parasites accumulate in the skin, but then decrease in number over time - partly due to protective immune responses of the host, partly because scratching destroys burrows and thereby eliminates mites. On the average not more than 10 mites are present after six months of infestation¹⁵.

Transmission of mites requires prolonged intimate body contact, such between mother and her child, or during sexual intercourse. Mites can also be transmitted through contaminated fomites, however, the importance of inanimate reservoirs is usually overestimated by the patient. Off-host survival depends on temperature and humidity¹⁶.

In primary infestations, the incubation time is 3 to 6 weeks. Reinfestation is associated with a brisk immune response and an onset of symptoms within 24 to 72 hours.

General remarks

Currently, there is no satisfactory method of diagnosing scabies. Usually, diagnosis is made via clinical signs and microscopic examination of skin scrapings, but experience has shown that the sensitivity of these approaches is less than 50%¹⁷. Detecting visible lesions can be difficult, as they are often obscured by impetigo or eczema or are atypical. Given the many differential diagnoses, the specificity of clinical

diagnosis is poor. Furthermore, there is a problem in distinguishing among active infestation, residual skin reaction, and reinfestation. A presumptive diagnosis can be made on the basis of a local intense pruritus, pruritus that is worse at night, the topographic localization of the suspicious lesion, and a history of contact with other scabies cases.

Clinical findings

Scabies can mimic a broad range of skin diseases (Table 7-2). When a patient uses cosmetics extensively, typical appearances may be absent ("scabies incognito"). The systemic or topical administration of corticosteroids – even if only for a couple of weeks – also masks the clinical picture.

Clinical appearances are differentiated into **primary** (macules, papules, vesicles, burrows, nodules) and **secondary lesions** (crusts, excoriation, eczematization, secondary infection). The combination of primary and secondary lesion types produces a multifaceted clinical picture¹⁸.

Itching is invariably present and extends to areas adjacent to the lesion¹⁸. In the majority of patients itching is severe and is responsible for an important restriction of life quality¹⁹. Itching intensifies at night. **Excoriations** are the consequence of scratching. Scratching leads to haemorrhagic crusts forming on the top of **vesicles** and **secondary infection**. Superinfection is present in up to 40% of the patients¹⁸. If massive, the superinfection resembles pyoderma.

The characteristic **burrow** is the excavated tunnel in which the mite lives. It consists of a thin, curvy tract with a length of 1-10mm. A single clearly visible burrow is pathognomonic. However, in the tropics, burrows are only inconsistently present, and are difficult to see in pigmented skin^{18,20}. **Papules** are small and erythematous. They may be sparse or numerous and closely set. Over time papules may change into **vesicles**, and rarely into **bullae**.

Very young children often have widespread **eczematous erythema** or a **vesiculobullous rash**, particularly on the trunk, which is sometimes more symptomatic than the lesions themselves²¹. These lesions often extend over the

TABLE 7-2—Differential Diagnosis of Scabies

"Normal" scabies	Atopic eczema, contact dermatitis, lichen planus
Bullous scabies	Acropustulosis, bullous pemphigoid, pemphigus, arthropod bites, bullous impetigo, dystrophic bullous epidermolysis, drug reaction, cutaneous porphyria
Nodular scabies	Insect bites, urticaria pigmentosa, pseudolymphoma, Langerhans' cell histiocytosis, mastocytoma, prurigo simplex
Crusted scabies	Psoriasis, seborrhoeic dermatitis, Darier disease, ichthyosis, exfoliative dermatitis, chronic eczema

whole body, affecting skin folds, the palmoplantar region and the buttocks. The face and scalp can also be affected. Pruritus makes infants agitated. Very young babies do not scratch and may just look miserable or feed poorly²².

Elderly patients, especially those living in institutions, often have atypical scabies. They present with a **papular, vesicular and erythematous rash** disseminated over the trunk, limbs and even the back; burrows may be absent²³.

Crusted or disseminated scabies ("Norwegian scabies") is a hyperinfestation with myriads of mites present in **exfoliating scales** (up to thousands of mites per gram of scales). Typically, individual lesions confluent, so that the **hyperkeratosis** affects large areas. A variable degree of **erythema** is common. These patients are highly contagious. The condition occurs in individuals with a compromised immune responsiveness such as in AIDS, in HTLV-1 infection, after immunosuppressive therapies, in malignancies, and in patients with congenital immune defects. Cases have been reported in patients with leprosy and tuberculosis, endocrinopathies (diabetes mellitus and hypoparathyroidism), rheumatic conditions (systemic lupus erythematosus and dermatomyositis), or after treatment with corticosteroids²³. Children with neuropsychiatric disorders, or with Down's syndrome, are also prone to develop crusted scabies,

because they may be unable to eliminate mites through scratching.

Nodular scabies is a clinical variant in which extremely pruritic nodules are present on soft skin areas such as in the axillae, groins, on the buttocks, and genitals. It is a common presentation in infants. Nodules are firm, dull red or brownish masses that may persist for months and probably represent an intense hypersensitivity reaction to the mite or its products. Nodules do not contain mites. Superinfection and secondary eczematous changes due to intense scratching are common.

Bullous scabies is a distinct subtype that may arise in young children²⁴. Thinness of the stratum corneum and a loose adherence of the epithelial layers favour the appearance of bullae.

It is commonly assumed that mites penetrate and accumulate at certain predilection sites. However, a population-based study showed that lesions may develop at any area of the skin and that predilection sites vary between adult and pediatric patients¹⁸ (Table 7-3). Hence, the topographic site of a characteristic lesion is not sufficient to confirm a presumptive diagnosis. There are two exceptions: itchy papules on the scrotum and penis and itchy nipples associated with pruritic papular eruption in women are considered to be pathognomonic^{22,25}.

TABLE 7-3—Topographic Distribution of Lesions According to Age

Localization of lesions ^a	All (%)	Individuals infested <=7 years (%)	Individuals infested >7 years (%)	p-value

Case history/Family history/Travel history

Recent adoption may be a hint for the diagnosis of scabies in the mother²⁶. In children scabies occurred after regularly visits to an infested grandparent²⁷. Scabies in sexually active male adults may be associated with recent travel to developing countries²⁸.

Burrow Ink Test

The Burrow Ink consists of gently rubbing a suspect papule with the underside of a fountain pen, covering it with ink. The excess ink is then wiped off with alcohol-saturated gauze. If a burrow is present, the ink will track down it and outline the limits of the canal (Figure 7-3).

For several decades, the Burrow Ink Test was the diagnostic procedure most widely used in routine dermatology²⁹. However, its suitability is limited by several factors. First, burrows are inconstantly present and their occurrence varies between 7% and 92%²⁹. Second, burrows are often obliterated by scratching, formation of crusts, or superinfection. Third, in darkly pigmented skin neither a burrow is visible nor ink penetrating into it. Fourth, a visible burrow is not necessarily inhabited by a mite³⁰.

Studies on the diagnostic validity of the Burrow Ink Test are inconclusive. Sarwat et al.³¹ used this approach in Egyptian patients with scabies. Only 40% of the patients had visible burrows; in 85% of these patients the Burrow Ink Test was positive. Woodley and Saurat²⁹ compared sensitivity and specificity of the Burrow Ink Test with a superficial shave biopsy. The Burrow Ink Test had a specificity of 100%, but a sensitivity of only 24%.

Extraction of mites from burrows

Kenawi et al.³² removed mites from their burrows by the aid of a hand lens using a flat sharp needle and transferred the ectoparasite to a slide for microscopical analysis. The

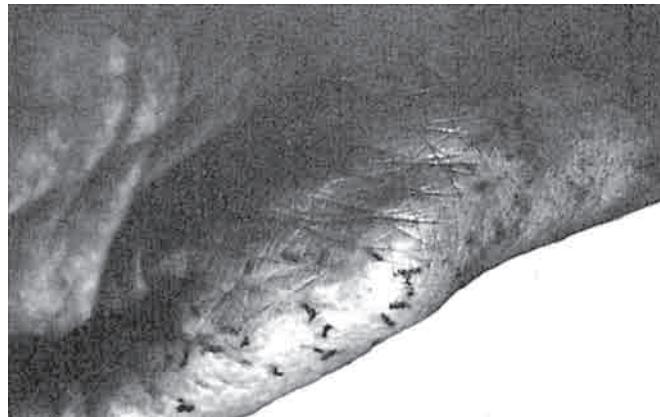

FIGURE 7-3 The thenar area with multiple burrows stained with ink
Source: Woodley and Saurat JAAD 1981: 4:715–722, reprinted with permission.

method has never been compared to other diagnostic approaches and has the same constraints as described for the Burrow Ink Test.

Skin scraping

Various types of skin scraping procedure exist. Usually a suspicious lesion is scraped with the edge of a scalpel blade or a sterile scarificator and the material obtained is transferred to a slide. A drop of 10-40% potassium hydroxide is added and the specimen is then examined at 100x magnification (Figure 7-4). Chlorasol Black E stains the cuticle of mites dark blue and allows to differentiate between fecal pellets (scybala) and artifacts³³ (Figure 7-5 A,B). A variation of the technique is to mix the scraping with a drop of glycerol or mineral oil³⁴. A drop of mineral oil can also be applied on the skin first and the scraping is performed afterwards. No comparisons with regard to diagnostic validity for the different modifications of skin scraping exist.

Palicka et al.³⁴ modified skin scraping in the way that first they wetted a suspicious lesion with a cotton swab dipped into 10% potassium hydroxide. The lesion was left to macerate for one minute in children and two minutes in adults. With the stump edge of a scalpel blade the lesion was scraped thoroughly. The specimen was transferred to a slide, mixed with a drop of water and examined at 100x magnification. The macerated area of the skin was neutralized with an acid ointment, such as unguentum acidi borici. Whether this modification performs better than the original method is not known.

Skin scraping has several constraints. First, the sensitivity seems to depend on the age of the patient, being considerably lower in adults than in children, as well as on gender³⁴. Second, it also depends on the topographic localization of the lesion and the clinical presentation (unscratched lesions are more valuable)¹⁷. Third, scrapings contain all developmental stages of the parasite. In a study in 151 patients Palicka et al.³⁴ observed adult mites

FIGURE 7-4 Sarcoptes mite identified in skin scraping (original magnification x200) Source: Neyhaber und Wolff, CMAJ, 2008;178:1540–1541, reprinted with permission.

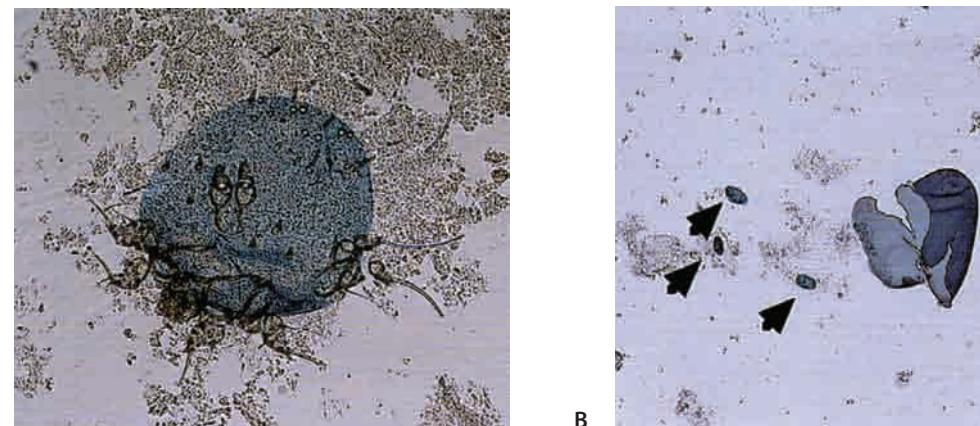

FIGURE 7-5 Staining of skin scraping with Chlorazol Black E. Adult female (A), eggshell fragments and scybala (B). Original magnification x100

in only 18% of the samples, larvae and juveniles in 9%, eggs in 68%. The remaining specimens contained egg shells and other parasite debris. Bhutto et al.³⁵ made similar observations. This is of importance, since only adult mites are easily identified and the identification of other developmental stages requires experience or a special staining (see above). Finally, even if several scrapings are performed and all are negative this does not exclude the presence of scabies¹⁷.

Bhutto et al.³⁵ embedded scraped material in non-fluorescent glycerin and examined the specimen with a fluorescence microscope. The authors claimed that eggs and egg shells were easily detectable by fluorescence microscopy, whereas they are difficult to visualize under a light microscope. In glycerol preserved specimens can be kept for at least six months, allowing re-examination of a slide by an expert. Siderits et al.³⁶ have prepared a commercially available kit containing the necessary material for several skin scrapings.

Taken together, skin scraping has an excellent specificity but only a low sensitivity for ordinary scabies, due to the low numbers of parasites. The sampler's experience also influences its sensitivity

Dermoscopy, epiluminescence microscopy, confocal microscopy

In 2004 Prins et al.³⁷ suggested the use of a handheld dermoscope with a 10x magnification for the in vivo detection of *S. scabiei*. The authors described a delta-glider-like triangle (synonym “delta wing jet sign”, “jet with contrail pattern”) which they considered to represent an adult mite. In fact, it had been shown previously that the dark triangle corresponds to the head of the mite and its front legs³⁸. These are brown in color, whereas the abdomen is milky transparent. In French the hang-glider-like triangle is called the “circumflex-accent-sign” (“^”)³⁹ (Figure 7-6).

Recently, Yoshizumi and Harada detected another pathognomonic pattern and called it the “wake sign”,

because of its reminiscence of the wake left on the surface of water by a moving bird⁴⁰. The “wake” indicates the direction of the burrow at the end of which the head of the mite is visible as a “^”.

In a prospective, evaluator-blinded study the diagnostic validity of dermoscopy was compared to the ex vivo microscopic examination of oriented skin scraping; i. e. scraping of an area where a mite had been identified/suspected by dermoscopy³⁹. The sensitivity of dermoscopy was 91% (95% confidence intervals 86-96%) and that of oriented skin scraping 90% (95% CI 85-96%). The specificity of dermoscopy clearly depended on the experience of the dermoscopist and was 73% for “beginners”, 81% for trained and 92% for experienced dermoscopists; sensitivity, though, did not depend on experience. Diagnostic accuracy also increased with experience. Patients in this study were mostly Caucasians, presumably with lightly pigmented skin.

Walter et al. (2010)⁴¹ also used a prospective, evaluator-blinded design in patients from a slum in Brazil to compare

FIGURE 7-6 “Delta-wing sign” identified b dermoscopy (original magnification x10). Source: Dupuy et al. *JAAD* 2007;56: 53–62, reprinted with permission.

the diagnostic validity of dermoscopy and of skin scraping performed without help by the dermoscopist. The majority of the patients had colored skin. The authors determined a sensitivity of 83% (95% CI 70-94%) for dermoscopy and of 46% (95% CI 30-62%) for skin scraping. The sensitivity of dermoscopy was higher in recent as compared to chronic infestations (88% versus 76%) and increased with the severity of scabies (light scabies 80%, moderate scabies 85%, severe scabies 93%). The authors were unable to identify the characteristic delta wing in patients with dark skin.

Dermoscopy may require extensive time to come to a conclusive diagnosis: Dupuy et al.³⁹ needed 10-20 minutes in 18%, 5-10 minutes in 33% and less than 5 minutes in 49% of the cases.

In videodermatoscopy a camera equipped with a special lens is applied to the skin which allows a magnification from 10x to 1000x. This technique allows examination of the skin to the level of the superficial papillary dermis. Micali et al. have introduced videodermatoscopy for the diagnosis of scabies in 2000⁴². Lacarruba et al. compared videodermatoscopy to skin scraping in small case series and noticed a similar sensitivity⁴³. However, the study design was not sufficiently robust to come to a definitive conclusion. A hand-held epiluminescent stereomicroscope with a magnification of 20x to 40x seems equally suitable⁴⁴ and can replace the expensive stationary instrument. Recently, Levitt⁴⁵ showed that in light skin a burrow can also be identified using a high-resolution digital camera equipped with a macro lens, when the photo is magnified by 150%.

Argenziano et al.³⁸ applied epilumiscence microscopy with a 40x magnification and considered it a valid diagnostic tool. Again, this study was not sufficiently robust to conclude on the diagnostic validity of the technique. Burrows and mites can also be visualized with reflectance-mode confocal microscopy⁴⁶.

Since videodermatoscopy and epiluminescence microscopy require considerable skills and investment, their application is restricted to well-resourced tertiary care centers. Whether these approaches can be successfully used in patients with dark skin remains to be demonstrated. They clearly are an alternative in children when it is difficult to perform skin scrapings.

Histopathology

Although, in scabies a biopsy is not indicated – except if a malignancy has to be ruled out as a differential diagnosis - in single cases the examination of multiple step sections might reveal diagnostic hints in patients in whom dermoscopy and skin scraping have failed. Kristjansson et al.⁴⁷ noticed pink, pigtail-like structures that connected to the stratum corneum. The authors provided evidence that the pigtail-like structures are egg fragments left behind after the mite had hatched. Usually, the histological appearance of a lesion is that of a nonspecific, delayed hypersensitivity reaction with superficial and

deep perivascular inflammatory mononuclear cell infiltrates containing eosinophils, as well as papillary edema and epidermal spongiosis⁴⁸.

Immunodiagnosis

A few studies have addressed B cell responses in patients with scabies. Roberts et al. (2005)⁴⁹, Arlian et al., (2004)⁵⁰, and recently Walton et al.⁵¹ observed extremely high levels of polyclonal IgE and IgG4 in patients with crusted scabies (with median IgE levels at 17 times the upper-limit of normal), but normal levels in patients with only few mites. Eosinophilia occurred in about 60% of the patients with crusted scabies⁵¹. Whether these patients were concomitantly infected with intestinal helminths was not reported by the authors.

It is known that patients sensitive to house dust mites, but with no history of scabies, have circulating IgE antibodies that recognize antigens in *S. scabiei* var. *canis* extract⁵². Furthermore, Western blot and radioallergosorbent assays demonstrated that individuals with scabies showed strong IgE binding to house dust mite extract⁵³. Since scabies mites and house dust mites are phylogenetically related arthropods, it is not surprising that they have homologous allergens¹⁷. Taskapan and Harmanyeri explored the cross-reactivity of mite allergens for the diagnosis of scabies⁵⁴. Eighty-eight % of their patients showed positive reactions in a skin prick test and 68% had a positive allergy patch test against house dust mite. Patients had no history of atopy. However, the study design did not allow to conclude on sensitivity and specificity of the reactions.

Enzyme-linked immunosorbent assays developed for the detection of antibodies to *S. scabiei* in pigs and dogs are commercially available. These assays rely on whole-mite antigen preparations derived from *S. scabiei* var. *suis* or the itch-mite of the red fox, *S. scabiei* var. *vulpes*¹⁷. A recent study looking at cross-reacting IgG antibodies to the fox mite antigen in human scabies reported a sensitivity of only 48%, in comparison with 80% in pig scabies and 84% in dog scabies⁵⁵. Purified, well-characterized recombinant scabies mite allergens with standardized protein contents could potentially be useful in the future¹⁷.

PCR is unlikely to become a reliable test for widespread use, due to the generally low mite burden and, thus, low sensitivity¹⁷.

Resource-poor setting

In endemic areas in the developing world scabies is usually diagnosed using a case definition. Obviously, the sensitivity and specificity of a case definition depends on the setting and tends to be overestimated. For instance, a case definition used in a population-based study in a scabies-endemic area in rural Brazil had a sensitivity of 65% and a specificity of only 43% (Feldmeier H. unpublished observation). In this study scabies was diagnosed,

if two out of three requirements were fulfilled: pruritus which intensified at night, presence of the lesions for >2 weeks, at least one more household member with similar lesions¹⁸.

In an observer-blinded, prospective study in an impoverished community Walter et al.⁴¹ used the adhesive tape test described by Katsumata and Katsumata³⁰. In this test an adhesive tape of the size of a glass slide is firmly pressed on a lesion, then pulled off rapidly, transferred to a slide and examined at x 10 to x 40 magnification. The adhesive tape test had a sensitivity of 68% (95% CI 52-81%) and a specificity of 100%. Its sensitivity was significantly better than that of skin scraping and it did neither depend on the duration of infestation nor on the severity of scabies.

In a setting with poor health infrastructure presumptive therapy with oral ivermectin (2x200µg/kg body weight) can be used as a substitute of clinical diagnosis. In patients with scabies itching disappears or decreases shortly after the first or the second dose of ivermectin.

TUNGIASIS (SAND FLEA DISEASE)

Parasite and life-cycle/Epidemiology

With a maximal length of 1 mm, *Tunga penetrans*, also called chigoe- or jigger-flea (Linneus 1758), is the smallest flea species. True to its species name, the female burrows into the skin of its host. There it remains for a period of up to 5 weeks, during which it matures, produces and releases eggs and finally dies. Within 1–2 weeks, the flea increases its volume by a factor of roughly 2,000, frequently reaching a diameter of up to 10 mm⁵⁶. The entire parasite remains completely buried in the epidermis, with the exception of the posterior parts of the abdomen bearing the anus, the genital opening and four pairs of large stigmata. The protruding rear end leaves a sore, 240–500 mm in diameter, which serves an entry point for pathogenic micro-organisms.

When eggs reach the ground larvae develop into adult fleas. Off-host development needs about 18 days and depends on soil temperature and humidity. Adult fleas can jump, but usually reach a human host by running on the surface of his skin.

Tungiasis is a zoonosis affecting a broad range of wild and domestic animals. Man is as appropriate as a host as other mammals. Sand flea disease occurs in most countries of South America, in the Caribbean and in sub-Saharan Africa. It is endemic in many resource-poor communities in urban centers, in the hinterland or the littoral.

Clinical findings

The infestation with *T. penetrans* is a dynamic process, and the aspects of the lesion changes with time. Eisele et al.⁵⁶ have described the natural history of tungiasis in man

and have classified the disease into five stages ("Fortaleza Classification"). In stage I the flea is in *statu penetrandi* (30 min to several hours), and a reddish spot of about 1 mm appears (Figure 7-7A). In stage II the hypertrophy of the flea's abdomen begins and the parasite becomes obvious as a growing whitish or mother-of-pearl-like nodule (one to two days after penetration) (Figure 7-7B). In the protruding rear cone of the flea, the anal-genital opening appears as a central black dot. The lesion is surrounded by an erythema. In stage III the hypertrophy is maximal. A round, watch glasslike patch appears which is frequently accompanied by hyperkeratosis and desquamation of the surrounding skin (Figure 7-7C). Expulsion of eggs and feces are typical in this stage (Figure 7-7C). The lesions are usually painful and produce the sensation of a foreign body expanding under the skin. In stage IV a black crust covers an involuted lesion with a dead parasite (three to five weeks after penetration) (Figure 7-7D). A residual "scar" in the *stratum corneum* is characteristic for stage V (six weeks to several months after penetration) (Figure 7-7E). The appearance of the lesion may be changed by superinfection and manipulation of the lesion by the patient or a carer.

Typically, *T. penetrans* affects the periungual area of the toes, the heels and the soles. However, embedded sand fleas can be found on almost every part of the body, such as the hands, elbows, neck, buttocks and the genital region⁵⁷. If several lesions exist simultaneously they are usually located in clusters. Such lesions show a honeycomb-like aspect. In the endemic area severe infestations with hundreds of embedded sand fleas are not rare.

In single cases lesions may take the aspect of a tumourous growth and in histological sections appear as pseudoepitheliomatous hyperplasia⁵⁸. Although tungiasis is a self-limited infestation, complications are common in the endemic area. Many patients report severe pain, and inflammation and fissures commonly hinders individuals from walking normally⁵⁹. Sequels include deformation and loss of toenails, as well as deformation of digits. Superinfected lesions lead to formation of pustules, suppuration and ulcers. *Staphylococcus aureus* and streptococci frequently occur, but other aerobic and anaerobic bacteria (including clostridia) are also found⁶⁰. In non-vaccinated individuals tungiasis may lead to tetanus⁵⁷.

The diagnosis of tungiasis is made clinically. Patients from an endemic area diagnose tungiasis correctly. In travelers even the untrained physician will recognize the ectoparasitose if he considers the natural history of the disease. The patient typically complains about local itching, pain and the sensation of a foreign body.

The observation of eggs being expelled or eggs attached to the skin around the rear cone and the release of brownish threads of faeces are pathognomonic signs. Faeces threads are of a helical structure and often spread into the dermal papillae (Figure 7-7F). Expulsion of eggs can be provoked by massaging the hypertrophy zone slightly.

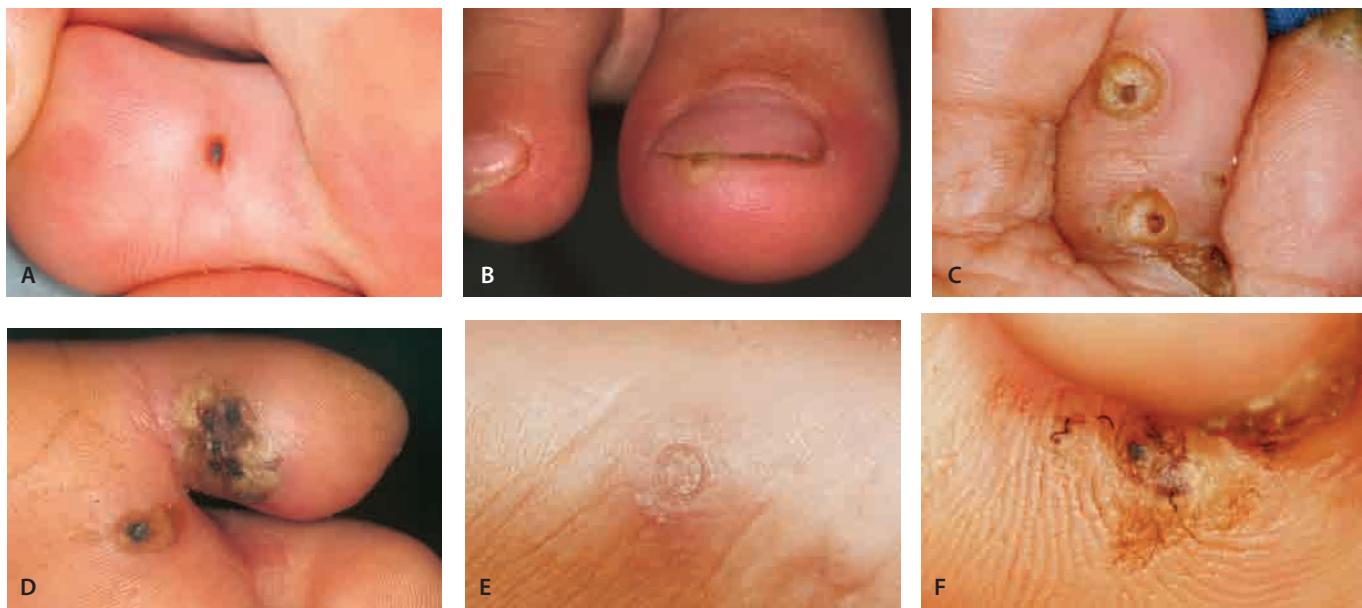

FIGURE 7-7 Recently penetrated sand flea. The black dot in the center of the lesion indicates the last abdominal segments of the parasite (A). Lesion in stage II at the rim of the nail. The circular yellow-whitish area is the hypertrophied abdomen of the embedded flea (B). Two lesions at the base of a toe. The distal lesion shows a wrinkled appearance, an indication that involution of the lesion has already begun (stage III). Next to the other lesion an egg is visible. A fissure has formed below the distal metatarsal joint (C). Cluster of lesions at the base of the fifth toe surrounded by pus. Lesions are covered by a black crust (stage IV) (D). Circular 'scar' at the rim of the foot. A sand flea was embedded here several weeks ago (E). A cluster of three lesions at the base of a toe. Two faecal threads are located left to the cluster. One faecal thread is being ejected. Faecal material is spread in dermal papillae (F).

Differential diagnoses include verrucae vulgaris, myiasis, pyogenic infection/abscess, foreign bodies, acute paronychia, cutaneous larva migrans, dermoid cysts, dracunculiasis, melanoma, deep mycosis and bites or stings of other injurious arthropods.

Case history/Travel history

Residence in an endemic area is a good hint. Travelers with tungiasis commonly report having walked in infested places such as beaches or areas with stray dogs and cats.

Histopathology

A biopsy of the lesion followed by a histopathological examination is not indicated. However, in atypical tungiasis, such as lesions with a pseudoepitheliomatous appearance, a biopsy is useful. Histological sectioning may demonstrate the presence of the ectoparasite or of chitinous fragments. A systematic study in 86 patients showed – mostly unspecific – histological alterations in the epidermis in 70% and in the dermis in 95% of the patients (Table 7-4)⁶¹.

Laboratory methods

Hematological investigations are not helpful.

CUTANEOUS LARVA MIGRANS

Parasite and life cycle/Epidemiology

Hookworm-related cutaneous larva migrans (CLM) is a parasitic skin disease caused by infestation of human skin with larvae of animal nematodes, such as *Ancylostoma braziliense*, *Ancylostoma caninum*, or *Uncinaria stenocephala*. These nematodes live in the intestine of dogs and cats. Eggs shed in feces hatch in the superficial layer of the soil within 1 day, and develop into infective third-stage larvae after about 1 week. In a warm and humid environment, they can survive and remain infective for several months. Larvae penetrate into the corneal layer of the epidermis when human skin comes into contact with soil contaminated by animal feces.

Infestation through contaminated fomites is rare. In Italy a small outbreak of hookworm-related cutaneous larva migrans was reported involving six individuals with lesions on the anterior part of thighs, arms, and chest, caused by contaminated dried flowers used for decoration purposes⁶².

Because humans are an incidental host, in whom the normal larval development is abrogated, CLM is self-limiting. However, the ectoparasitosis may persist for several months, and rarely for a year⁶³.

Hookworm-related cutaneous larva migrans is endemic in resource-poor communities in the developing world, particularly in Brazil, India, and the West Indies. The

infestation is frequent in areas where stray dogs and cats are common or where pets are not treated regularly with anti-helmintics. The disease occurs sporadically or in the form of small epidemics in children in high-income countries

and is an important disease in tourists who have visited tropical beaches. There is a distinct seasonal variation of hookworm-related cutaneous larva migrans, with a peak incidence during the rainy season.

General remarks

For decades, the terms cutaneous larva migrans and creeping eruption have been used as synonyms. The first term describes a syndrome and the second a clinical sign, present in a variety of conditions. A creeping eruption is defined clinically as a linear or serpiginous, slightly elevated, erythematous track that moves forward in an irregular pattern (Figure 7-8A). It can be caused by animal hookworm and other nematode larvae (e.g. larva currens by *Strongyloides stercoralis*), or by parasites such as *Gnathostoma* spp and *Loa loa*, and larvae of parasitic flies (migratory myiasis).

Clinical findings

Usually, itching begins shortly after larvae have started to penetrate into the epidermis. A reddish papule appears at the penetration site in immunologically naive individuals and also in individuals sensitized previously. In most cases, 1–5 days after penetration the elevated track appears. However, studies on travelers have shown that the incubation period may last a month or even longer⁶⁴. The itching is intense and described as very uncomfortable by patients. A recent study demonstrated that 81% of patients with hookworm-related cutaneous larva migrans were prevented from normal sleep because of the intensity of itching⁶⁵. Pain indicates the presence of superinfection.

A study in an endemic area in Brazil showed that CLM is considered an important restriction of life quality⁶⁶. Lesions tend to become superinfected with pathogenic

FIGURE 7-8 Hookworm-related CLM on the hand. Two tracks with two excoriations are located closely to each other (A). Two larva migrans-associated bullae at the sole (B).

bacteria as a result of scratching. In resource-poor communities in Brazil, superinfection of lesions was observed in 8–24% of patients⁶⁵. Vesiculobullous lesions (Figure 7-8 B) occur in 9–15% of cases, with bullae sometimes reaching an impressive size of several centimeters⁶³. Very rarely, animal hookworm larvae may invade the viscera and cause pulmonary eosinophilia (Loeffler's syndrome).

Patients in endemic areas usually have multiple tracks. Up to 45 tracks have been observed in individuals living in slums⁶⁶. Travelers returning from an endemic area commonly present only a single or a few tracks.

The topographic distribution varies according to age. Small children show lesions on the buttocks, genitals, hands, and feet, whereas in older patients, the majority of lesions are located on the feet and buttocks⁶⁵ (Table 7-5). In tourists, typically the feet, buttocks, and thighs – body areas that typically come into contact with contaminated sand while walking or sitting on the beach – are affected.

In a population-based study Jackson et al.⁶⁵ noticed that on the average a larva migrated 2.7 mm per day. The length of the track is therefore a proxy of the duration of the infestation and helps to identify the place where exposure had happened.

The diagnosis of hookworm-related cutaneous larva migrans is easily made clinically and is supported by a travel history, or in an endemic setting, by possibility of exposure.

CLM may mimic scabies, loiasis, myiasis, cercarial dermatitis (the early phase of schistosomiasis), tinea corporis, and contact dermatitis. Considering the characteristic features of CLM, these conditions are ruled out

TABLE 7-5—Localization of Larval Tracks According to Setting

easily. CLM can mimic herpes zoster; however, the latter follows the anatomic path of a peripheral nerve and does not progress in the manner that the creeping eruption in CLM does. A serpiginous ganglion cyst has also to be considered as a differential diagnosis. Another condition of non-parasitic origin resembling creeping eruption has been a hair growing horizontally in the skin.

Videodermatoscopy

Micali and Lacarruba⁶⁷ have suggested videodermatoscopy as a tool to diagnose CLM. However, as even a single

What We Know

Pediculosis capitis

- The most sensitive method to diagnose active pediculosis capitis is wet combing. Visual inspection is the method of choice to identify a historical infestation. In resource-poor settings self-diagnosis by the patient or his carer is reliable.

Scabies

- The numerous modification of skin scraping and of the Burrow Ink Test indicate that none of the approaches are actually efficient. The sensitivity of both methods depends on a number of variables and usually is disappointingly low.
- Dermoscopy, videodermatoscopy, epiluminescence microscopy, and confocal microscopy are able to visualize adult mites (dermoscopy) or all developmental stages (videodermatoscopy, confocal microscopy) in patients with white skin. Specificity of these imaging techniques largely depends on the experience of the examiner.
- A presumptive diagnosis can be made on the basis of a local intense pruritus, pruritus that is worse at night,

the topographic localization of the suspicious lesion, and a history of contact with an other scabies case.

- Except in disseminated “Norwegian scabies” immunological investigations are not helpful.
- In resource-poor settings a locally validated case definition is a practical alternative. A presumptive therapy with oral ivermectin (2x200µg/kg body weight) can be used as a substitute of clinical diagnosis.

Tungiasis

- Tungiasis is diagnosed clinically taking into consideration the dynamic changes of embedded sand fleas and the natural history of sand flea disease.

Cutaneous larva migrans

- The diagnosis of cutaneous larva migrans is based on the clinical characteristics of hookworm-related creeping eruption together with a history of exposure. Histopathology is not helpful. A presumptive treatment with oral ivermectin is a practical alternative, since the pruritus disappears within 48 hours.

creeping eruption is diagnostic, there is no reason to use expensive instrumentation.

Histopathology

The invasive procedure only rarely identifies the parasites. Since the anterior end of the track does not necessarily indicate the place where the larva is located, it is difficult to perform the biopsy at the right place.

Laboratory investigations

Eosinophilia may or may not be present and is not specific. In a study on returning travelers only eight (20%) of 40 patients with CLM presented with eosinophilia, but infection status regarding other helminths was not known⁶⁸. However, a high eosinophil count can indicate migration of helminth larvae into the viscera, a rare complication.

Medical history/Travel history

A recent travel history to an endemic area, particularly in the rainy season, is a good hint for a presumptive diagnosis.

Resource-poor setting

In endemic area patients usually correctly identify their disease and paramedicals are experts, even if lesions are altered by intense scratching and superinfection. After a presumptive treatment with oral ivermectin (200µg/kg bodyweight) itching disappears or significantly decreases within 48 hours, and the lesion involutes within a couple of days.

ACKNOWLEDGEMENT

I thank Dr. Hannah Lesshafft for critically reviewing the manuscript.

Diagnosis of Hirsutism

Diane Turvy, M.D., M.S., Ally-Khan Somani, M.D., Ph.D., F.A.A.D.,
Swetha Kandula, M.D., F.A.C.P., and Najwa Somani, M.D., F.R.C.P.C.

INTRODUCTION

Hirsutism is defined as the presence of terminal (coarse) hairs in a male-like pattern of distribution in women and affects approximately 5-15% of premenopausal women worldwide.¹⁻⁴ Androgens are the strongest determinant for the transformation of fine vellus hairs to coarse terminal hairs in androgen-sensitive areas. Testosterone is the main circulating androgen and is produced in women by both the ovaries and the adrenals. The ovaries and adrenals produce 40-50% of the testosterone with the remaining 50-60% being produced by conversion of precursors, such as androstenedione in peripheral sites such as the liver and adipose tissue. Hirsutism must be distinguished from hypertrichosis, which is generalized excessive vellus hair

growth, that is primarily influenced by heredity or exogenous medications, such as glucocorticoids, but can be exacerbated by androgen excess.⁵

HORMONAL PATHWAYS

In women, the ovaries and adrenal glands are the source of androgens (Figure 8-1). The ovaries secrete androstenedione, testosterone, and dehydroepiandrosterone (DHEA). The adrenals primarily secrete DHEA and dehydroepiandrosterone sulfate (DHEAS), but also produce androstenedione and testosterone.⁶ Androstenedione, from the ovaries and adrenals, can either be converted to estrogen in granulosa cells or to testosterone in theca cells.⁷⁻⁸ Testosterone circulates in a free bioactive form and an

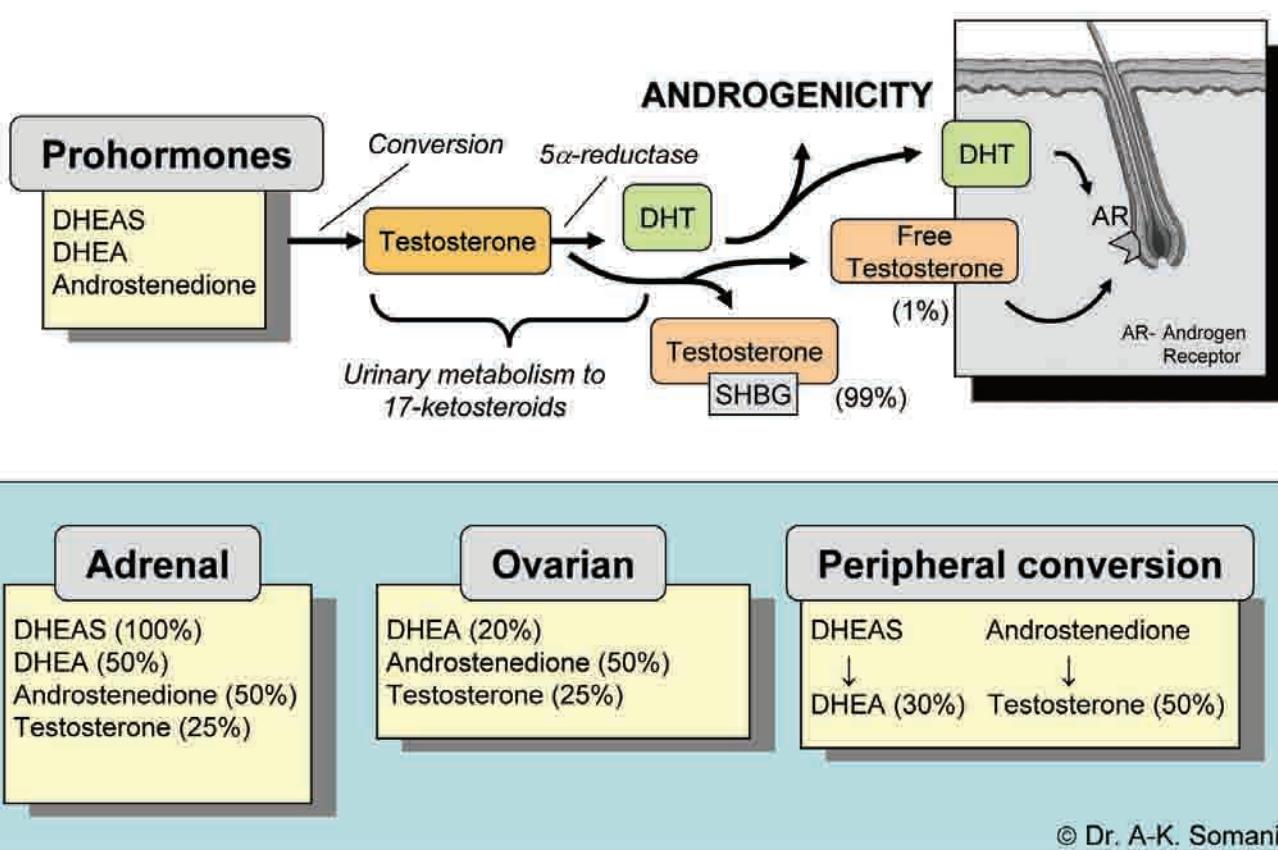

FIGURE 8-1 Sources of Androgens in Women. DHEA: dehydroepiandrosterone; DHEA-S: dehydroepiandrosterone sulfate; DHT: dihydrotestosterone; SHBG: sex hormone binding globulin.

inactive form bound to sex hormone-binding globulin (SHBG). Consequently, reduced levels of SHBG can lead to hyperandrogenism due to elevated levels of free testosterone. While estrogens increase the hepatic synthesis of SHBG, androgens, some synthetic progestins and glucocorticoids reduce SHBG synthesis. Excess insulin also decreases levels of SHBG.⁹⁻¹⁰

In the skin, testosterone can be converted to dihydrotestosterone (DHT), a potent stimulant for hair growth in androgen-sensitive areas, by the enzyme 5-alpha reductase. DHT acts directly on hair follicles producing terminal hairs where small, straight, nonpigmented vellus hairs once were. Weaker androgens, such as androstenedione and DHEA are also converted to testosterone and DHT in the skin to produce hair growth. The rate and amount of androgen secreted along with the rate of conversion in the periphery and the sensitivity of the androgen receptors on hair follicles are all factors in the development of hirsutism.¹¹⁻¹³ Both the androgen receptor activity and the 5-alpha reductase activity levels are influenced by genetics and may be heritable.¹⁴

Some areas of hair growth are independent of androgen effects (eyelashes, eyebrows, lateral, and occipital aspects of scalp), while other areas are very sensitive and respond with conversion to terminal hairs even at low levels of androgens (lower pubic triangle and axillary region). However, other areas such as the chest, lower abdomen, lower back, thighs,

arms, chin, face, and upper pubic triangle, only respond to high levels of androgens. Terminal hair growth in these areas defines hirsutism in women. Interestingly, androgens have a miniaturizing effect on terminal hairs over the vertex and crown of the scalp leading to androgenetic or patterned alopecia.¹³

Several studies have documented the psychosocial impact of hirsutism. Hirsutism is significant not only because of the social stigma it can carry leading to depression, social phobia, or body dysmorphic disorders,¹⁵⁻¹⁷ but also because it is often a visible sign of an underlying endocrine abnormality. Identification of the abnormality is important, as it is typically associated with increased risks for other disease processes, which may benefit from treatment (Figure 8-2). Eighty to 90% of patients with hirsutism will have measurable hyperandrogenemia, making it a powerful clinical marker for a potential underlying androgen excess disorder.¹⁸

Polycystic ovary syndrome (PCOS) is by far the most common underlying cause of hirsutism, accounting for 70-80% of hirsute women.¹⁹⁻²² Additional less common causes of hirsutism include hyperandrogenism, insulin resistance, Acanthosis nigricans (HAIRAN) syndrome accounting for 3%,¹⁸ 21-hydroxylase (21-OH) deficient nonclassic adrenal hyperplasia (NCAH), accounting for approximately 2%,²³⁻²⁴ androgen secreting tumors (approx. 0.2%), hyperprolactinemia, acromegaly, and thyroid dysfunction.

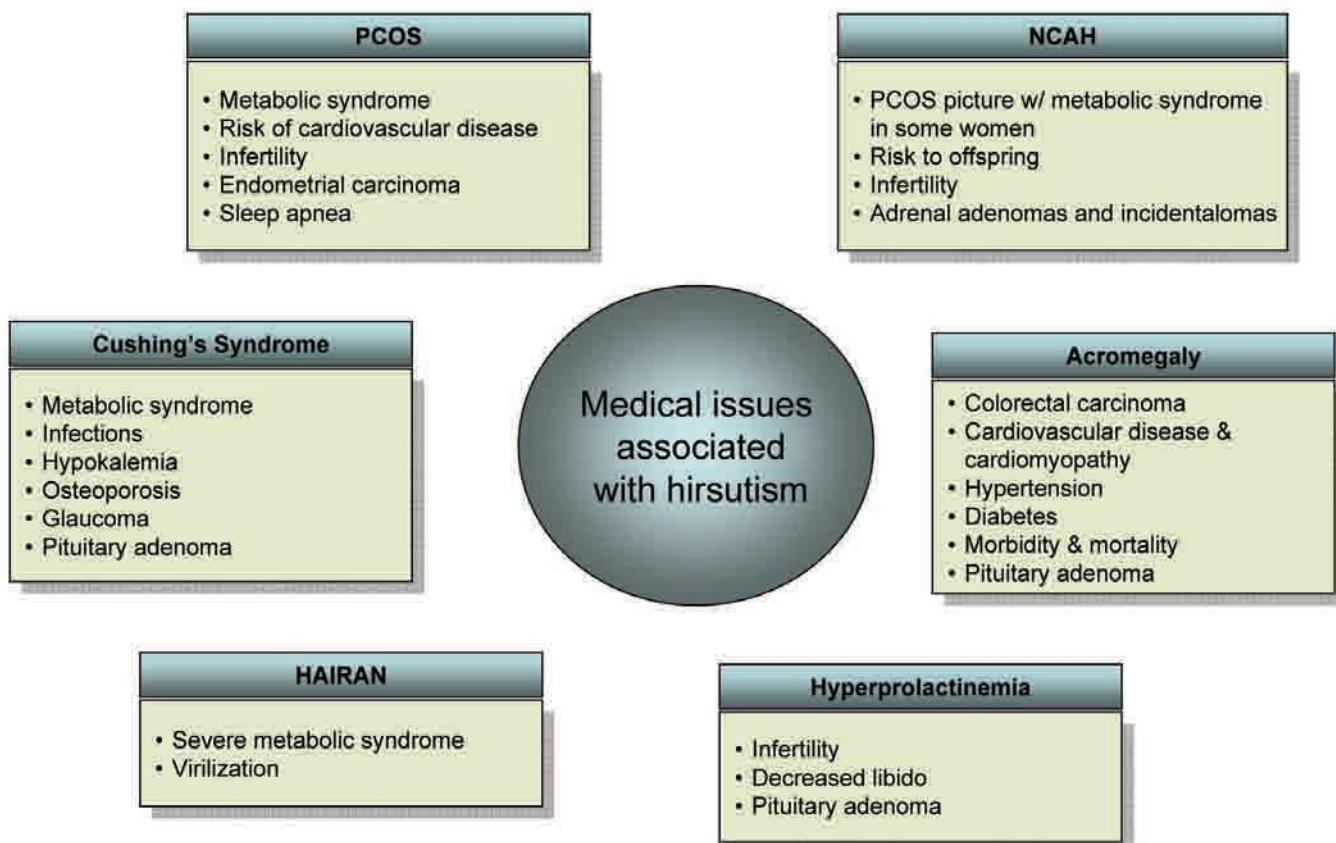

FIGURE 8-2 Medical issues associated with hirsutism

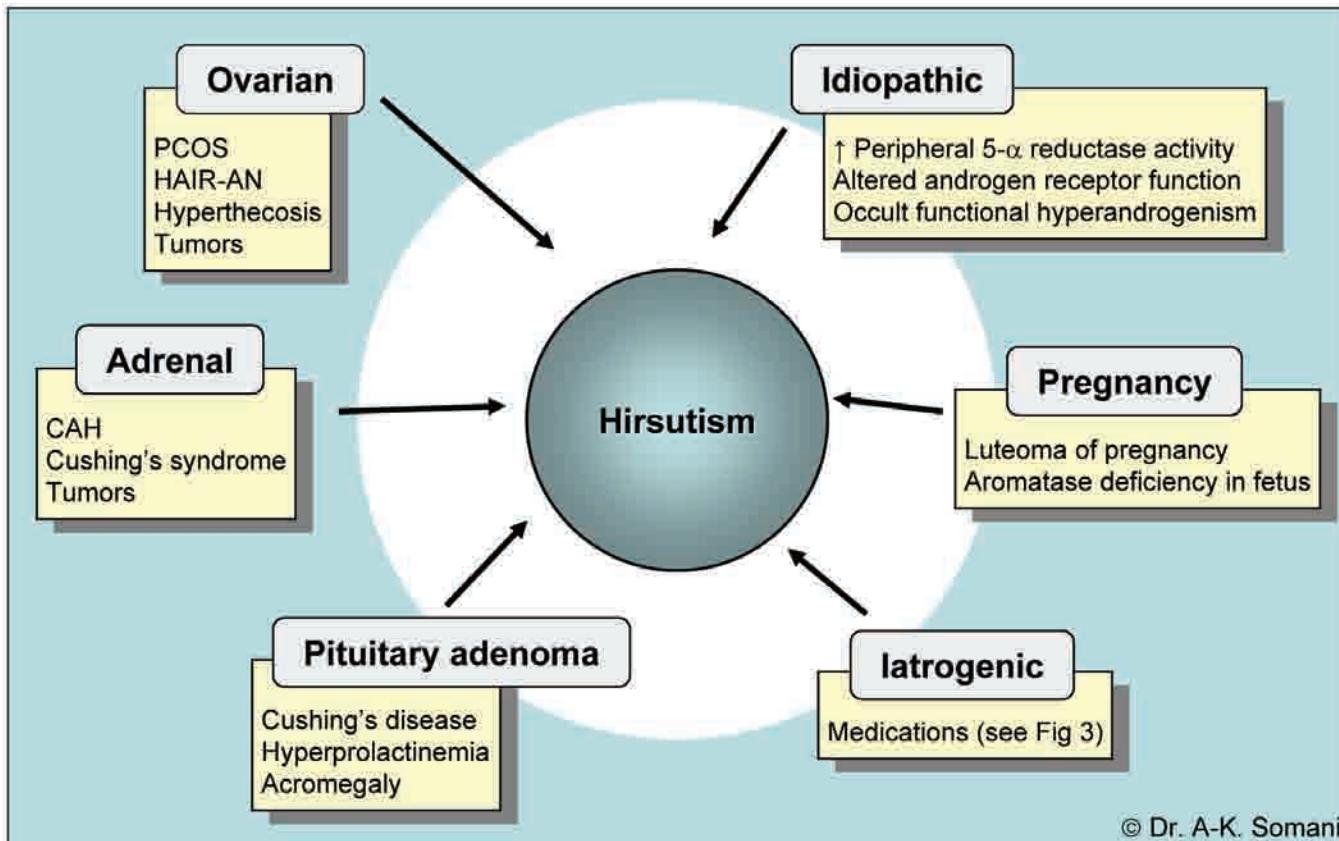

FIGURE 8-3 Etiologies of Hirsutism. PCOS: Polycystic ovary syndrome; HAIRAN syndrome: hyperandrogenism, insulin resistance, acanthosis nigricans; CAH: congenital adrenal hyperplasia.

(Figure 8-3). Five to 15% of hirsute women have “idiopathic” hirsutism. By definition, these women have regular menstrual cycles and no detectable androgen excess by conventional testing methods.^{12,18,25} Excess androgens can also be from exogenous sources such as androgen containing creams, danazol for endometriosis, oral contraceptives with an androgenic progestin, anabolic steroids and other medications (Figure 8-4).^{13,18,26–28}

Ovarian Causes

Polycystic ovary syndrome is estimated to affect 6.5–8% of reproductive age women worldwide and is inherited in an autosomal dominant pattern. Male relatives are carriers and may present with balding before age 30 and possible insulin-resistance.^{4,29–32} According to the 2008 Androgen Excess Society Guidelines, PCOS is defined by hyperandrogenism (clinically or biochemically) in association with ovarian dysfunction (oligo-anovulation and/or polycystic ovaries) with the exclusion of related disorders.³³ A proper diagnosis of PCOS is important, because it is associated with an increased risk for infertility, dysfunctional uterine bleeding, metabolic syndrome (i.e., type II diabetes, hypertension, hyperlipidemia, and increased BMI) and possibly cardiovascular disease.³⁴ Other studies have linked PCOS with obstructive sleep apnea, depression, nonalcoholic fatty liver disease and certain cancers such as endometrial

carcinoma.^{35–38} Hyperandrogenemia in PCOS is predominately caused by gonadotropin-dependent functional ovarian hyperandrogenism and to a lesser degree adrenal hyperplasia.^{39–40} As noted above, elevated androgen and insulin levels are associated with decreased levels of SHBG synthesis leading to elevated free testosterone in patients with PCOS.^{9–10} Insulin also directly affects ovarian androgen production.

HAIRAN syndrome is described as an extreme variant of PCOS with higher insulin levels and insulin resistance. HAIRAN syndrome actually represents a series of inherited syndromes, in which insulin receptor or post receptor defects lead to insulin resistance and a compensatory rise in circulating insulin. In addition to reducing SHBG levels, the excess insulin along with increased pituitary secretion of luteinizing hormone (LH), stimulates ovarian androgen secretion leading to hyperandrogenemia and virilization, that may mimic an androgen tumor.²⁷ Acanthosis nigricans results from the mitogenic effect of insulin on basal cells of the epidermis.^{41–42} Although there is clinical overlap with PCOS, women with HAIRAN syndrome are likely to have a greater degree of associated morbidity.

Ovarian hyperthecosis is caused by hyperplastic ovarian theca cells that have differentiated into luteinized stromal cells and actively produce androgens. These women are typically postmenopausal and have a long history of hirsutism in conjunction with signs of virilization. Their

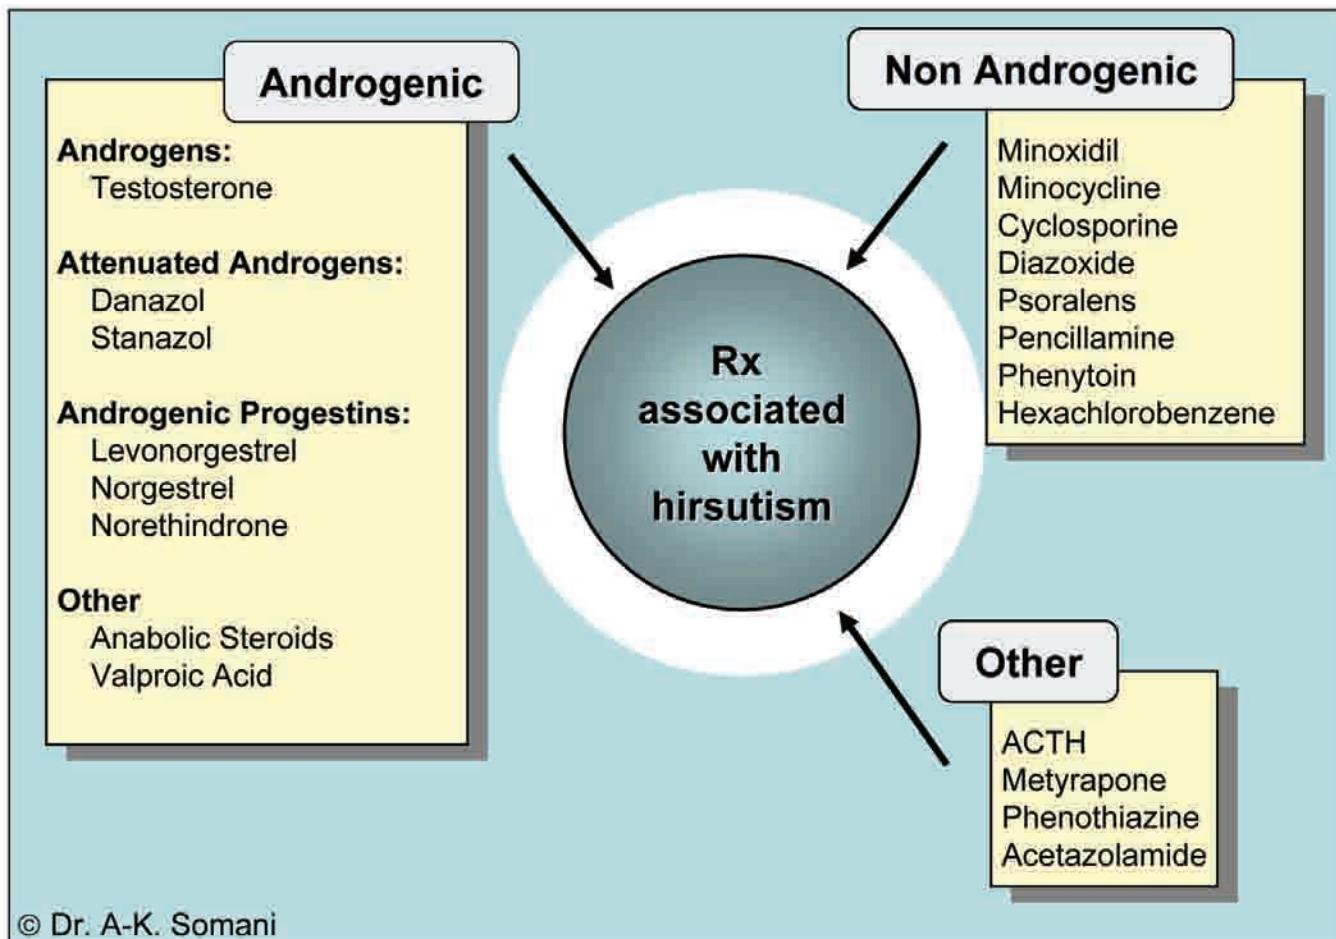

FIGURE 8-4 Medications associated with Hirsutism

clinical presentation may mimic that of androgen-secreting tumors. Like PCOS and HAIRAN, these patients are likely to develop insulin resistance.⁴³⁻⁴⁴

Adrenal Causes

Nonclassic adrenal hyperplasia is autosomal recessively inherited and is most commonly caused by a partial defect in the 21-hydroxylase enzyme (less commonly by defects in 11-hydroxylase or 3-β hydroxyl- Δ^5 -steroid dehydrogenase). It presents with a clinical picture similar to PCOS.^{18,45-46} The worldwide prevalence is approximately 2%; however, reports vary from 0.6-8.4% depending on the ethnicity of the population studied.²³ Patients commonly present with hirsutism in the prepubertal years, premature pubarche, menstrual irregularities, and virilization.⁴⁷⁻⁴⁸ The defective 21-hydroxylase enzyme results in accumulation of steroid precursors, including 17-hydroxyprogesterone (17-HP) and androstenedione. A decrease in cortisol production leads to an increase in ACTH, which stimulates the adrenals to produce steroids resulting in the accumulation of additional precursor steroids. Although typically a rare cause of hirsutism, it should be suspected in certain ethnic populations in which it occurs more frequently (see below).^{18,46}

Cushing syndrome is the result of adrenocortical hyperfunction leading to excess adrenal androgen and cortisol production and secretion. Cushing syndrome presents with signs and symptoms associated with corticosteroid excess, such as fat redistribution (central obesity, moon facies, dorsocervical fat pad), thinning of skin with striae, glucose intolerance, osteoporosis and proximal muscle weakness, in combination with signs and symptoms of hyperandrogenism and menstrual irregularities.²⁷

Hyperprolactinemia can affect the adrenal glands because they have a rich supply of prolactin receptors. Stimulation of these receptors can lead to increased synthesis of androgens.⁴⁹ However, the increased prolactin levels can also have an inhibitory effect on the conversion of testosterone to DHT. As a result, hyperprolactinemia rarely causes hirsutism, with an estimated prevalence of only 0.3%.^{18,50}

Additional Causes

Androgenic tumors of the ovary or adrenal gland are rare and are typically associated with androgen levels two times or greater the upper limit of normal along with a rapid onset of hirsutism and virilization. Signs and symptoms of virilization include a deepened voice, clitoromegaly,

increased muscle mass, and increased libido. When these are noted in association with Cushingoid features, adrenal tumors should be suspected, warranting imaging studies for confirmation.^{27,51}

Five to 15% of hirsute women have no evidence of biochemical androgenic excess or irregular menses and are defined as having “idiopathic” hirsutism.^{25,52} It has been demonstrated that as many as 40% of hirsute women reporting regular menstrual cycles, were actually found to be oligo-ovulatory when thoroughly evaluated with basal body temperature charting and luteal phase progesterone levels. These patients likely suffer from PCOS without overt menstrual irregularities.⁵² Some women with “idiopathic” hirsutism have a normal level of androgens, but have increased androgenic receptor sensitivity or increased local levels of 5 α -reductase resulting in relative peripheral hyperandrogenism at the hair follicle.⁵²⁻⁵³ Occult hyperandrogenemia can be uncovered in a large number of these women by gonadotropin-releasing hormone (GnRH) and corticotropin (ACTH) stimulation tests.⁵⁴ These are advanced tests that are currently available only on an experimental basis.

Some of the endocrine disorders underlying hirsutism may be inherited (e.g. PCOS, NCAH). Genetics can also influence the expression of hirsutism. For example, up to 30% of women with PCOS are not hirsute despite having elevated serum androgen levels comparable to their hirsute counterparts. This may be due to differences in peripheral androgen metabolism and in particular to variations in the 5 α -reductase type 1 and type 2 genes.⁵⁵⁻⁵⁶ Future development of genetic tests may be helpful in this regard.

CLINICAL EVALUATION

The goal of evaluating hirsutism is to identify the underlying etiology. The first step involves identifying and quantifying the degree of hirsutism as a baseline using one of the described visual scoring methods. The degree of hirsutism does not always correlate with the degree of hyperandrogenemia,¹⁸ but is often used to determine the extent of evaluation warranted.^{39,57} A thorough assessment of methods used to camouflage or remove hair is essential to accurately appreciate the degree of hirsutism. Many women with seemingly “mild” hirsutism use various methods to camouflage or remove unwanted hair, especially in more visible areas, and this may impact the examiner’s assessment if this information is not accurately obtained from the patient.¹² In addition, a focused history and appropriate physical examination are essential for guiding more extensive investigations to identify rare underlying etiologies or associated comorbidities. Tables 8-1 and 8-2 describe the key features of a focused history and physical examination for evaluating hirsute women. Current and prior medications should be assessed for those potentially linked to hirsutism (Figure 8-4), and assessment for associated medical problems, family history and psychosocial impact should be ascertained.

TABLE 8-1—Key Points for History Assessment

Clinical Data	History
History of present illness	Onset and progression of hirsutism—key determinant for further evaluation Sites & extent of hirsutism Psychosocial impact Treatments to date Use of skin irritants Change in body habitus
Associations	Alopecia Acne Seborrhea
Menstrual history	Age of onset Regularity Dysfunctional uterine bleeding
Reproductive history	Infertility
Past Medical History	Diabetes Hypertension Cardiovascular disease
Family History	Hirsutism Male relatives with excess hair or diabetes Male patterned alopecia prior to age 30
Medications	Use of medications associated with hirsutism (see Table 8-3) Use of oral contraceptive pills
PCOS	Weight gain, polydipsia, polyuria due to glucose intolerance, hypertension, hyperlipidemia, sleep apnea
HAIR-AN	Weight gain, polydipsia, polyuria due to glucose intolerance, hypertension, hyperlipidemia +/- virilization
Insulin resistance syndromes	Polydipsia, polyuria
NCAH	Ethnicity, amenorrhea, irregular menstrual cycles, premature pubarche, infertility +/- polydipsia, polyuria
Thyroid dysfunction	Hot or cold intolerance, weight changes, tremors
Cushing syndrome	Weight gain, striae, increased infections, easy bruising, fragile skin, weakness with rising from sitting position or when combing hair, insomnia
Hyperprolactinemia	Galactorrhea, infertility, oligo or amenorrhea, decreased libido
Pituitary Tumor	Visual disturbance, headache
Tumors- Adrenal/Ovarian	Virilization-increased libido, muscle mass, deepened voice, and clitoromegaly

TABLE 8-2—Focused Physical Examination

Clinical Data	Physical examination
Vital Signs	Height, weight and BMI Blood Pressure
Quantification of hirsutism	mFG score
Skin	SAHA: acne, seborrhea, hirsutism, patterned alopecia
PCOS	Acanthosis nigricans, SAHA, obese or lean
HAIR-AN	Acanthosis nigricans +/- signs of virilization-increased muscle mass, deepened voice and clitoromegaly
NCAH	High risk ethnicity, ±PCOS phenotype
Thyroid dysfunction	Weight change, dull facies, malar rash, generalized myxedema, tremors, exophthalmos, pretibial myxedema
Cushing's syndrome	"Fat redistribution"*, ecchymosis, proximal muscle weakness
Hyperprolactinemia	Galactorrhea
Acromegaly	Frontal bossing, prognathism, enlarged face, hands and feet, macroglossia, excessive sweating, pigmented skin tags and acanthosis nigricans
Pituitary Tumor	Visual field defects
Tumors-Adrenal/Ovarian	Palpable ovarian/abdominal mass, Virilization – increased muscle mass, deepened voice and clitoromegaly.

*Fat redistribution with increased abdominal girth, moon facies, dorsocervical fat pad, and slim limbs. PCOS: Polycystic ovary syndrome; HAIRAN syndrome: hyperandrogenism, insulin resistance, acanthosis nigricans; NCAH: nonclassic adrenal hyperplasia.

SEARCH METHODOLOGY

A search of Medline was conducted on the Ovid database using the key word "hirsutism" and "diagnosis" including all its specific terms. Searches were limited to studies in humans and articles published in English. References were evaluated along with additional references found in the original documents reviewed. Evidence presented in this chapter is derived from primary evidence, consensus reports of expert committees and clinical practice guideline publications. Most of the primary evidence is based on retrospective and prospective studies. Randomized controlled trials and meta-analyses were not available in the literature.

RESEARCH QUESTIONS AND ANSWERS

1. Which of the described visual scoring systems for hirsutism is most widely accepted for clinical use?

The clinical diagnosis of hirsutism is most commonly made using the Ferriman-Gallwey (FG) scale or a modification

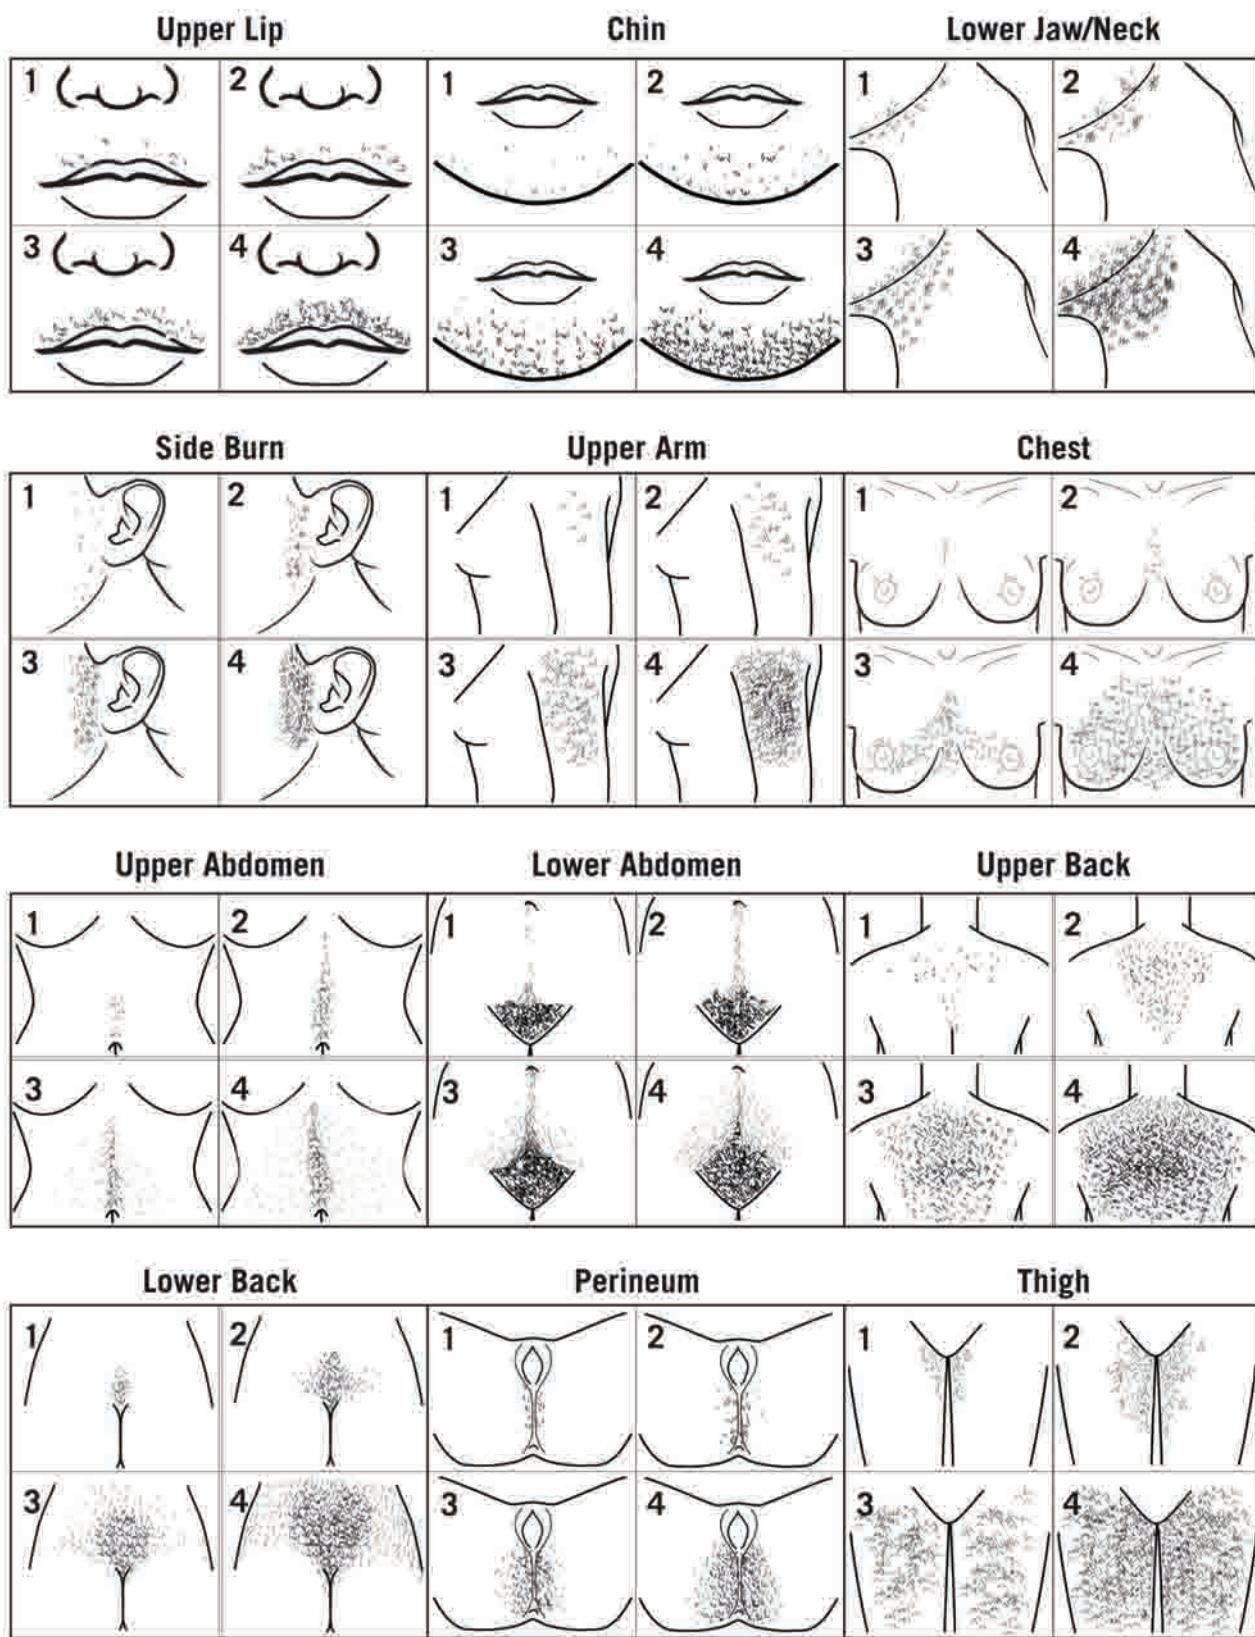

of it (Figure 8-5). The FG scale is a semi-quantitative visual scoring system originally described in 1961 based on a study of 430 consecutive women attending a general medical clinic in the United Kingdom of predominately-white race, ages 15-74 years. The system subjectively evaluated hair growth in 11 different areas (upper lip, chin, chest, upper back, lower back, upper abdomen, lower abdomen, arm, forearm, thigh and lower leg) and assigned each area a score from 0-4 based on the amount of hair present. A score of 0 is defined as the absence of terminal hairs and a score of 4 is defined as extensive terminal hair growth. It was noted that the forearm and lower leg were less sensitive to androgens and not further included, giving a maximum possible score of 36. It was determined that 4.3% of the subjects had a score greater than seven, which was consistent with the expected prevalence of hirsutism. Therefore, a score of 8 or greater was defined as hirsutism, with a score of 8-15 being defined as mild and >15 as moderate to severe hirsutism.¹

The Ferriman-Gallwey scale was later demonstrated in a study of 88 hirsute women to validly reflect androgen excess, but not directly correlate to more objective measures such as microscopic measurements of hair shaft diameter and counting of individual hair shafts when evaluating the forearm, abdominal wall and thigh.⁵⁸ Other more objective methods described in the literature include weighing hairs obtained by dry shaving or determining the density of hairs by direct counting or photography.⁵⁹⁻⁶⁰ These methods are more expensive, more complex and have poor patient acceptance, making them poorly suitable for routine clinical use.

In 2000, Knochenhauer et al. conducted a study to evaluate the utility of a significantly simplified modified FG (mFG) scale using only the chin and abdomen to correctly identify hirsutism.⁶¹ A total of 695 hyperandrogenic women were evaluated with both the standard mFG scale and with the simplified index.⁶² Based on an mFG score of ≥8, 50.1% of the participants were determined to have hirsutism. The specificity and sensitivity of evaluating only the chin and lower abdomen was then compared to the mFG results. A total of 84% and 91% of hirsute women had chin or abdomen hair scores respectively that were ≥2. Using a score of greater than or equal to two in the two areas had a sensitivity of 100%, but a specificity of only 27%. The PPV will vary depending on the population prevalence and if the general population prevalence is estimated at 5%, the simplified index would give a PPV of only 1%, making this method essentially useless in low prevalence populations.⁶¹

The Practice Committee of the American Society for Reproductive Medicine recommended a modification of the FG scale that includes the sideburns, lower jaw and upper neck, and the perineum in addition to the original nine areas described, giving a maximum score of 48 (Figure 8-5).²⁷ The European Consensus Guidelines acknowledge the limitations of the FG scale due to its subjective nature, but they too recommend the use

Modified Ferriman-Gallwey Scale

of a modification of the original FG scale.⁵⁷ A recent systematic review of the literature on scoring hirsutism concluded that the mFG scale has been more widely used in peer-reviewed articles than other assessment tools and continues to be a clinically useful instrument for visually assessing hirsute women.⁶³

2. What are the limitations of the FG scale?

The Ferriman-Gallwey scale either in its original form or in modified versions remains the current standard for grading hirsutism. However, it has significant limitations due to its subjective nature. Intra-observer variability has been shown to be within 3 points, but in a study of 21 hirsute patients, the inter-observer variation was found to be as much as 60% higher or 46% lower between observers.⁶⁴ The scale criticized for assuming that hair growth in each area is of equivalent significance and for not considering additional androgen-sensitive areas, such as sideburns and buttocks, which have been added to subsequent versions of the scale.^{13,65–66} In addition, the FG scale fails to consider ethnic variations in hair growth. For example, hirsutism is a less prevalent sign of excess androgens in women from the Shandong region of China. Only 48% of the PCOS patients demonstrated hirsutism compared to other populations where 70–80% of hyperandrogenic women demonstrate hirsutism.^{67–68} Studies of Thai women found that only 2.2% of women evaluated at annual gynecologic examinations had a mFG score of greater than 2 and none had a score greater than 5.⁶⁹ This is compared to studies by DeUgarte where 5.4% of US women had a mFG ≥ 8 .⁷⁰ Studies of Japanese women have also shown a lower prevalence of hirsutism.⁷¹ This is in contrast to studies of PCOS patients from Southern Asia (Pakistani, Bengali, Gujarati or Dravidian Indian), where hirsutism was found to be more prevalent and more severe compared to Caucasians.⁶⁷ These ethnic differences may necessitate the need for different mFG cutoff scores to define hirsutism in different populations and such variations should be considered when clinically evaluating women of different ethnicities.

3. What FG cutoff score should be used to define hirsutism?

There are varied opinions in the literature regarding the appropriate cutoff score to define hirsutism. Some have suggested a score as low as 3 defines hirsutism,⁷⁰ while others use a cutoff of 6.^{14,18,72} The bulk of the literature continues to reference the original FG score of 8–15 as defining mild hirsutism.^{1,4,13,73} This scoring system does not incorporate the impact that unwanted hair has on the

individual patient's well-being and some groups advocate for the use of a quality of life self-assessment.⁷⁴

Primary Evidence

Several studies have evaluated the modified Ferriman-Gallwey scale in which nine areas (upper lip, chin, chest, upper and lower abdomen, thighs, upper and lower back and arms) are evaluated and scored on a scale of 0 to 4 (Figure 8-4).¹ A prospective study by Knochenhauer et al., (1998), screened 369 consecutive women presenting for pre-employment physicals and found that 7.6% of the women had a mFG score of ≥ 6 , 4.6% had a score of ≥ 8 and 1.9% had a score of ≥ 10 .⁴ Based on previous estimates that hirsutism occurs in 5–15% of Caucasian women, the investigators chose to define hirsutism as an mFG score of ≥ 6 .^{2–3} This is consistent with estimates by others that hirsutism affects about 8% of the population of reproductive age women.^{1–2,4}

A prospective observational study of 349 African-American and 278 Caucasian women using the nine-area mFG scale, defined a new mFG score cutoff and demonstrated that no significant difference in prevalence of hirsutism exists between the races.^{62,70} The earlier studies by Hatch defined the mFG cut-off as greater than the 95th percentile. Using those same criteria, this study found an mFG of 7.7 to be the 95th percentile and chose to use an mFG of at least eight to define the upper limit of normal. This corresponded to 5.4% (15 of 278) Caucasians and 4.3% (15 of 349) African Americans, a difference that was not statistically significant. However, the 95th percentile method may not correspond to population or natural cutoffs. When univariate distribution was calculated it was demonstrated that the bulk of the data points were no more than a FG score of 2 and the remainder were at least 3 and it was determined that a mFG of at least 3 was out of the norm in that population. Using the mFG of ≥ 3 , 21.9% (61 of 278) of Caucasians, and 22.6% (79 of 349) of African Americans had scores above this cutoff. Again there was no statistically significant difference between the two races. The authors suggest that a mFG cutoff score of 2 is appropriate based on similar findings in a study of Dutch women that determined a score of 2 or more when evaluating upper lip, sideburns, chest, lower back, lower abdomen, thighs, and arm was abnormal.⁷⁵ In addition, they reported that 69.3% of women who had a score greater than 3 considered themselves hirsute. In contrast, only 15.8% of the women with scores below three considered themselves hirsute. When an mFG score of eight was evaluated it was found that 70% of the women considered themselves hirsute. Based on these results the authors suggested that an mFG of at least 3 is consistent with the population that considers their hair growth to be out of the norm. This study did not correlate mFG scores to serum androgen levels. The women studied were questioned about hair removal and camouflage techniques. The authors estimate that the diagnosis of

hirsutism was missed in 4% of women because of prior hair removal when using a cutoff score of 3. However, if a cutoff score of 8 was used the number of women potentially missed was approximately 50%.⁷⁰

In an additional study of 228 consecutive patients complaining of unwanted hair growth with a mFG score between 1 and 5, it was determined that 55% had androgen excess and would have been missed using a cutoff of 6-8.⁷⁶ As mentioned above, the prevalence and degree of hirsutism varies among ethnicities, and mFG cutoff scores have not been clearly defined for specific populations.⁷¹

Consensus Reports and Clinical Guideline Recommendations

The American Society for Reproductive Medicine advocates the use of a modified Ferriman-Gallwey Index that includes 12 areas: upper lip, sideburn area, chin, lower jaw and upper neck, upper back, lower back, arm, thigh, chest, upper abdomen, lower abdomen and perineum. The practice guidelines do not recommend a cutoff score to use for further evaluation of hirsute patients.²⁷ Other sources citing use of this same modified FG Index report using a score of 8-15 as mild hirsutism, as originally described by Ferriman and Gallwey.⁷³

The Endocrine Society Task Force recommends the use of an mFG scale with the original nine body areas, although they acknowledge the limitations of this scoring system. They recommend using a score of 8-15 to define mild hirsutism and ≥ 15 to define moderate to severe hirsutism.³⁹

The 2009 European Consensus Practice Guidelines recommend use of the mFG index evaluating nine areas and a score of ≥ 8 as defining hirsutism.⁵⁷

A recent systematic review on scoring hirsutism recommends that an mFG score $\geq 6-8$ is appropriate for most populations, with the exception of Mongoloid races. An mFG $\leq 2-3$ may reflect what is considered a “normal” amount of hair. However, for those women with an mFG of 3-5, up to 50% will have an androgen excess disorder.^{63,76}

4. What are the key elements of a focused history and physical exam when evaluating a patient for hirsutism?

Recommendations by experts, and guidelines published by the American College of Obstetricians and Gynecologists, the American Society for Reproductive Medicine, the Endocrine Society and the European Consensus Practice Guideline all concur that an appropriate history and physical examination are key factors in directing subsequent evaluation of hirsutism including laboratory workup and imaging.^{14,27,39,57,77}

A focused history (Table 8-1) should begin with the age of onset, progression, sites of hair growth, psychosocial impact, and treatments used to date. A rapid speed of progression should raise suspicion for androgenic tumors as should symptoms of virilization such as increased libido, deepened voice, or clitoromegaly. A history of galactorrhea is suspicious for hyperprolactinemia and visual disturbances and headaches may be associated with pituitary tumors. It is also important to obtain a current and past medication list (Figure 8-3). Menstrual and fertility history and weight gain are important because non-neoplastic causes of hirsutism most commonly manifest around puberty or following a period of weight gain. A family history of hirsutism or its associated etiologies including PCOS, androgenic alopecia, type II diabetes, early male pattern baldness, and NCAH should be specifically evaluated. Glucose intolerance should be considered if the patient reports polydipsia or polyuria. Cushing syndrome features include mood or sleep changes, weight gain, proximal muscle weakness, excessive thirst, or striae.^{57,73}

A focused physical examination (Table 8-2) should include an assessment of facial and body hair with an mFG scale. Excess androgens may also lead to acne, seborrhea, and patterned alopecia. These clinical findings constitute “SAHA syndrome” (seborrhea, acne, hirsutism and alopecia), a descriptive constellation of clinical features.⁷⁸ Height, weight, and body mass index should be obtained. Central obesity is commonly associated with PCOS and Cushing syndrome. Skin should be evaluated for acanthosis nigricans, more commonly seen in PCOS and HAIRAN syndrome, but also in hyperthecosis, Cushing syndrome, acromegaly, and occasionally NCAH. Clinical evidence of virilization and abdominal and pelvic exams are key indicators for androgenic tumors. Coarse facial features and large hands are indicative of acromegaly. As noted above galactorrhea and visual field testing are important for the diagnosis of hyperprolactinemia and pituitary tumor, respectively. Cushing syndrome features are hypertension, proximal muscle weakness, moon facies, central obesity, striae, and cutaneous infections.^{57,73}

5. What laboratory test(s) should be used in the initial screening of women diagnosed with hirsutism?

Hirsutism by itself is a purely clinical diagnosis and the purpose of further testing is to identify the etiology and associated comorbidities for management, not to confirm the diagnosis of hirsutism (Figure 8-2). Again, based on expert opinion and published Practice Guidelines, the decision to pursue laboratory testing is made based on the mFG score in the context of the history and physical examination findings (Table 8-3). Hirsutism is not always associated with elevated androgen levels, and the underlying cause

TABLE 8-3—Evidence-based First Line and Advanced Testing for Hirsutism and Its Various Etiologies

Etiology	First line	Advanced testing
Hirsutism • FG≥8 (debatable) • FG<15 (i.e moderate severity) • Rapid progression, sudden onset, signs of virilization, clitoromegaly, menstrual irregularity, infertility, acanthosis nigricans, central obesity	AM total testosterone	Free testosterone (preferred if available)
PCOS	DHEAS, 17-HP, PRL to rule out other etiologies	Lipid panel, fasting glucose/insulin, OGTT
NCAH	Am follicular phase 17-HP	ACTH stimulation test
Cushing's syndrome	24 hr urine cortisol	Dexamethasone suppression test (higher false positive rate than 24 hr urine) Lipid panel fasting glucose/insulin, OGTT, potassium ACTH stimulation test (determines ACTH dependent vs. independent Cushing's)
Hyperprolactinemia	Prolactin	CNS imaging if signs and symptoms warrant
Thyroid dysfunction	TSH, T4	Anti-microsomal antibodies
Acromegaly	Somatomedin C(IGF-1)	GH suppression after a glucose load CNS imaging if signs and symptoms warrant
Pituitary, ovarian, adrenal tumor	Androstenedione, DHEAS	MRI

does not always alter management. However, hirsutism may be an identifiable indicator of a medical disorder that does require a specific treatment or assessment. All women with amenorrhea of reproductive age should be initially screened for pregnancy with a urine or serum beta-HCG. A list of laboratory and imaging tests that may be used to evaluate hirsute women along with normal reference ranges is summarized in Table 8-4.

A prospective study of 350 women complaining of hirsutism or androgenic alopecia were tested for serum testosterone, androstenedione, DHEAS, SHBG, LH, follicle stimulating hormone (FSH), 17-hydroxyprogesterone (17-HP), and prolactin (PRL) and a pelvic ultrasound (US) was performed in order to determine the necessity for routine biochemical testing in such women. Clinical assessment along with measurement of serum testosterone as part of the baseline assessment was shown to be sufficient for excluding enzyme deficiencies and virilizing tumors.⁵⁰ PCOS was the most common etiology identified (81% of women with irregular cycles and 52% of women with regular cycles). Only 13 women in total had a significantly elevated baseline testosterone. Eight patients had an endocrine disorder or virilizing tumor.⁵⁰

A large prospective study of 873 women with androgen excess found that only 7% had a specific identifiable disorder such as NCAH, HAIRAN syndrome or

androgen-secreting tumor.¹⁸ The positive predictive value of total testosterone >200 ng/dL has been shown to be low (approximately 10%),⁷⁹ but it is suggested that total testosterone may aid in the diagnosis of some patients with androgen secreting tumors that are less obvious clinically.¹⁸ Additional studies with similar results have also demonstrated that the prevalence of serious endocrine disease causing hirsutism is low, and they are largely apparent on history and clinical examination alone.^{22,51}

Total Testosterone

From a technical perspective, testosterone assays have excessively broad normal ranges and are therefore, often difficult to interpret. The excessively wide reference ranges are likely attributed to the fact that the normative values derived from the “general population” includes women with undiagnosed excess androgens.⁸⁰ Ideally, total testosterone should be tested in the early morning on days 4-10 of the menstrual cycle, because this is how the normal values were established. Specialty laboratories with validated assays allow for more accurate measurements and should be used when available.⁸¹ It should be noted that patient’s taking oral contraceptives would have a falsely low testosterone level. A normal level of total testosterone cannot be used to rule out androgen excess. If this value

TABLE 8-4—Laboratory and Imaging Testing for Women with Hirsutism

Simple Screening Tests	Clinical Information	Normal Values
Total Testosterone	AM level on D 4-10 of menstrual cycle. Levels vary by ~25% with phase of menstrual cycle.	<12 y: 0-100 ng/dL. >12 y: 25-125 ng/dL Tumor work-up indicated if >200 ng/dL
T-SHBG ratio (free testosterone)	The ideal measure for biologically active testosterone.	>18 y : 30-135 nmol/L
DHEA-S	Adrenal androgen. Highest levels are in the morning. Levels affected by stress and exercise.	<12 y: 10-60 mcg/dL >12-35 y: 35-430 mcg/dL Rule out tumor if >600 mcg/dL
Androstenedione	Levels fluctuate widely, hence not measured routinely in the initial evaluation.	Adult women: 30-200 ng/dL Rule out tumor if >500 ng/dL.
<i>Extensive evaluation</i>		
17-OH Progesterone	Screening test for CAH. Early AM measure during the early follicular phase (between D 1-14 of menstrual cycle).	Follicular phase: 20-100 ng/dL. >200 ng/dL strongly suggests NCAH ACTH stimulation testing can confirm the diagnosis
Dihydrotestosterone		Adult women: 6-33 ng/mL
FSH*	Elevated in ovarian failure.	Follicular phase: 2.5-10.2 mU/mL Mid cycle: 3.4-33.4 mU/mL Luteal phase: 1.5-9.1 mU/mL Postmenopausal: 23.-116.0 mU/mL
LH*	An LH:FSH ratio >2 is suggestive but not diagnostic of PCOS.	Pre-menopausal: 2-15 mU/mL Follicular phase: <1-18 mU/mL Mid cycle: 22-105 mU/mL Luteal phase: 0.4-20 mU/mL Post-menopausal: 16-64 mU/mL
Serum estradiol	Should be measured in the setting of oligo/anovulation to rule out hypogonadotropic hypogonadism.	Early follicular phase: 30-100 pg/mL Late follicular phase: 100-400 pg/mL Mid cycle: 90-500 pg/mL Luteal phase: 50-300 pg/mL Post-menopausal: 0-40 pg/mL
Serum prolactin	Elevated in prolactinoma, acromegaly, thyroid disorders, PCOS and with certain medications like opiates and risperidone.	Non-pregnant women: 2-23 ng/mL Pregnant women: 10-209 ng/mL Suspect prolactinoma if: >250 ng/mL Prolactinoma less likely if: <100 ng/mL. Intermediate: >100 ng/mL or <250 ng/mL. The physician must decide whether imaging is indicated.
24 hour urinary free cortisol	Screen for Cushing's syndrome	>50 to 100 mcg/dL in an adult suggests the diagnosis. Three urine free cortisol levels within the normal range are required to exclude Cushing's syndrome
Dexamethasone suppression testing	An abnormal response to the low-dose test may indicate adrenal tumor/ pituitary tumor/ectopic source of ACTH The high-dose test distinguishes a pituitary cause (Cushing's disease) from other causes.	<u>Low dose (1 mg):</u> Overnight: 8 a.m. plasma cortisol <1.8 mcg/dL <u>High dose (8 mg):</u> Overnight: >50% reduction in plasma cortisol Normal suppression is seen with Cushing's disease.
ACTH stimulation test/ Cosyntropin test	Helpful in determining: Acute adrenal crisis Addison's disease (decreased adrenal output) Low pituitary function Pituitary tumors	An increase in cortisol (>18-20 mcg/dL) after stimulation by ACTH is normal, depending on the dose of cosyntropin used.

(Continued)

TABLE 8-4—Laboratory and Imaging Testing for Women with Hirsutism (Continued)

Simple Screening Tests	Clinical Information	Normal Values
Serum ACTH	Higher levels may be due to: Cushing's disease Ectopic tumor producing ACTH Lower levels may be due to: Cushing syndrome related to adrenal tumor Exogenous Cushing syndrome Pituitary insufficiency	8-25 mcg/mL
Combined stimulation test: ACTH and GnRH analogue	Experimental; rarely performed, to evaluate for minor forms of functional ovarian and adrenal hyperandrogenism in patients with idiopathic hirsutism.	
Serum β-HCG	Consider in women of reproductive age presenting with amenorrhea and hirsutism.	Non-pregnant: <3 mU/mL
Imaging		
CT/MRI abdomen/pelvis	To exclude an ovarian or adrenal tumor especially in the presence of virilization or rapid/sudden onset of hirsutism	
Cranial MRI	To exclude pituitary neoplasm if Cushing syndrome, thyroid disease, hyperprolactinemia, acromegaly are suspected.	
Transvaginal ultrasound	Evaluates for polycystic ovaries. Polycystic ovaries are not required for the diagnosis of PCOS nor are they diagnostic (can be seen in CAH)	
Ancillary tests		
Fasting blood glucose	Screening test for type II diabetes.	70-100 mg/dL
Fasting Insulin	For evaluating insulin resistance.	3-19 μ IU/mL
OGTT	An abnormal OGTT requires annual screening with fasting blood glucose to evaluate for development of type II diabetes.	Normal glucose value 2 hours after a 75g load of glucose: <140 mg/dL Abnormal if 2-hour serum glucose \geq 200 mg/dL
Hemoglobin A1c	An early indicator of glucose tolerance.	<7%
Lipid panel	Screen for Hyperlipidemia	TC < 200 mg/dL TG < 150 mg/dL HDL < 40 mg/dL LDL < 100 mg/dL
Potassium levels	Patients with Cushing syndrome can develop hypokalemia and hypokalemic metabolic acidosis.	3.6-5.2 mmol/L
WBC count	Elevated in Cushing syndrome due to effects of cortisol on marginated leukocytes.	3200-10,600 cells/ μ L
IGF-1/Somatomedin-C	Screen for acromegaly.	12 to 15 yrs. 261-1096 ng/mL 16 to 24 yrs. 182-780 25 to 39 yrs. 114-492 40 to 54 yrs. 90-360 55 + yrs. 71-290 80 yrs. 1-71
Serum Growth Hormone	To evaluate acromegaly	0-6 years: 0.10-8.80 ng/mL 7-17 years: 0.06-23.80 ng/mL 18 years and older: 0.03-10.00 ng/mL
TSH, T4, antimicro-somal antibodies	To screen for thyroid disease.	TSH: 0.3-5.0 mIU/L T4: 5.0-12.5 ug/dL

*Note normal reference lab values vary by laboratory.

SHBG, sex hormone binding globulin; DHEA-S, dehydroepiandrosterone sulfate; FSH, follicle stimulating hormone; LH, luteinizing hormone; ACTH, adrenocorticotrophic hormone; GnRH, gonadotropin releasing hormone; HCG, human chorionic gonadotrophin; CT, computer tomography; MRI, magnetic resonance imaging; OGTT, oral glucose tolerance test; TC, total cholesterol; TG, triglyceride; HDL, high density lipoprotein; LDL, low density lipoprotein; WBC, white blood cell; IGF-1, insulin-like growth like factor-1; TSH, thyroid stimulating hormone; T4, thyroxine.

is normal, but the patient has progression of hirsutism or risk factors for hyperandrogenism, then an early morning total and free testosterone should be measured in a reliable specialty laboratory. Normal ranges vary by laboratory and assay method, but normal is approximately 0-100 ng/dL (0.21-2.98 nmol/L). A cutoff value of 200 ng/dL is frequently used as the threshold above, which evaluation for androgenic secreting tumors is warranted.

Free Testosterone

Free testosterone is the biologically active form in the body and the measurement of serum free testosterone is 50% more sensitive than total testosterone in detecting elevated androgen levels.⁸²⁻⁸⁴ Free testosterone was shown by one retrospective study of over 800 hyperandrogenic women to be the solely elevated marker in 15% of cases.¹⁸ Most testosterone is bound to sex hormone-binding globulin (SHBG). Because of this, some women may have levels of testosterone within normal limits, but because of low levels of SHBG, still have elevated levels of free testosterone.⁸⁴ For example, SHBG levels can be suppressed in states of hyperinsulinemia and hyperandrogenemia.⁹ Normal values vary by assay method used and by laboratory, and therefore individual laboratory reference ranges should be used. Normal values also vary by population (pre vs. postmenopausal).⁸²

Unfortunately, testing methods for free testosterone are not as accurate as those for total testosterone and are not as widely available. There is no uniform standard for determining free testosterone, and there is large variability among assays.⁸²⁻⁸⁴ Currently, the most accurate method is to calculate the free testosterone from measurements of both total testosterone and SHBG using the law of mass action, however, the accuracy of this calculation is dependent on the assay methods used to measure the total testosterone and SHBG.⁸⁵⁻⁸⁶ This method was shown to correlate well with the values obtained by equilibrium dialysis ($r=0.99$; $P<0.0001$).⁸² Equilibrium dialysis is labor-intensive and expensive and typically only performed in specialty laboratories.⁸⁷ Assays to measure free testosterone directly have proven to be inaccurate and are not used.⁸⁶

Dehydroepiandrosterone Sulfate (DHEAS)

Dehydroepiandrosterone sulfate is produced almost exclusively by the adrenals and can serve as a marker of adrenal hyperandrogenism. A retrospective study of over 800 hyperandrogenic women found that DHEAS was the sole abnormality detected in 17% of the studied women.¹⁸ Elevated levels of DHEAS in conjunction with clinical findings of a rapid onset or progression of hirsutism and signs of virilization are associated with an increased likelihood of malignancy and warrant additional evaluation with abdominal CT or MRI.^{51,79,88} Adrenal tumors should be suspected if the DHEAS level is greater than 600 mcg/mL

and testosterone level is greater than 200 ng/dL.⁸⁹ However, 10% of androgen producing adrenal tumors do not present with levels to this extreme.¹³ In a retrospective study of 14 women, an elevated total testosterone and/or DHEAS level was able to detect all 14 women with adrenal carcinoma or adenoma. The combined test sensitivity was 100% (95% CI, 77-100) with a specificity of 50% (95% CI, 38-62) for detection of adrenal tumors.⁵¹ One caveat to note is that DHEAS levels decline with age suggesting a need for age-related normative values.⁹⁰

Androstenedione

Androstenedione along with testosterone and DHEAS may help to predict the source of excess androgen. If the testosterone and androstenedione levels are elevated, but the DHEAS level is within normal limits, then the ovaries are the likely source of excess androgen.⁹¹ A prospective study of 350 hirsute women demonstrated that the measurement of androstenedione in conjunction with total testosterone did not aid in identifying or excluding disorders.⁵⁰ Androstenedione is not routinely used in the initial evaluation of hirsutism by many clinicians because its concentration can fluctuate widely, even in normal women and there is little direct evidence to support obtaining this laboratory value.⁹¹

Consensus Report and Clinical Guideline Recommendations

The 2009 European Consensus Clinical Practice Guideline recommends using free testosterone determined by measuring both total testosterone and SHBG (calculating the free androgen index [FAI] by dividing total testosterone by SHBG level and multiplying by 100) to assess hyperandrogenemia in women with a FG score of at least 8. For women with a FG score greater than 15 they describe free testosterone evaluation as “prudent.” The guidelines do not recommend the use of serum total testosterone alone because it has a low sensitivity for the diagnosis of PCOS, failing to detect 20-40% of PCOS cases.⁹²⁻⁹³ The guidelines do recommend additional testing for thyroid function, serum prolactin, serum 17-HP, and 24-hour urine cortisol as warranted by clinical suspicion in women with either mild ($FG>8$) or moderate ($FG>15$) hirsutism. If patients have a testosterone level greater than 1.5-2 times the upper limit of normal or a history of rapid onset of virilization, they recommend additional testing with DHEAS and androstenedione to identify an adrenal or ovarian source, respectively. Pelvic ultrasound is recommended as a useful screen for both PCOS and neoplasms, when suspected based on history and clinical symptoms.^{34,57}

The 2008 Endocrine Society Clinical Practice Guideline does not suggest testing for elevated androgen levels in women with isolated mild hirsutism (mFG 8-15), because

they describe the likelihood of uncovering a diagnosis that would alter management or outcome as low.³⁹ They do, however, suggest testing androgen levels in women with moderate to severe hirsutism, or any degree of hirsutism that is associated with a sudden onset, rapid progression or menstrual irregularity, infertility, central obesity, acanthosis nigricans, or clitoromegaly. These guidelines are considered weak recommendations by the task force and were based on “very low quality evidence” according to the guideline. Because of the weak evidence to support these recommendations, the task force recommends that patients’ circumstances, values, and preferences be evaluated before testing decisions are made. These recommendations are based on the following evidence: in approximately one-half of women with mild hirsutism (FG score of 8-15), elevated androgen levels are not found. However, in the other half and in women with moderate to severe hirsutism (FG score >15), the measured levels of both total and free testosterone are found to be elevated.^{18,89} If testing is deemed warranted they recommend an early morning plasma testosterone level as the initial test with the addition of an early morning follicular phase 17-HP for women at high risk for NCAH.³⁹ They do note that if the measurement of free testosterone could be done reliably and was less costly, they would recommend plasma-free testosterone as an initial test for hyperandrogenism in all hirsute women.³⁹

The 2006 American Society for Reproductive Medicine Guidelines recommend testing for total and free testosterone, DHEAS and morning follicular phase 17-HP for patients suspected to have androgen excess based on mFG scale and physical examination findings.²⁷

The 2002 Clinical Management Guidelines from the American College of Obstetricians and Gynecologists recommend that because of the high frequency of association between hirsutism and PCOS, along with the significant medical risks linked to PCOS, an evaluation of testosterone and 17-HP in patients presenting with hirsutism and menstrual irregularities is recommended.⁹⁴

6. What additional testing is recommended for the diagnosis of PCOS and what ancillary tests should be done for these patients?

Based on a review of the literature and consensus conference, the 2009 Androgen Excess and PCOS (AE-PCOS) task force defined criteria for PCOS by hyperandrogenism (clinically or biochemically), ovarian dysfunction (menstrual irregularities or polycystic ovaries) and the exclusion of other related disorders.³³ An LH:FSH ratio greater than 2:1 has limited sensitivity and is no longer part of the criteria for diagnosis of PCOS.³⁴ Polycystic ovaries visualized by ultrasound are considered a diagnostic marker of PCOS by the American Society for Reproductive Medicine, but are not required for the diagnosis and are not specific to PCOS.³⁴

In women diagnosed with PCOS, a fasting lipid profile, fasting serum glucose, fasting serum insulin, and glucose tolerance test should be obtained to identify abnormalities in glucose metabolism, hyperlipidemia, and hyperinsulinemia. Calculation of BMI for these patients is also recommended because of the prevalence of central obesity in PCOS.⁵⁷ Patients with abnormal glucose tolerance tests need to be followed annually because of the risk for progression to diabetes, which has been demonstrated to be 3-7 times greater in women with PCOS.^{27,39,95} Based on the WHO diabetes criteria, a study evaluating 254 women with PCOS found that, 31.1% demonstrated glucose intolerance and 7.5% had diabetes. This is significantly higher than control women ($p=0.001$; odds ratio (OR) = 2.76 (95% CI, 1.25-6.57)).⁹⁶

A retrospective study of women with PCOS in the United Kingdom, demonstrated that all cause cardiovascular mortality was similar between women with PCOS and controls, however, risk factors for cardiovascular disease were increased (i.e., diabetes (OR 2.2 (0.9-5.2)); hypertension (OR 1.4 (0.9-2.0)); and hypercholesterolemia (OR 3.2 (1.7-6.0)) (Figure 8-2).⁹⁷ Furthermore, total cholesterol and low density lipoprotein levels were increased in obese PCOS women compared to obese controls (mean difference of 29 mg/dL (95% CI, 14-45 mg/dL; $P < 0.001$).⁹⁸ Similar results were found in nonobese women with PCOS compared to nonobese controls.⁹⁸ Insulin resistance was shown to increase with BMI in women with PCOS and overweight PCOS patients are more likely to suffer from menstrual irregularities than their “lean” PCOS counterparts.^{95,99-100}

Polycystic ovary syndrome is inherited in an autosomal dominant pattern with 90% penetrance.⁵⁵ Male pattern baldness prior to age 30 was shown to be a useful phenotypic predictor for male carriers.⁵⁵ Men with premature male pattern balding were shown to have elevated testosterone levels when compared to controls ($P=0.02$). These men may also develop insulin-resistance and increased body hair secondary to elevated androgen levels.³¹⁻³²

7. When should *nonclassical adrenal hyperplasia* (NCAH) be suspected and what tests are used for screening and diagnosis?

Nonclassical adrenal hyperplasia cannot reliably be distinguished clinically from other causes of hyperandrogenism. Like PCOS, these patients are likely to present peripubertally with mild to moderate hirsutism, acne, or oligomenorrhea, and have subsequent studies revealing elevations in testosterone, DHEAS and androstenedione along with polycystic ovaries detected by ultrasound in some patients.¹⁰¹ It has been demonstrated that the mean levels of androstenedione are higher in NCAH than in controls, but there is significant overlap with PCOS, which limits the diagnostic value of this finding.⁴⁶ Even in the setting of a normal serum total testosterone, the diagnosis of NCAH

should be pursued in certain high-risk hirsute populations (i.e., those with a family history of CAH or women of certain high-risk ethnicities [Ashkenazi Jews 1:27; Hispanics 1:40; Slavics 1:50; compared to US Caucasians 1:1000 and African-Americans rare]). Correctly diagnosing NCAH in hyperandrogenic women is important for several reasons: (1) patients with severe CYP21 alleles may require genetic counseling because of the risk of delivering a child with classic congenital adrenal hyperplasia (CAH); (2) women with CAH and male and female carriers have an increased risk for developing adrenal adenomas and incidentalomas; (3) early treatment with OCPs protects the ovaries from becoming polycystic and sclerotic; and finally (4) the choice of infertility treatment for adult women with NCAH varies from PCOS, with glucocorticoid therapy often restoring ovulation.²³

Primary Data

In a recent prospective study of 270 women in Spain with hyperandrogenic complaints, it was demonstrated that screening for NCAH with serum androgen tests alone has poor specificity.²³ The preferred screening test for CAH is an elevated early morning 17-HP. A random test of 17-HP may be normal. A study by Azziz et al. demonstrated that a basal 17-HP level of less than 2 ng/mL could be used to rule out NCAH with a NPV of almost 100%.⁴⁶ A subsequent study of 266 hyperandrogenic women reported that follicular phase samples have a higher specificity and a lower false-positive rate than luteal phase samples and that obtaining a morning sample is essential, because 5-15% of the cases of NCAH would have been missed if afternoon samples were used.¹⁰²

In the previously mentioned Spanish study, it was demonstrated that a single basal serum 17-HP test has a 0.97 (95% CI; 0.934-1.008) chance of detecting NCAH in hyperandrogenic women using the Immuchem 17-HP RIA assay. The 17-HP cutoff value recommended by this study is 1.7 ng/mL or greater based on 100% sensitivity and 88.6% specificity. This value is lower than the 2 ng/mL value recommendation by the Endocrine Society, which corresponds to a sensitivity of 83.3% and 93.6% specificity.²³ The authors argue that reaching 100% sensitivity for the screening test is important because proper diagnosis is important for both genetic counseling and infertility treatment. Further confirmatory testing requires an ACTH stimulation test (measurement of 17-HP level after administration of an IV bolus of ACTH).⁴⁶ A cutoff of ≥ 10 ng/mL has been shown to be consistent with women subsequently confirmed to have NCAH by genetic analysis of CYP21.^{23,46,103}

Consensus Report and Clinical Guideline Recommendations

Both the Rotterdam guidelines and the European Consensus report include 17-HP in the initial recommended laboratory

investigations for screening of NCAH in hyperandrogenic women.⁵⁷

In high-risk populations, the Endocrine Society Task Force recommends measuring an early morning 17-HP during the follicular phase of the menstrual cycle.³⁹ If the 17-HP is greater than 2 ng/mL, then an ACTH stimulation test should be performed. If the 17-HP is greater than 10 ng/mL after ACTH stimulation the diagnosis of NCAH is confirmed.^{46,102}

8. Which tests are used to differentiate HAIRAN syndrome from PCOS and what ancillary tests need to be performed after the diagnosis?

The clinical presentation of HAIRAN syndrome can mimic androgen-secreting tumors and therefore, the latter must be excluded. HAIRAN is characterized by extremely high insulin levels, but may be difficult to differentiate from PCOS, with which it has significant clinical overlap. This syndrome can be confirmed by measuring the basal insulin level and serum glucose and insulin after a glucose tolerance test. Patients with HAIRAN typically have a basal insulin level greater than 80 uU/mL if fasting and greater than 500 uU/mL after glucose challenge.^{42,104} Prospective studies by Azziz et al. demonstrated that HAIRAN patients had higher fasting insulin ($88.1\mu\text{M}/\text{mL} +/- 4.5$) compared to PCOS ($21.1\mu\text{M}/\text{mL} +/11.0$).¹⁸ Another recent study showed that the degree of fasting hyperinsulinemia had the greatest amount of influence on the severity of hirsutism when compared to testosterone and 17-HP serum levels (Spearman correlation 0.175; Spearman P value 0.0006).⁷²

Women diagnosed with HAIRAN syndrome should receive a lipid panel and HbA1c because of their increased risk for hyperlipidemia and diabetes. They are also at increased risk for cardiovascular disease, hypertension, and infertility. Due to its significantly higher associated morbidity, the American Society for Reproductive Medicine emphasizes the need to differentiate HAIRAN syndrome from PCOS.²⁷

9. What are the clinical indicators for androgenic neoplasms and what studies are used to confirm the diagnosis?

Primary Evidence

Androgenic neoplasms are a rare, but serious cause of hirsutism and hyperandrogenemia. Sudden onset and rapid progression of hirsutism, signs, and symptoms of virilization and palpable abdominal or pelvic masses are clinical indicators for an androgenic neoplasm. Two studies have examined the utility of elevated androgen levels at identifying an androgenic neoplasm. The first study examined 14 hirsute women with histologically proven adrenal tumors

compared to 73 women with hirsutism of non-neoplastic etiology. An elevated serum total testosterone or DHEAS had a 100% sensitivity (95% CI, 77-100) and specificity of 50% (95% CI, 38-62) at detecting adrenal neoplasms. Further testing with dexamethasone suppression reduced DHEAS and urinary 17-ketosteroid (testosterone metabolite, Figure 8-1) values to within the normal range only in women with non-neoplastic hirsutism (sensitivity 100% (95% CI, 74-100); specificity 100% (95% CI, 89-100) for detecting adrenal tumors). They conclude that serum testosterone and DHEAS are appropriate initial tests for detecting an androgenic tumor, and that a positive response to dexamethasone suppression in those identified to have elevated values can virtually rule out an underlying adrenal tumor as the cause.⁵¹

A second study over a 10-year period examined 478 hyperandrogenic women (defined by total or free testosterone or DHEAS >95th percentile of controls). Eighty percent of these women also had hirsutism (defined by FG ≥6). Overall, 11 or 2.3% of the patients had a total testosterone >250 ng/dL (8.7 nmol/L), and only one of these patients had an androgen-secreting neoplasm. Based on these findings a testosterone level >250 ng/dL was 100% sensitive and 98% specific. The NPV was 100%, but the PPV was only 9%. None of the patients had a DHEAS >600 ng/mL. The authors suggest that testosterone and DHEAS are not a cost-effective method for screening of these tumors in unselected hyperandrogenic women because of the low frequency of the disorder. They recommended testing serum androgens when a neoplasm is suspected based on clinical evaluation.⁷⁹

Consensus Report and Clinical Guideline Recommendations

The Endocrine Society Clinical Practice Guidelines recommend evaluation for androgenic tumors, when there is sudden onset and rapidly progressive hirsutism along with evidence of virilization. They recommend a pelvic ultrasound, serum testosterone, serum androstenedione and serum DHEAS, followed by a CT of the abdomen and pelvis if a tumor remains suspected. They do not identify reference ranges and cut-off values for the serum androgens, but they do acknowledge that height of the androgen levels has a poor predictive value unless testosterone level is very high (adult male range) or DHEAS >700 µg/dL, both of which are described as useful predictors of an androgenic tumor.³⁹

The European Consensus Guidelines recommend that patients presenting with testosterone levels greater than 1.5-2 times the upper limit of normal (70-90 ng/dL defined as normal), those with rapid onset of hirsutism, or those with evidence of virilization, should have DHEAS and androstenedione levels measured to identify

the source of hyperandrogenemia as either adrenal or ovarian, respectively. They also recommend ultrasound of the ovaries and adrenals as a useful tool when findings suggest an underlying neoplasm. When possible, transvaginal ultrasound is the preferred method for evaluation of the ovaries.⁵⁷

10. Who should be evaluated for Cushing syndrome?

Patients with hypertension, fat redistribution (dorsocervical fat pad, moon facies, central adiposity, and slim limbs), purple striae, hyperpigmentation, menstrual irregularities, cutaneous fungal and bacterial infections, and proximal muscle weakness should be evaluated for Cushing syndrome. Cushing syndrome is a rare cause of hirsutism with prevalence reported to be 0-1% in hirsute women.^{20,50} Cushing syndrome is screened for with a 24-hour urine cortisol and an overnight dexamethasone suppression test with a fasting early morning cortisol. The overnight dexamethasone suppression test involves administering 1 mg of dexamethasone at 11 p.m. and then measuring the plasma cortisol in the fasting patient the following morning at 8 a.m. The plasma cortisol value should be <1.8 mcg/dL (normal values vary). Urine cortisol is the most specific test for Cushing, with a value greater than 50-100 mcg/dL (normal values vary between labs) being diagnostic. In order to exclude Cushing syndrome, the urine cortisol test must be negative three times. Twenty-four hour urinary cortisol has a 95-100% sensitivity and specificity. A dexamethasone suppression test is only 80% specific, leading to many false positives that need to be confirmed by 24-hour urine cortisol test.¹⁰⁵ Further testing can be performed to determine if the disease is ACTH-dependent or independent, with ACTH-dependent Cushing being more likely to cause hyperandrogenemia.

Patients found to have Cushing syndrome should also have a fasting blood glucose, glucose tolerance test, lipid panel, and potassium level because of their increased risk for cardiovascular disease and hypokalemia. They are also at risk for osteoporosis and glaucoma, which may warrant additional screening tests (Figure 8-2).^{73,106-107}

Consensus Report and Clinical Guideline Recommendations

The American Society for Reproductive Medicine recommends the use of the dexamethasone suppression test or a 24-hour urine cortisol if Cushing syndrome is clinically suspected.²⁷

The European Consensus Guideline recommends a 24-hour urine cortisol test as part of the investigation of hirsute women, if there is clinical suspicion of Cushing syndrome.⁵⁷

11. Is hypothyroidism associated with hirsutism and how should it be evaluated?

Hypothyroidism should be suspected in a hirsute patient if they also present with diffuse alopecia, weight change, or cold intolerance. On physical examination, a goiter may be detected. Additional diagnostic testing should include TSH, free T4, and thyroid antimicrosomal antibodies. There is little evidence to suggest an association of thyroid disease and hirsutism other than a single report of a higher incidence of thyroid disease (55%) in patients with "idiopathic" hirsutism compared to control patients (12.5%).¹⁰⁸ This is contradictory to studies by Ferriman and Purdie¹⁰⁹ and Azziz et al. who reported 0 of 467 hirsute women and 1 in 873 women with androgen excess, respectively, were found to have hypothyroidism (although 5 of the 873 had been previously diagnosed).¹⁸ Both groups reported that the prevalence of thyroid dysfunction in hirsute and hyperandrogenic women studied was actually less than the prevalence reported in the general population.¹¹⁰ Despite the low yield for identifying an etiology for hirsutism, the 2003 Rotterdam PCOS Consensus contends that it is still reasonable to test because thyroid disease screening is advised for all women of reproductive age.⁴⁰

12. When should patients be evaluated for acromegaly?

Acromegaly is a rare cause of hirsutism and is the result of unregulated oversecretion of growth hormone (GH) most often caused by a pituitary adenoma.¹¹¹ Prolonged exposure to elevated levels of GH and its target hormone, insulin-like growth factor-1 (IGF-1), results in tissue enlargement and metabolic abnormalities, including insulin resistance leading to glucose intolerance and diabetes. GH and SHBG levels are inversely correlated ($r = -0.6$; $P < 0.01$) in patients with acromegaly.¹¹² The decrease in SHBG and resultant increase in free testosterone contributes to menstrual irregularities (reported in 81% of patients), and hirsutism, (noted in 55%).¹¹² Characteristic physical findings include coarse facial features, large hands, acanthosis nigricans, pigmented skin tags, and hyperhidrosis. Patient morbidity and mortality are increased because of increased risk of colorectal cancer and cardiovascular disease related to cardiomyopathy, hypertension, and diabetes (Figure 8-2). Somatomedin C (IGF-1), which is GH dependent, is the preferred screening test (normal values vary by age). Serum somatomedin C is elevated in almost all acromegalic patients, but uncontrolled diabetes, starvation, and liver failure can lead to falsely low values. In these cases, a serum GH level after a glucose load can be measured. The GH level fails to suppress to $<1\mu\text{g/L}$ in patients with true acromegaly.¹¹³⁻¹¹⁴ 30-40% of acromegalic patients are

also hyperprolactinemic.¹¹² Cranial MRI is subsequently used to identify a possible pituitary tumor.²⁷ Evaluation of somatomedin C (IGF-1) levels is not part of the routine evaluation of hirsute women, and should only be performed in the appropriate clinical context.

13. Are prolactinomas associated with hirsutism and how are they diagnosed?

Hyperprolactinemia is a rare cause of hirsutism as demonstrated by O'Driscoll with 1 in 350 women with hirsutism and/or androgenic alopecia having hyperprolactinemia and by Azziz with comparable findings of 3 in 873 women diagnosed with hyperandrogenemia.^{18,50} In patients with spontaneous or expressible galactorrhea, oligo or amenorrhea, or visual field defects, evaluation of prolactin levels can rule in or out a prolactin-producing pituitary adenoma. A subsequent cranial MRI is useful for confirming the clinical suspicion of a pituitary adenoma.^{27,39} Additional causes of elevated prolactin include PCOS, acromegaly, thyroid disorders, and certain drugs.

Consensus Report and Clinical Guideline Recommendations

The European Consensus Guidelines recommend a prolactin level test to exclude hyperprolactinemia in women with moderate to severe hirsutism.⁵⁷

The American College of Obstetricians and Gynecologists describes hyperprolactinemia as a rare cause of hirsutism, but recommends evaluation of prolactin levels in patients with amenorrhea or galactorrhea.⁹¹

CONCLUSION

Hirsutism affects 5-15% of premenopausal women worldwide and is one of the dermatologic expressions of hyperandrogenemia or of increased peripheral androgen activity. Societal norms of acceptable amounts of excess body and facial hair in women vary among populations. Although most women present only for treatment of the excess hair, there can be significant underlying associated medical disorders (Figure 8-2), that if detected and treated early, can minimize patient morbidity. Therefore, understanding the diagnostic work-up of the hirsute patient and the timing and utility of various hormonal tests is important for optimal patient management (Figure 8-6). The specific hormonal abnormalities that may be seen in the various etiologies underlying hirsutism are summarized in Table 8-5. Evidence related to diagnosis and work-up of hirsutism is generally weak; however, several recent practice guidelines make recommendations in this regard and are excellent resources for further reference on the topic.

Labs	Normal	Normal/elevated	Elevated	Idiopathic	PCOS	HAIR-AN	CAH	Cushing's syndrome	Prolactinemia	Thyroid	Acromegaly	Adrenal Tumor	Ovarian Tumor
Testosterone	Normal	Normal/elevated	Elevated							Normal	Normal/elevated	Elevated	
DHEA-S	Normal	Normal/elevated	Elevated							Normal	Normal/elevated	Elevated	
17-OH Progesterone	Normal	Normal/elevated	Elevated				Normal	Normal/elevated					
LH/FSH	Normal	Normal/elevated	Elevated				Normal	Normal/elevated					
Cortisol	Normal	Normal/elevated	Elevated				Normal	Normal/elevated	Normal	Normal	Normal	Normal	Normal/elevated
Prolactin	Normal	Normal/elevated	Elevated				Normal	Normal/elevated	Normal	Normal	Normal	Normal	Normal

DHEA-S: dehydroepiandrosterone sulfate; 17-OH- Progesterone: 17- hydroxyprogesterone; LH: luteinizing hormone; FSH: follicle stimulating hormone; PCOS: Polycystic ovary syndrome; HAIR-AN syndrome: hyperandrogenism, insulin resistance, acanthosis nigricans; CAH: congenital adrenal hyperplasia.

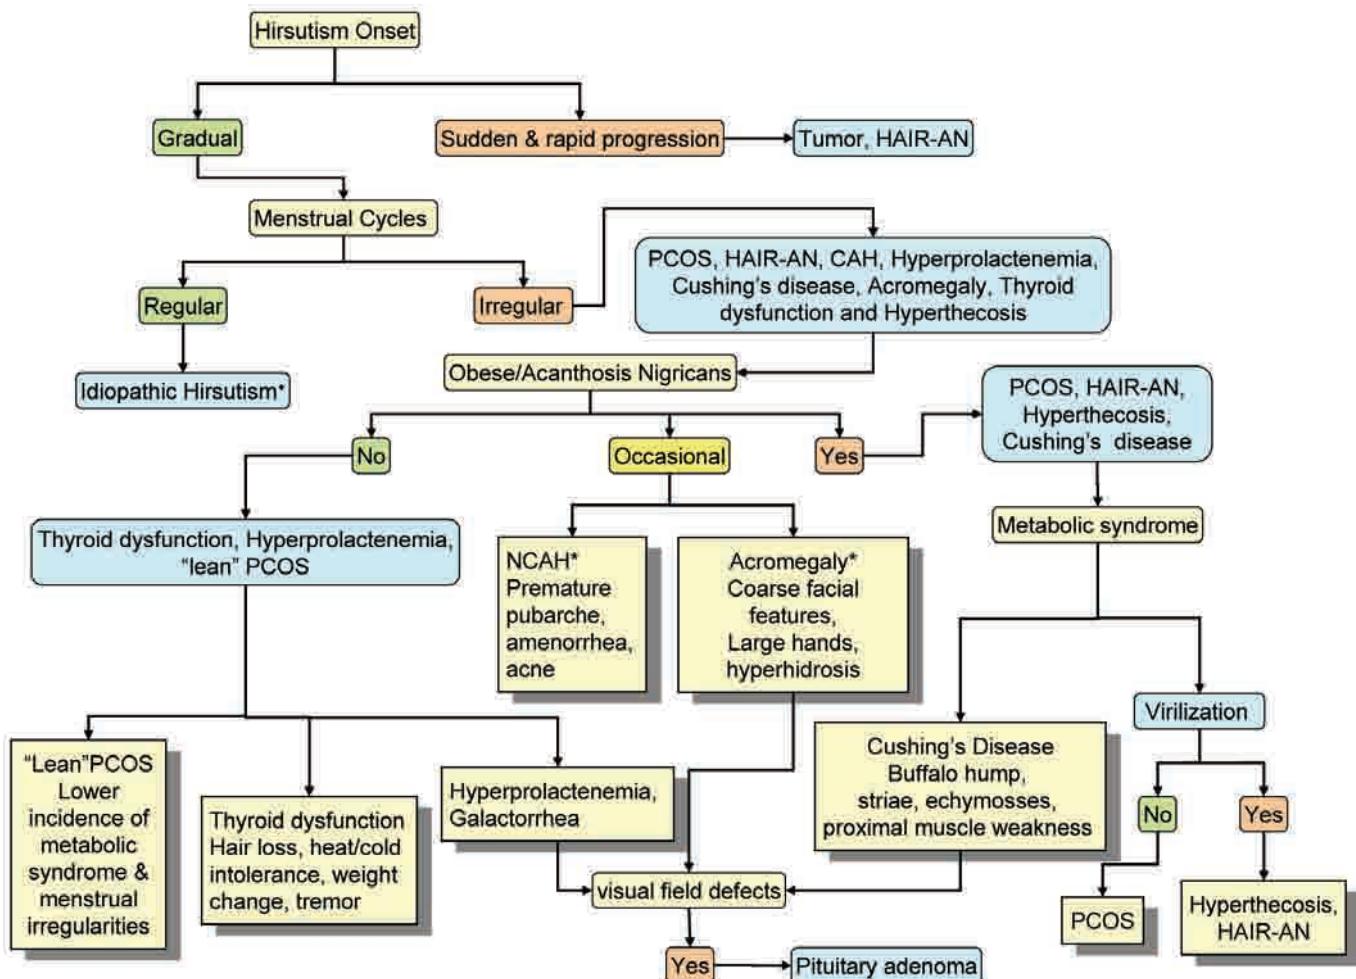

FIGURE 8-6 Evidence based algorithm for the clinical evaluation of hirsutism. HAIR-AN syndrome: hyperandrogenism, insulin resistance, acanthosis nigricans; PCOS: Polycystic ovary syndrome; CAH: congenital adrenal hyperplasia; NCAH: nonclassic adrenal hyperplasia.

What We Know

- Despite limitations, the mFG scale is the standard tool for assessment of hirsutism. Score cutoffs to define hirsutism are largely based on a Caucasian population and may not adequately reflect severity of hirsutism in women of other ethnicities.
- An mFG score of ≥ 8 is commonly used to define mild hirsutism; however, in some populations, approximately 50% of women with a score of 3 to 5 will have an androgen excess disorder.
- There is weak evidence suggesting against testing androgen levels in women with mild hirsutism, because of the low likelihood of uncovering a diagnosis that would alter management or outcome.
- There is consensus that women presenting with signs and symptoms of virilization, those with rapid progression or sudden onset of hirsutism, those with menstrual irregularity or infertility, central obesity, acanthosis nigricans, clitoromegaly, or moderate to severe hirsutism should have androgen levels tested.
- Testosterone is the most recommended first choice test for women presenting with hirsutism. Free testosterone is 50% more sensitive, but is expensive and requires a specialty laboratory test to be measured accurately.
- Clinical assessment including history and physical examination findings are the key determinants for directing more extensive testing and evaluation.
- DHEAS is a marker of adrenal hyperandrogenemia.
- Women with PCOS, require monitoring of glucose, insulin, and lipid levels. Patients with abnormal glucose tolerance tests need to be followed annually because of the risk for progression to diabetes.
- Some cases of “idiopathic” hirsutism may actually be unrecognized PCOS.
- Not all hirsute women have measurable hyperandrogenemia and not all hyperandrogenic women are hirsute. This variability reflects differences in peripheral androgen metabolism.
- Women with NCAH can have a PCOS phenotype. Early morning 17-HP level is the preferred screening test for NCAH.
- HAIRAN patients are at risk for diabetes, hypertension, cardiovascular disease, and infertility and are affected more severely than patients with PCOS.
- Androgenic tumors should be suspected clinically if there is rapid onset of hirsutism and virilization, and biochemically if testosterone levels are 1.5-2 times the upper limit of normal and DHEAS is >600 ng/mL. Visual field defects suggest a pituitary adenoma.
- Cushing syndrome, acromegaly, and prolactinomas are very rare causes of hirsutism.
- The most sensitive and specific screening test for Cushing syndrome is a 24-hour urine cortisol and the next best test is a dexamethasone suppression test.
- Acromegaly is diagnosed by clinical features and elevated somatomedin C levels.
- Clinical features of galactorrhea, oligomenorrhea, or infertility should prompt evaluation for a prolactinoma.
- Although there is poor evidence that hypothyroidism can cause hirsutism, screening is advised for all women of reproductive age and is best done with a TSH, followed by a free T4.

Therapy

Systematic Review and Meta-Analysis

Phyllis Spuls, M.D., Ph.D., and Tamar Nijsten, M.D.

EVIDENCE-BASED MEDICINE (EBM)

Evidence-based medicine is defined as ‘the conscientious, explicit, and judicious use of current best evidence in making clinical decisions about the care of individual patients.¹ Practicing EBM is not practicing ‘cook book medicine’, but it encourages clinicians to integrate valid and useful evidence with their clinical expertise and the unique features of their patients. This combination of knowledge should lead to optimal patient care.

To practice EBM there are five steps:

1. Formulate a clear clinical question.
2. Search the literature to identify relevant articles: tracking down the best evidence with which to answer the question.
3. Critically appraise the articles for quality and the usefulness of results. Assess the study’s validity (i.e., closeness to the truth), impact (i.e., size of the effect), and applicability (i.e., usefulness in clinical practice on individual patient level). In this stage recommendations may be formulated.
4. Implement clinically useful findings into practice by integrating the critical appraised findings with our clinical expertise and with our patient’s unique biology, values, and circumstances.
5. Evaluating our effectiveness and efficiency in executing steps 1-4 and seeking ways to improve them both for next time.

In clinical practice, the emphasis on each of the five EBM steps may vary and depends in part on the frequency with which we see patients with a specific disease. Step 4 remains crucial for applying EBM in the treatment of all conditions. For conditions encountered daily (e.g., treatment of mild psoriasis, atopic dermatitis, hand eczema and warts), we need to be up to date in our knowledge and very sure about what we are doing. Step 2 (searching) and 3 (critically appraising) are important operating in this “appraising” mode.

For conditions that we encounter less frequently, sources are searched that have already undergone rigorous critical appraisal such as Cochrane reviews, synthesis in Best Evidence and reviews in the Database of Abstracts of Reviews of Effects (DARE). Databases of pre-appraised

resources increase the feasibility of this approach for busy clinicians. Thus, we look for available appraised evidence and focus on eligibility criteria and critical appraisal procedure used. Therefore, the question ‘can I apply this valid, important evidence to my patient’ (step 4) remains very important in integrating EBM in the care of these diseases.

For rare conditions (e.g., cicatricial alopecia caused by pseudolymphoma), we seek, and are likely to accept and apply the recommendations received from peers with high levels of expertise in this specific condition. This “replicating” mode is blind to whether the advice received from experts is authoritative (evidence based, resulting from their operating appraising mode) or merely authoritarian (opinion based, resulting from pride and prejudice). References and background information of the recommendations received assist to judge the validity of the expert source and opinion.¹

In all circumstances, healthcare professionals should apply their general medical knowledge and clinical judgment in both the assessment of the importance of recommendations and the application of the recommendations. The following questions should be asked when deciding on the applicability of the available evidence to patients:

- Is my patient so different from those in the study that results cannot be applied?
- Is the treatment feasible in my setting?
- What are my patient’s likely benefits and harms from the therapy?
- How will my patient’s preferences influence the decision^{2,3}

In total quality management (TQM) principles, the patient is the main and central customer of the health care system and a patient’s requests and preferences are the first priorities. The goal is to emphasize applicability of EBD facts to a specific patient.

Searching for the best available evidence and analyzing and summarizing the data, which is the essence of a systematic review (SR), is one of the main tools used in EBM. In SRs the level of evidence of the underlying studies will be given, and if recommendations are formulated, the grade of recommendations is provided.

LEVELS OF EVIDENCE AND RECOMMENDATIONS

Currently, a variety of grading systems for evidence and recommendations are being used in EBM. The system used for assessing the level of evidence in a study should be clearly defined. The hierarchy of evidence and the recommendation grading's (based on the available evidence) relates to the strength of the literature and not necessarily to clinical importance.⁴

The hierarchy of studies for obtaining evidence on therapeutic interventions is:

LEVELS OF EVIDENCE

The Levels of Evidence from the Oxford Centre for EBM (May 2001):⁵

- Ia: Systematic review or meta-analysis of randomized-controlled trials (RCT)
- Ib: At least one RCT
- IIa: At least one well-designed controlled study without randomization
- IIb: Controlled observational studies: at least one well-designed quasi-experimental study such as a cohort study or case control studies
- III: Uncontrolled observational studies: well-designed non-experimental descriptive studies such as comparative studies, correlation studies, case-control studies and case series
- IV: Expert committee reports, opinions and/or clinical experience of respected authorities

Expert opinion must not to be confused with personal experience that is sometimes called eminence-based medicine. Expert opinion is the lowest level of evidence in this hierarchy and below experimental evidence but in the absence of experimental evidence may be the best guide available.⁶

Recommendation may be formulated following the hierarchy of the level of evidence of the underlying studies:

GRADING OF RECOMMENDATIONS

- A: Based on hierarchy I evidence
- B: Based on hierarchy II evidence or extrapolated from hierarchy I evidence
- C: Based on hierarchy III evidence or extrapolated from hierarchy I or II evidence
- D: Directly based on hierarchy IV evidence or extrapolated from hierarchy I, II or III evidence

A simpler system of A, B or C is recommended by the US Government Agency for Health Care Policy and Research (AHCPR):⁷

- A: Requires at least one RCT as part of the body of evidence.

- B: Requires availability of well-conducted clinical studies but no RCT in the body of evidence.
- C: Requires evidence from expert committee reports or opinions and/or clinical experience of respected authorities. Indicates absence of directly applicable studies of good quality.

The focus of the above-mentioned grading systems is only applicable for therapeutic interventions. In addition to therapy, Table 9-1 presents also the Oxford levels of evidence of other domains that are important in medicine such as prevention, harm, etiology, prognosis, and diagnosis.

Other systems are available. See also The US task force grading system: *<http://www.uspreventiveservicestaskforce.org/3rduspstf/ratings.htm>*

QUALITY OF EVIDENCE

The U.S. Preventive Services Task Force (USPSTF) grades the quality of the overall evidence for a service on a 3-point scale (good, fair, and poor):

Good: Evidence includes consistent results from well-designed, well-conducted studies in representative populations that directly assess effects on health outcomes.

Fair: Evidence is sufficient to determine effects on health outcomes, but the strength of the evidence is limited by the number, quality, or consistency of the individual studies, generalizability to routine practice, or indirect nature of the evidence on health outcomes.

Poor: Evidence is insufficient to assess the effects on health outcomes because of limited number or power of studies, important flaws in their design or conduct, gaps in the chain of evidence, or lack of information on important health outcomes.

STRENGTH OF RECOMMENDATIONS

The USPSTF grades its recommendations according to one of five classifications (A, B, C, D, I), reflecting the strength of evidence and magnitude of net benefit (benefits minus harms).

A.—The USPSTF strongly recommends that clinicians provide (the service) to eligible patients. *The USPSTF found good evidence that [the service] improves important health outcomes and concludes that benefits substantially outweigh harms.*

B.—The USPSTF recommends that clinicians provide (this service) to eligible patients. *The USPSTF found at least fair evidence that (the service) improves important health outcomes and concludes that benefits outweigh harms.*

C.—The USPSTF makes no recommendation for or against routine provision of (the service). *The USPSTF found at least fair evidence that (the service) can improve health outcomes but concludes that the balance of benefit and harm is too close to justify a general recommendation.*

D.—The USPSTF recommends against routinely providing (the service) to asymptomatic patients. *The USPSTF found*

TABLE 9-1—Oxford Center for Evidence-based Medicine Levels of Evidence (May 2001)

TABLE 9-1—Oxford Center for Evidence-based Medicine Levels of Evidence (May 2001)					
Level	Therapy/Prevention, Etiology/Harm	Prognosis	Diagnosis	Differential diagnosis/ symptom prevalence study	Economic and decision analyses
1a	SR (with homogeneity*) of RCTs	SR (with homogeneity*) of inception cohort studies; CDR [†] validated in different populations	SR (with homogeneity*) of Level 1 diagnostic studies; CDR with 1b studies from different clinical centers	SR (with homogeneity*) of prospective cohort studies	SR (with homogeneity*) of Level 1 economic studies
1b	Individual RCT (with narrow Confidence Interval [‡])	Individual inception cohort study with ≥ 80% follow-up; CDR [†] validated in a single population	Validating ^{**} cohort study with good ^{†††} reference standards; or CDR tested within one clinical centre	Prospective cohort study with good follow-up ^{***}	Analysis based on clinically sensible costs or alternatives; systematic review(s) of the evidence; and including multi-way sensitivity analyses
1c	All or none [§]	All or none case-series	Absolute SpPins and SnNouts ^{††}	All or none case-series	Absolute better-value or worse-value analyses ^{††††}
2a	SR (with homogeneity*) of cohort studies	SR (with homogeneity*) of either retrospective cohort studies or untreated control groups in RCTs	SR (with homogeneity*) of Level >2 diagnostic studies	SR (with homogeneity*) of 2b and better studies	SR (with homogeneity*) of Level >2 economic studies
2b	Individual cohort study (including low quality RCT; e.g., <80% follow-up)	Retrospective cohort study or follow-up of untreated control patients in an RCT; Derivation of CDR [†] or validated on split sample ^{§§} or databases only	Exploratory ^{**} cohort study with good ^{††††} reference standards; CDR [†] after derivation, or validated only on split sample ^{§§} or databases	Retrospective cohort study, or poor follow-up	Analysis based on clinically sensible costs or alternatives; limited review(s) of the evidence, or single studies; and including multi-way sensitivity analyses
2c	"Outcomes" Research, Ecologic studies	"Outcomes" Research		Ecological studies	Audit or outcomes research
3a	SR (with homogeneity*) of case-control studies		SR (with homogeneity*) of 3b and better studies	SR (with homogeneity*) of 3b and better studies	SR (with homogeneity*) of 3b and better studies
3b	Individual Case-Control Study		Nonconsecutive study; or without consistently applied reference standards	Nonconsecutive cohort study, or very limited population	Analysis based on limited alternatives or costs, poor quality estimates of data, but including sensitivity analyses incorporating clinically sensible variations.
4	Case-series (and poor quality cohort and case-control studies ^{§§})	Case-series (and poor quality prognostic cohort studies ^{***})	Case-control study, poor or non-independent reference standard	Case-series or superseded reference standards	Analysis with no sensitivity analysis
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or "first principles"	Expert opinion without explicit critical appraisal, or based on physiology, bench research or "first principles"	Expert opinion without explicit critical appraisal, or based on physiology, bench research or "first principles"	Expert opinion without explicit critical appraisal, or based on physiology, bench research or "first principles"	Expert opinion without explicit critical appraisal, or based on physiology, bench research or "first principles"

By homogeneity we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies. Not all systematic reviews with statistically significant heterogeneity need be statistically significant. As noted above, studies displaying worrisome heterogeneity should be tagged with a “*w*” at the end of their designated level.

Clinical Decision Rule. (These are algorithms or scoring systems that lead to a prognostic estimation or a diagnostic category.)
See note above for advice on how to understand, rate and use trials or other studies with wide confidence intervals.
Met when all patients died before the Rx became available, but some now survive on it; or when some patients died before the Rx became available, but none now die on it.
By poor quality cohort study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded) objective way in both exposed and non-exposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor quality case-control study we mean one that failed to clearly define

§ Split-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into "derivation" and "validation" samples.

Absolute sensitivity is a diagnostic test's sensitivity in a specific population. An absolute sensitivity of 100% means that all patients with the disease will test positive. A test with 100% absolute sensitivity has no false negatives.

Standard where the test is included in the reference, or where the testing affects the reference. It implies a level 4 study. Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive. Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using regression analysis) to find which factors are 'significant'.

* By poor quality prognostic cohort study we mean one in which sampling was biased in favour of patients who already had the target outcome, or the measurement of outcomes was accomplished in <80% of study patients, or outcomes were determined in an unblinded, non-objective way, or there was no correction for confounding factors.

** Good follow-up in a differential diagnosis study is >80%, with adequate time for alternative diagnoses to emerge (for example 1-6 months acute, 1-5 years chronic)

“grades of Recommendation

- consistent level 1 studies
 - consistent level 2 or 3 studies or extrapolations from level 1 studies
 - level 4 studies or extrapolations from level 2 or 3 studies
 - level 5 evidence or troublingly inconsistent or inconclusive studies of any level

at least fair evidence that (the service) is ineffective or that harms outweigh benefits.

I.— The USPSTF concludes that the evidence is insufficient to recommend for or against routinely providing (the service). Evidence that (the service) is effective is lacking, of poor quality, or conflicting and the balance of benefits and harms cannot be determined.

NARRATIVE VERSUS SYSTEMATIC REVIEWS

Conventional reviews, so-called narrative reviews, are often subjective and may be biased because there are no explicit methods for searching the literature and reporting the findings (selection bias). Moreover, these reviews often lack a critical appraisal of the quality of the included studies. The absence of a standardized methodology makes it nearly impossible to replicate the results and conclusions made by a such traditional review which may introduce bias.

In an attempt to decrease bias and increase transparency, SRs use systematic methods to control bias and imprecision; use rigorous scientific methodology to search literature, to report and to critically appraise the underlying evidence. The transparency of the methods used for the EBM steps increase the likelihood that the results can be replicated by others.

HISTORY

While some find traces of SRs and EBM's origin in ancient Greece, others trace its roots to ancient Chinese medicine. Although testing medical interventions for efficacy has existed since the time of Avicenna's *The Canon of Medicine* in the 11th century, it was only in the last quarter of the 20th century that this effort evolved to impact almost all fields of health care and policy. Archie Cochrane's, a Scottish epidemiologist, advocacy for SRs caused increasing acceptance of the concepts behind evidence-based practice. Cochrane's work was honored through the naming of EBM research centers (*Cochrane Centers*) and an international organization, the Cochrane Collaboration. The explicit methodologies used to determine "best evidence" was largely established by the McMaster University research group led by David Sackett and Gordon Guyatt. The term "evidence based" was first used in 1990 by David Eddy⁸ and the term EBM first appeared in the medical literature in 1992 in a JAMA paper by Guyatt et al.⁹ The following years, the term EBM proved extraordinarily popular and the influence of EBM has been widely recognized both in lay publications (e.g., the *New York Times* listed EBM as one of its ideas of 2001) and academic press (e.g., the *BMJ* listed EBM as one of the 15 greatest medical milestones since 1840).

THE COCHRANE COLLABORATION

The Cochrane Collaboration is a group of over 10,000 volunteers in more than 90 countries who review the effects of health care interventions tested in randomized-controlled trials.¹⁰ A few reviews that are more recent have also studied the results of non-randomized, observational studies. The results of these systematic reviews are published as "Cochrane Reviews" in the Cochrane Library.

The Cochrane Collaboration was founded in 1993 under the leadership of Iain Chalmers. It was developed in response to Archie Cochrane's call for up-to-date, SRs of all relevant RCT of health care. Cochrane's suggestion that the methods used to prepare and maintain reviews of controlled trials in pregnancy and childbirth should be applied more widely was taken up by the Research and Development Program, initiated to support National Health Service in the United Kingdom. Funds were provided to establish a 'Cochrane Centre' to collaborate with others, in the UK and elsewhere, to facilitate systematic reviews of randomized-controlled trials across all areas of health care.¹¹

The goal of the collaboration is to help people make evidence-based decisions about health care by preparing, maintaining, and ensuring the accessibility of systematic reviews of the effects of health care interventions.

The systematic review of published research studies is a method used for evaluating particular treatments. The Cochrane Collaboration is one of the best-known, respected examples of SRs. A 2007 analysis of 1016 SRs from all 50 Cochrane Collaboration Review Groups found that 44% of the reviews concluded that the intervention was "likely to be beneficial", 7% concluded that the intervention was "likely to be harmful", and 49% concluded that evidence "did not support either benefit or harm". Almost all (96%) recommended further research.¹²

The Cochrane Skin Group (CSG) is a review group of the Cochrane Collaboration directed at dermatologic health care. The Cochrane Skin Group is a network of people from all over the world committed to producing and updating reviews of trials relating to skin conditions. The aim of the Cochrane Skin Group is simply to produce the best possible evidence on the effectiveness of health care interventions for people with skin problems.

The scope of the Skin Group is wide, and includes any skin problem that leads an individual to seek help from a health care provider. The Group also considers evidence about skin treatments that are sold over-the-counter or are widely available.

THE NEED FOR SYSTEMATIC REVIEWS

Physicians often base treatment decisions on a combined understanding of the pathogenesis of a disease, pharmacologic properties of possible drugs, known effectiveness, and logic. Although this paradigm seems appropriate, it

may be problematic, because its components may change over time resulting in different treatment regimens over time. The data on which treatment's effectiveness rely also varies from personal experience and empirical observations to large multicenter double blind RCTs. Keeping up with treatment innovations is now more challenging than ever because of the overwhelming information on clinical research. It is impossible, even for the most conscientious dermatologist to keep abreast of the 100 or so specialist dermatology journals.¹³ In 1995 already, it was estimated that healthcare professionals would need to read an average of 17–20 original articles daily to keep abreast of their field.¹⁴ It is unlikely that healthcare providers, consumers, researchers, and policy makers will have the time, skills and resources to find, appraise and interpret this amount of evidence and to incorporate it into healthcare decisions.

Systematic reviews (and EBM) respond to this challenge by identifying, appraising and synthesizing research-based evidence and presenting it as “the current state of clinical practice” in an accessible format.^{15,16} Also, SRs detect gaps of evidence. For example, the lack of RCT data of methotrexate in the treatment of psoriasis was identified in systematic reviews,^{17,18} and was subsequently assessed in a comparative RCT with cyclosporine in 2003.¹⁹ The importance of SRs is also illustrated by the observation that Cochrane SRs are highly cited in the literature. The impact factor of the Cochrane Database of Systematic reviews (CDSR), published within the Cochrane Library, and is growing. In 2007, the first impact factor was 4.654, then in 2008, 5.182 and in 2009, 5.653. So on average each Cochrane review is cited over five times by researchers around the globe within two years of publication.²⁰ On July 2 2010, the Lancet have announced that they will ask authors of all research reports submitted after August 1 2010 to put their work into the context of what has gone before, by either reporting their own, up-to-date systematic review or citing a recent systematic review done by others. This is important recognition of systematic reviews as a key element in understanding the findings from all new research.²¹

Additionally, in applications for research funds, SRs may be used to support the necessity of the research proposed and sometimes they are compulsory in research proposals. Furthermore, SRs are often used as a base for (inter)national guideline development and patient information leaflets.

Besides providing a nice summary of ‘all’ information available, SRs could also include some statistical methods for combining the results of individual studies (called meta-analyses).²² Pooling of data from a SR in a meta-analysis may increase the precision of the estimate (e.g., treatments’ efficacy) by increasing the study population, reduce biases and random error of individual studies and assess the heterogeneity between the available studies. Therefore, systematic reviews and meta-analysis may result in more reliable estimates than each individual study

separately (this is reflected in higher level of evidence in the grading system; see above).

WHAT IS A SYSTEMATIC REVIEW?

A systematic review attempts to collect all empirical evidence that fits pre-specified eligibility criteria in order to answer a specific research question. It uses explicit, systematic methods that are selected with a view to minimizing bias, thus providing more reliable findings from which conclusions can be drawn and decisions made.^{23,24} The key characteristics of a SR reflect the 5 steps of EBM.

Its goal is to minimize both bias (usually not only restricting itself to RCTs, but also seeking published and sometimes even unpublished reports, in every language) and random error (by amassing very large numbers of individuals).

Systematic reviews can cover a variety of domains, but the most commonly assessed domains are: (1) therapy and prevention (e.g., interventions for nail psoriasis), (2) diagnostic tests (e.g., the value of fluorescence to detect tinea capitis), and (3) others such as prognosis, etiology (causes of disease) and severe damage (e.g., the relationship between smoking and the occurrence of psoriasis). Until Issue 4, 2008, of the Cochrane Database of Systematic Reviews (CDSR), this database was only including SRs of therapeutic interventions and from thereon, it includes SR on diagnostic test accuracy as well.²⁵ Diagnostic test accuracy reviews are full-text systematic reviews of studies that assess the accuracy of a diagnostic test or tests for a given target condition in a specific patient/participant group and setting.²⁶

SRs on therapy should ideally be based on large, well designed RCTs because they provide the highest strength of evidence. If there are no such RCTs available, a SR may be based on studies with a lower level of evidence (see above), such as low quality RCT, nonrandomized studies or patient series at a cost that the SR’s conclusions are more likely to be biased. However, for many interventions there are no RCTs available or RCT investigations are not possible (e.g., in HIV research with clear data of retrospective analyses of the effect of certain anti-retroviral agents). SRs of observational studies are then appropriate. Cochrane reviews about the efficacy of interventions focus on only RCTs.

HOW AND WHERE TO FIND SRs?

Besides in PubMed and EMBASE, SRs can especially be found in the Cochrane Library, especially in the Cochrane Database of Systematic Reviews (CDSR), the Database of Abstracts of Reviews of Effects (the DARE database), the Turning Research into Practice (TRIP) database and in SUMSearch. There is no Medical Subject Heading (MeSH) term for systematic review and also no publication type systematic review. However, these are available

for meta-analyse; “meta-analysis”[Publication Type] OR “meta-analysis as topic”[MeSH Terms]. The first one is a meta-analyse, the second one (MeSH) is concerning a meta-analyse.

In November 2001, a Systematic Reviews search filter was added to PubMed on the Clinical Queries screen to make it easier to retrieve citations for these distinctive articles.

See http://www.nlm.nih.gov/pubs/techbull/jf02/jf02_systematic_reviews.html

However, SR-filter finds more than SRs (e.g., guidelines) alone and it is and will be updated frequently. The SR-filter at this moment can be found at http://www.nlm.nih.gov/bsd/pubmed_subsets/sysreviews_strategy.html

THE SEVEN STEPS IN CONDUCTING A SYSTEMATIC REVIEW (CDSR)

A SR on therapy will be taken in the rest of this chapter as the base for describing the seven steps in conducting a SR. Prior to conducting a SR, a protocol has to be made. The protocol needs to describe the way the SR will be conducted. The 5 steps of EBM can be translated into 7 steps of SR describing the methodology of the SR.

Systematic reviewers may need to modify their original review protocol during its conduct, but changes should be reported and explained.

Step 1—The Aim of the SR

In this part, the background of the review will be discussed in the context of what is already known and the objective of the SR will be formulated in one or more clear clinical questions. The clinical questions can be translated into a PICO (Table 9-2). The ‘P’ stands for patient/population and may report on age, gender, disease and disease characteristics (e.g., adult patients with papulopustular rosacea) of the study population. The ‘I’ stands for intervention, which can be specified in for example administration mode, dose, frequency, duration (e.g., oral doxycycline, minocycline, and tetracycline). The ‘C’ stands for control/comparison

of the intervention studied (e.g., versus other active antibiotic treatments, versus placebo, versus topical agents). The ‘O’ of outcome, such as outcome parameters for efficacy (e.g., number of papels and pustels, Physician Global Assessment), or safety parameters (e.g., number of serious adverse events).

The objectives of the SR can be divided into primary objectives and secondary objectives. These should be clearly stated and the number of objectives should be restricted. The review’s primary objectives should normally reflect at least one potential benefit and at least one potential area of harm, and should be as few as possible. It is normally expected that the SR should be able to analyse these objectives if eligible studies are identified, and that the conclusions of the review will be based in large part on the effects of the interventions on these objectives.

Step 2—Search Methods

For the search of relevant studies often the ‘P’ and ‘I’ of the PICO will be used. If the focus is on specific controls or outcomes, this can be included as well. When looking for appropriate evidence the following databases can be searched.

Guidelines: National guidelines and guidance sites include among others the National Institute of Clinical Excellence (NICE), the Scottish Intercollegiate Guidelines Network (SIGN), British Association of Dermatology (BAD), The Dutch Society of Dermatology and Venereology (NVDV), National Guideline Clearinghouse. Guidance on many topics is also available at the Clinical Knowledge Summaries (formerly PRODIGY) website.

Systematic reviews, e.g. Cochrane Database of Systematic Reviews (Figure 9-1) and Database of Abstracts of Reviews of Effects (DARE database). The Cochrane Library is published on a monthly basis and made available both on CD-ROM and the Internet. In addition to Cochrane Reviews, The Cochrane Library provides other sources of reliable information: other SRs abstracts, technology assessments, economic evaluations, and individual clinical trials – all the current evidence in one single environment. DARE is the only database to contain abstracts of SRs that have been quality-assessed and is produced by the Centre for Reviews and Dissemination (CRD) at the University of York, UK. Each abstract includes a summary of the review together with a critical commentary about the overall quality. The database is a key resource for decision makers and can be used for answering questions about the effects of specific interventions, whether such questions arise from practice or in health care policy. DARE covers a broad range of health-related interventions and includes over 3,000 abstracts of reviews in fields as diverse as diagnostic tests, public health, health promotion, pharmacology, surgery, psychology and the organization and delivery of health care. DARE complements the Cochrane Database of Systematic Reviews by quality-assessing and summarizing reviews that have not yet been carried out by The Cochrane Collaboration.

TABLE 9-2—Explanation of the Acronym Pico in Defining the Aim of the SR

P	Patient population	Age, gender, disease characteristics
I	Intervention	Administration mode, dose, frequency, duration
C	Control/comparison	Placebo, active treatment or no treatment
O	Outcome	Outcome parameters for efficacy, health-related quality of life, adverse events, safety aspects, costs

FIGURE 9-1 Levels of Evidence. (Liberati A Altman DG, Tetzlaff J, Mulrow C, Gotzsche PC, Ioannidis JPA, Clarke M, Devereaux PJ, Kleijnen J, Moher D. The PRISMA statement for reporting systematic reviews and meta/analyses of studies that evaluate health care interventions: explanation and elaboration. *J Clin Epidemiol* 2009;62:e1/e34.)

Primary studies can be identified using PubMed, Medline, EMBASE, Cochrane Central Register of Controlled Trials (CENTRAL), Bandolier and Lilacs.²⁷

CENTRAL includes details of published articles taken from bibliographic databases (notably MEDLINE and EMBASE), and other published and unpublished sources. CENTRAL records include the title of the article, information on where it was published (bibliographic details) and, in many cases, a summary of the article. They do not contain the full text of the article.

About three-fifths of the records in CENTRAL are taken from MEDLINE. In addition, each Cochrane Review Group maintains and updates a collection of controlled trials relevant to its own area of interest; these are called ‘Specialized Registers’.

Also, the Cochrane Skin Group has developed a specialized register of studies. A standard description of this register can be referred to and information should be included on when the specialized register was searched for the current version of the review and the search terms used should be listed.

As *grey literature* sources, internal reports, clinical trial registries and conference proceedings may be used. These sources of grey literature should be listed. Preferably, a list

of people (e.g., trial doctors or topic specialists) and organizations who were contacted for additional evidence. List any other sources used, which may include, for example, reference lists, the World Wide Web or personal collections of articles.

Clinical librarians are specialized in searching and may be very helpful to improve your search. In the method section of the SR, the methods used to identify studies should be summarized. The methods section should state the bibliographic databases searched, the dates and periods searched and any constraints such as language should be stated. Describe the search terms. The full search strategies for each database should be listed in an appendix to the review. Ideally, there are no language restrictions in order to minimize publication bias. International publications (English language) will overweight the evidence.

Present in a flow diagram the number of references found with the searches, the number of selected articles based on title and abstract, included based on full text, excluded and the reasons for exclusion see before. As studies with negative results of interventions (especially if industry sponsored) are less likely to be published than studies with positive results (i.e., publication bias),

perhaps not all the performed studies are published, so be aware of a (often) overestimation or underestimation of the effect.

Step 3—Criteria for Selection

Objective selection for studies to answer the question after extensive searching in several databases usually ends up with a large number of hits (e.g., 800–2,000 items). The eligibility criteria for excluding studies should be clearly stated. The selection based on these criteria should be done independently by two or more authors who agree on their decision. In case of disagreements, involvement of an additional author or by discussion may lead to consensus. After the search the first selection will be based on title or title and abstract. After this stage of crude selection, a finer selection will take place on the full text of the articles. Selecting the items should be taken on the basis of clear pre-established inclusion (e.g., papulopustular rosacea, RCTs, oral antibiotic treatments) and exclusion criteria (e.g., in vitro studies, animal studies, rosacea telangiectasia studies, case reports with less than 5 patients) based on the objective of the review and PICO.

The selection criteria are based on the following aspects:

Types of studies

Eligible study designs should be stated here, along with any thresholds for inclusion based on the conduct of the studies or their risk of bias. For example, ‘All randomized-controlled comparisons’ or ‘all RCTs with blind assessment of outcome’. Exclusion of particular types of randomized studies (for example, cross-over trials) should be justified.

Types of patients/participants/ Type of diseases

Patients groups, diseases, or conditions of interest should be described here, including any restrictions such as diagnostic subtypes, age groups and settings. Subgroup analyses should not be listed here.

Types of interventions

Experimental and comparator interventions should be defined here, under separate subheadings if appropriate. It should be made clear which comparisons are of interest. Restrictions on dose, frequency, intensity, or duration should be stated. Subgroup analyses should not be listed here.

Types of outcome measures

Specify here the efficacy and effectiveness outcomes, outcomes on adverse events or economic data. A subdivision of main outcomes and other outcomes is possible.

The main outcomes may be used in the ‘Summary of findings’ table. The timing of the outcome assessment may be used. Note that outcome measures do not always form part of the criteria for including studies in a review. If they do not, then this should be made clear. Outcome measures of interest should be listed in this section whether or not they form part of the eligibility criteria. It is important to address patient-reported outcomes.

Step 4—Critical Appraisal

Subsequently, the eligible articles have to be critically appraised for their methodologic quality. In accordance with the selection of the articles, this appraisal should preferably be done independently by two objective authors and disagreements have to be solved by discussion. The value or validity of the final recommendations in a SR depends strongly on the quality of the original articles. Many tool(s) are used to evaluate the methodologic quality of the studies such as Consolidated Standards of Reporting Trials (CONSORT statement) and the risk of bias table of the Cochrane. The use of a specific tool should be described or referenced. To appraise the methodologic quality of a study included in the review and thereby to detect various forms of bias, a series of validity items has to be scored for each article. Validity items include blinding for the allocation of intervention (solution: concealment of allocation), blinding of the outcome assessment (solution: blinding of outcome assessment) and completeness follow-up (solution: no selective failure).

For the Cochrane SRs, the risk of bias table is introduced as a tool for assessing the validity of the individual studies.

In case of bias, the effect of bias on the results of the study should be analyzed.

Step 5—Objective Data Collection

The methods for data collection should be described. Preferably, a data collection form is used and data are extracted independently by more than one author, because the difference in reading and interpreting the data from the studies can occur. If relevant, methods for processing data in preparation for analysis should be described.

Data extracted for methodologic quality and outcomes could be presented in so-called evidence tables. It contains aspects of the reference, the methodologic quality (methods of blinding, concealment of allocation, intention to treat analyses, level of evidence) (Table 9-3), study characteristics (endpoints, duration of follow-up), patients characteristics (gender, type of disease, severity, duration), treatment characteristics (the intervention(-s), treatment frequency, duration, dose, setting), the outcome parameters (number of adverse events, the number of serious adverse events [SAE] and the number of dropouts

TABLE 9-3—Risk of Bias of Included RCT

	Adequate randomisation?	Adequate concealment of allocation?	Adequate blinding?	Incomplete data reported?	Free of selected reporting?	Free of other bias?
Author et al.	Yes	Unclear	Participants no	No	Unclear	Unclear
Year of publication	Yes		Researchers no Outcome assessment no			

because of AE) and results (impact, efficacy, safety, cost (Table 9-4). Additionally, the source of funding may be reported.

Step 6—Analysis (If Possible Meta-Analysis)

The results of the reviewed studies will be scrutinized and examined to what extent these results can be merged. Either a descriptive summary will be given or, when it is possible to combine the results numerically (statistical pooling), a meta-analysis will be performed. The effect measures of choice should be stated. For example, odds ratio (OR), risk ratio (RR) or risk difference (RD) for dichotomous data; mean difference (MD) or standardized mean difference (SMD) for continuous data.

Meta-analyses

As mentioned before in this chapter, pooling of data from a SR in a meta-analysis may increase the precision of the estimate (e.g., treatments' efficacy) by increasing the study population, reduce biases and random error of individual studies and assess the heterogeneity between the available studies. Thus in addition to a qualitative summary, a quantitative summary (statistical pooling or meta-analysis) may be a part of a SR. By combining data from several studies, the possibility of a more accurate estimate of the effect increases and subgroup analyses may be carried out.

Not always, is it possible or desirable to combine data in meta-analyses. It became clear about meta-analyses that there could be serious methodologic limitations because the pooled results may give an apparent accuracy. There is need for a certain clinical, methodologic, and statistical homogeneity between the studies. Performing and interpreting meta-analysis can be potentially misleading if the included studies are clinically or statistically heterogeneous. Studies that are included in meta-analysis may differ (i.e., show heterogeneity) in several ways: (1) heterogeneity of inclusion/exclusion criteria (demography/past medical histories/present illnesses of patients, method of disease diagnosis, duration/severity of the disease, etc), (2) heterogeneity of therapies (Different drugs from one class such as topical corticosteroids), different treatment durations, different routes of administration, different comparators compared to the targeted drug. (3) heterogeneity of pooled outcome measures, (4) Mixing high and low quality RCTs ** (low sample size, pseudorandomized/nonrandomized, non-blind, lack of follow-up, incomparable baseline data, in some studies), (5) Heterogeneity of effect size in included studies (some studies show pretty big effect size of efficacy/safety, some show no difference with placebo). Therefore, the eligibility criteria should be clearly stated and should try to minimize heterogeneity as much as possible. If heterogeneity of studies is present, the results of the analysis should be interpreted with great caution and it should be considered that a meta-analysis is inappropriate.

TABLE 9-4—Evidence Table: Results

	Efficacy/effectiveness	Time to response (weeks)	Duration of remission (months)	Concomitant medication	AE's (n of events)	SAE's (n of events)
Author et al.	% Complete remission active treatment ($p<0.05$)	e.g. 8 weeks	e.g.18	e.g. Prednisolone 10–60 mg (all)	e.g.Gastrointestinal complaints (1)	e.g. Septic arthritis (1), epidural abscess (1)
Year of publication	% Complete remission in conventional group ($p>0.05$)					

AE, adverse event; SAE, serious adverse event.

Statistically, a meta-analysis calculates a weighted average of all effects. The weight given to the results of an individual study depend on the size of the study's populations. It is intuitively logical that larger studies with more "events" give more weight: larger studies provide more stable estimates than small studies. An investigation of two times in 1000 patients carries more weight than a study of 100 patients two times. Suppose the first study resulted in a relative risk (RR) of 10 and the second, smaller study in one of RR 2, and then the pooled RR come closer to 10 than to 2. The larger the size of the study and the more patients with the studied outcome, the greater the weight of research in a meta-analysis.

In the graphical representation of a meta-analysis (also called 'forest' plot), several characteristics of each study are presented such as its first author, year of publication, the number of patients, and the effect size (e.g., RR or OR), and its 95% confidence interval (95% CI). The blue square, the diamond, represents the "point estimates" of the effect size and its size often reflects the sample size and the horizontal lines reflect the 95% CI (which is often narrower for larger studies). The meta-analysis of a favorable outcome ("rehabilitation", "cure", "and improved") with an effective intervention will be graphically a diamond right of the neutral line (and the RR is greater than 1). The meta-analyses of an unfavorable outcome ("deceased", "myocardial infarction", "worse") and the protective effect of an intervention is reflected by the fact that the diamond is located left of the neutral line (and then the RR is less than 1). The vertical line gives the "value neutrality" of the risk estimate (for RR it is 1 and for OR 0) where there is no difference in effect. Below the forest plot figure, results of statistical tests are given. To pool data, program Review Manager 5 (free to download from the web)

Unit of analysis issues

Special issues in the analysis of studies with nonstandard designs, such as crossover trials, studies with multiple treatment groups and cluster-randomized trials, should be described. Alternatively, optional headings specific to the types of studies may be used.

Dealing with missing data

Strategies for dealing with missing data should be described. In most cases it concerns participants lost to follow (i.e., drop-outs) who were excluded from the presented analysis in a per-protocol analysis. For an intention-to-treat analysis, the (descriptive) statistics of the primary outcome have to be re-calculated. Ideally, the original data are acquired from the responsible researchers.

Assessment of heterogeneity

Approaches to addressing clinical heterogeneity should

be described, along with how the authors will determine whether a meta-analysis is considered appropriate. Methods for identifying statistical heterogeneity should be stated (e.g., visually, using I^2 , using a chi-squared test). Clinical homogeneity will be received if the studies that are included in the SR are sufficiently similar with respect to persons under investigation, the comparison, intervention (dose, duration of treatment, allowance of co-medication) and outcomes (outcome parameters, versions of the same outcome measure, tools to measure the effect). For clinical heterogeneity, there are no proper criteria available and depends on expertise.

Moreover, methodologic homogeneity is important. In- and exclusions criteria may incorporate aspects of the clinical and methodologic quality to homogenize the ingredients of the SR and meta-analyses.

If the results of different studies, despite the adoption of clinical and methodologic homogeneity differ, we speak of statistical heterogeneity. This may be due to coincidence and actual differences in clinical or methodologic quality. The assessment of statistical heterogeneity is difficult. Visual inspection of the degree of overlap in confidence intervals is a method to examine heterogeneity. The intervals overlap "enough" then there is no heterogeneity and the investigations can be pooled.

Assessment of reporting biases

This section should describe how publication bias and other reporting biases are addressed (for example, funnel plots, statistical tests, and imputation). However, authors should remember that asymmetric funnel plots are not necessarily caused by publication bias (and that publication bias does not necessarily cause asymmetry in a funnel plot).

Data synthesis

The choice of meta-analysis method should be stated, including whether a fixed-effect or a random-effects model is used. If meta-analyses are not undertaken, systematic approaches to synthesizing the findings of multiple studies should be described. All planned subgroup analyses should be listed (or independent variables for meta-regression).

Step 7—Conclusions and Recommendations

After the analysis, conclusions should be drawn to the initial clinical question (the PICO of the SR). In addition to providing a summary of the evidence, SR reflect to what extent a clinical question has been studied, the quality of the available studies and whether it confirms the original hypothesis (e.g., is a treatment effect positive, negative or neutral). A general interpretation of the results in the context of other evidence should be given. Although the primary goal of a SR is not to formulate recommendations, the findings of the SRs or meta-analyses are often the base on which recommendations are formulated in guidelines,

which may invite some subjective input on behalf of the authors and involved experts. If gaps of evidence are found, recommendations for further research should be listed.

In this step, the limitations of the SR may be discussed. The effect of different forms of bias, if applicable, should be explained. In this perspective, the funding sources for the systematic review should be described, as well as the role of funders for the SR.

CHECKLISTS OF SYSTEMATIC REVIEWS

The value of a SR depends on what was done, what was found, and the clarity of reporting. The reporting quality of SRs varies and therefore limits the ability for readers to assess the strengths and weaknesses of those reviews.^{28,29} In 1996, an international group developed a guidance called the QUOROM statement (Quality of Reporting Of Meta-analyses) which focused on the reporting of meta-analyses of RCTs.³⁰

PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) is a revision of this guideline, which have been updated to address several conceptual and practical advances in the science of SRs. The aim is to help authors to improve the reporting of SRs and meta-analyses. PRISMA is focussed on RCTs but can be used for other study types, particularly evaluations of interventions. It may be helpful for critical appraisal of published SRs.

PRISMA (www.prisma-statement.org) uses the current terminology used to describe SRs and meta-analyses and both SRs and meta-analyses are included. The conceptual issues in the evolution from QUOROM to PRISMA includes that completing a SR is an iterative process, the protocol should be publicly accessible to judge between appropriate and inappropriate modifications. Reviewers may need to modify their original protocol during its conduct. SRs should report the assessment of the risk of bias in the included studies. For studies included in a SR, a study level assessment (e.g., adequacy of allocation concealment) and for some features, an outcome level assessment are needed. An outcome level assessment involves evaluating the reliability and validity of the data for each important outcome by determining the methods used to assess them in each individual study.³¹ The quality of evidence may differ across outcomes, even within a study. The primary efficacy outcome may be carefully and systematically measured whether the assessment of harms rely on spontaneous reports by investigators. When this information is reported it allows an assessment to which the extent to which an estimate of effect is correct is. The PRISMA statement consists of 27 items and a 4-phase flow diagram. PRISMA is a living document. Readers are invited to comment on the revised version, through the PRISMA website.

AMSTAR

The objective of AMSTAR (Assessment of Multiple SysTemAtic Reviews) was to develop an instrument to

assess the methodologic quality of SRs, building upon previous tools, empirical evidence and expert consensus. The tool consists of 11 items and has good face and content validity for measuring the methodologic quality of systematic reviews. The authors conclude that additional studies are needed with a focus on the reproducibility and construct validity of AMSTAR, before strong recommendations can be made on its use.³²

COSMIN

The COSMIN (COnsenses-based Standards for the selection of health status Measurement Instruments) checklist is an instrument to assess the risk of bias in studies on clinometric properties, as a first step to improve the methodologic quality of SRs on clinometric properties. It was developed in an international Delphi study to evaluate the methodologic quality of studies measurement properties of health-related patient reported outcomes (HR-PROs).

For the measurement of health-related patient-reported outcomes, it is important to evaluate the methodologic quality of studies in which the measurement properties of these instruments are assessed. In methodologic good studies on measurement properties, the conclusions are more trust-worthy.³³

Limitations

Since SRs summarize large amounts of information there may be loss of information of individual studies.^{1,34} The search for evidence is stopped at a certain point in time and the final publication of the SR may take an additional year, therefore, SR may not include all the evidence at time of publication. This issue is particular important in treatments of diseases that are evolving quickly such as psoriasis. Updating SRs is a pivotal part of initiating, but also maintaining, a (Cochrane) SR.¹⁰ The content of a SR depends on the evidence found, of which the majority derives from published data in international journals. Therefore, treatments studied more rigorously in multiple RCTs are more likely to achieve the highest level of evidence (see later). Relatively new patented drugs are much more likely to be studied in large, high quality RCTs because of industry funding, which is in contrast to older drugs that ran out of patent.³⁵ For example, the level of evidence for methotrexate or fumaric acids in the treatment of psoriasis is fairly low compared to that of treatments that are on the market for less than 5 years. Moreover, studies yielding positive and significant results of a treatment are more likely to be published (i.e., publication bias) and therefore are overrepresented in SRs.³⁴ Ideally and in addition to published data, an attempt should be made to include nonpublished data from pharmaceutical companies and the abstracts of meetings. The degree of publication bias can also be estimated statistically.³⁶ This illustrates the importance of registration of clinical trials

in online freely accessible databases (e.g., www.clinicaltrial.gov). However, this system is not completely waterproof as recently demonstrated in a study on registered and published outcomes.³⁷ If language restrictions are applied (often with a focus on English publications), there is often an overestimation of the effect because positive findings are more likely published in international peer reviewed journals than studies with negative results. In the current categorization of level of evidence, RCTs are overemphasized: small, low quality RCTs rank higher than well-performed observational studies.³⁸ There is a trend to upgrade well-performed observational studies. One of the major advantages of this study types is that it assesses the effect of treatments (e.g., effectiveness, safety, preference, and costs) in real life situations. Patients included in RCTs reflect a healthy and well-defined subgroup of the entire patient population that a physician may encounter during daily practice.³⁹ In practice, many patients are much more complicated because they may be older or younger, may have important past or current medical problems, use other drugs, may have other disease subtypes, and be less compliant. Moreover, RCTs often do not last longer than 24 weeks and several therapies may lose some of its effectiveness over time, and its dosage has to be increased, has to be discontinued and/or combined with other drugs.

To adequately summarize different datasets, uniform outcome parameters are warranted (especially in meta-analysis) implying that studies using other endpoints may not fully weigh on the final result. For example, in contrast to the PASI75 in psoriasis, there is a wide variety of outcomes used in atopic dermatitis studies, which makes it difficult to compare and pool data from the different studies. To conclude, many more limitation could be listed here but the authors believe that to the best of our abilities, systematically summarising evidence is nowadays impossible to ignore in our work and very necessary.

Treatment of Hand Dermatitis

Sara Hylwa, B.S., and Mark Davis, M.D.

INTRODUCTION

Hand dermatitis (also known as hand eczema) is a relapsing-and-remitting disease that is common and frequently chronic. Our hands are important tools of communication and function, thus the location of this dermatitis and the pain and irritation associated with hand dermatitis affects patients' ability to perform daily tasks both at home and in the workplace. The visibility of the dermatitis is a source of embarrassment and psychologic stress for many patients impacted by this disease.¹

EPIDEMIOLOGY AND ETIOLOGY

Hand dermatitis is a very common disorder of the skin, affecting all age groups,² with a prevalence in the general population of roughly 10%³ and incidence of 7.7-9.9% cases per 1000 person-years.⁴ In certain occupational settings, prevalence may be increased to 30% or more, often making hand dermatitis the most common occupational skin disease.^{5,6} People particularly at risk are those who participate in "wet-work," such as construction workers,⁶ hairdressers,⁷ housekeeping personnel,⁸ hospital employees,⁹ gardeners,¹⁰ and metalworkers.¹¹ Some studies have documented a higher prevalence of hand dermatitis in women than men, attributed to women's increased exposure to 'wet work' because of their disproportionately greater role in household chores.¹²

The etiology of hand dermatitis is multifactorial, but disruption of the normal skin barrier is thought to be a key factor in its pathogenesis. Subtypes of hand dermatitis attempt to classify the disease based on both etiologic and morphologic characteristics. Currently, there is no universally accepted classification system available for hand dermatitis.¹³ Generally accepted sub-classifications, as documented by Warshaw et al.¹⁴ are: contact dermatitis (irritant or allergic), atopic hand dermatitis, recurrent vesicular hand dermatitis/pompholyx (also known as dyshidrotic eczema), hyperkeratotic hand dermatitis (also known as tylotis eczema), nummular (discoid) hand dermatitis, and chronic vesicular hand dermatitis.

Irritant contact dermatitis is the most frequent diagnosis, comprising 35% of patients in the general population with hand dermatitis. This is followed by atopic dermatitis

(22%) and allergic contact dermatitis (19%).¹² Recurrent vesicular hand dermatitis and hyperkeratotic hand dermatitis account for 5-20% and 2% of all hand dermatitis cases, respectively.^{15,16} In the occupational setting, irritant contact dermatitis may account for up to 76% of cases of hand dermatitis.¹⁷ In practice, it is not uncommon for a mixture of hand dermatitis subtypes to coexist.^{18,19}

Exogenous Etiology

Contact dermatitis is a cutaneous reaction to exogenous (external) factors within the environment.² Since our hands are so intimately involved with our environment, they are particularly predisposed to the development of contact dermatitis. There are two types of contact dermatitis: irritant contact dermatitis and allergic contact dermatitis.

Irritant contact dermatitis (ICD) is a reaction to direct damage of keratinocytes that results from contact with harmful chemicals or physical agents (irritants). This damage is not immune mediated, but is the result of the irritant itself.² Damage and the resulting dermatitis may be acute or chronic in type. Acute irritants, such as chemical acids and bases, will cause inflammation in anyone who is in contact with them. Chronic ICD is more common and results from the repetitive use of mild skin irritants, such as soap and water, which have a cumulative effect on the skin over time.¹⁵

Frictional irritants, such as repeated exposure to trauma, rubbing, vibration, or pressure, have also been reported to cause a form of contact dermatitis.²⁰ Chronically, frictional dermatitis has been implicated in the development of hyperkeratotic hand dermatitis.^{16,20}

Allergic Contact Dermatitis (ACD) is a cutaneous immune-mediated reaction that results from contact with a specific allergen to which a patient has developed sensitivity.²¹ It is a type IV, T-cell mediated, delayed hypersensitivity reaction. Lesions often appear more acutely than in ICD, generally occurring within 48 hours of reexposure to the allergen.¹⁵ ICD and atopic dermatitis may also predispose a patient to ACD because in both, the epidermal barrier function is disrupted allowing greater penetration of allergens.¹⁴

Endogenous Etiology

Atopic dermatitis (AD) is an inherited endogenous dermatitis. Although a maternal history of atopy is a strong predictor for the development of AD, interplay between genes and the environment most likely leads to development of the disease.²¹ One hypothesis suggests that atopic individuals have a genetic alteration in the integrity of their skin barrier, which leads to a potent Th2 allergic response when the skin is presented with antigen. This then leads to an increased production of IL-4 and IgE.²² Atopic hand dermatitis has also been associated with a mutation in the gene coding for filaggrin, a protein involved with skin barrier protection.²³ The loss of skin barrier integrity can predispose atopic individuals to contact dermatitis by allowing increased skin penetration of irritants.²⁴ One-third to one-half of patients presenting with hand dermatitis was found to be atopic, and atopic patients are at a 13.5-times greater risk of developing occupational dermatoses than nonatopic patients.^{24,25}

Exogenous or Endogenous Etiologies?

Acute or recurrent vesicular hand dermatitis (RVHD) is traditionally classified as an endogenous dermatitis, although there is increasing evidence that recurrent vesicular hand dermatitis is in many cases a cutaneous reaction to exogenous contact allergens: metal allergy (most notably to nickel, chromate, and cobalt), cosmetic and hygiene product sensitivity (especially shower gel), tobacco smoking, hyperhidrosis, history significant for atopy, and psychologic stressors have all been associated with the condition.^{26,27} Chronic vesicular hand dermatitis (CVHD) may be a chronic form of RVHD, although it may also result from other types of hand dermatitis.²⁸ RVHD may also be confused with a dermatophytid ('id') reaction—the formation of vesicles on the fingers in response to a distal infection—most commonly tinea pedis.^{27,28}

Both hyperkeratotic hand dermatitis and nummular hand dermatitis have unknown etiologies,^{25,29} although hyperkeratotic hand dermatitis has been associated with chronic exposure to friction.^{16,20}

CLINICAL MANIFESTATION

Hand dermatitis is not a uniform disease. Its morphology varies based on its etiology, chronicity, and severity. Common clinical manifestations include: erythema, edema, papules, vesicles, scaling, hyperkeratosis, dryness, lichenification, and fissuring that may involve a few fingers to the whole hand surface.³⁰ The subtypes of hand dermatitis frequently have morphologic and distributional patterns that may suggest causation, but this is rarely exact, and frequently, there is a mixture of subtypes present.^{12,30}

FIGURE 10-1 'Apron-like' pattern of irritant contact dermatitis.

Contact Dermatitis

In general, acute contact dermatitis is characterized by erythema, papules, vesicles or bullae, urticaria, excoriations, and crusts, while chronic contact dermatitis is characterized by dryness, scaling, lichenification, and fissuring that can result immediately or days after exposure to the irritant/allergen.¹⁸ Both forms can have associated pruritus and/or pain.¹⁸ Specific features of ICD and ACD are listed below:

Irritant Contact Dermatitis

ICD is commonly associated with wet work. It generally involves the finger web-spaces and may extend to the dorsal and/or ventral surfaces of the hand in an "apron-like" pattern (Figure 10-1).¹⁴

Allergic Contact Dermatitis

ACD is generally indistinguishable from ICD, but it favors the fingertips, nailfolds, and dorsal aspects of the hands—generally sparing the palms (Figure 10-2).²⁵ In fact, a dermatitis that spreads to the dorsal aspects of the hands is said to be characteristic for ACD.³¹ Edema and vesicles

FIGURE 10-2 Acute allergic contact dermatitis.

are common features.²¹ ACD lesions generally begin within 48 hours of allergen exposure and are well demarcated.¹⁵

Occasionally, ACD may be confused with the less common, contact urticaria. Contact urticaria is a form of type I, IgE mediated, hypersensitivity reaction, usually in response to natural rubber latex, although certain foods and ammonium persulphate, which is used in hairdressing bleach, have also been implicated.³² It is characterized by wheals that develop 30 minutes after contacting the allergic substance and usually resolve within 24 hours. 87% of patients with contact urticaria have predominant hand involvement.³² If contact urticaria is suspected, radioallergosorbent skin tests and skin prick testing to natural rubber latex and the patients own food samples should be performed.^{18,32}

Atopic Dermatitis

Atopic dermatitis lesions are eczematous and constantly pruritic.²¹ Acutely, the lesions are papulovesicular with associated pruritus, weeping, and scaling. Excoriations and crusting are common. Chronically, xerosis and lichenification predominate.²¹ Atopic dermatitis is associated with atopy, generally defined as a triad of allergic rhinitis, eczema, and asthma.¹³ Lesions typically begin in infancy and have different locations and morphologic features in infants, children, and adults. Infants typically have ill-defined, erythematous lesions with associated scaling and crusting located on the face, scalp, and extensor surfaces of the legs, often sparing the diaper area; lichenification is not present. Children have eczematous and exudative lesions most often in the flexural creases; lichenification, xerosis, excoriations, and crusting may be present (Figure 10-3). Adults generally have a regression of their lesions, but lichenification and xerosis persist.²¹ Up to 70% of patients with atopic dermatitis have hand involvement, most commonly on the dorsal aspect of the hands.¹⁵ Extension onto the volar wrist is classic for this subtype.^{15,31}

Acute or Recurrent Vesicular Hand Dermatitis/Pompholyx (also known as Dyshidrotic Eczema)

There is much confusion and controversy surrounding the terminology regarding acute or recurrent vesicular hand dermatitis.^{28,33} Originally, the presentation of recurrent crops of vesicles on the lateral aspects of the fingers and palms was referred to as '*dyshidrosis*' because it was believed that the etiology originated from a disorder of sweat glands;³³ however, that theory has been disproved.²⁶ Later, the term *pompholyx* (derived from the Greek *cheir*-*pompholyx* meaning "hand and bubble") was suggested to describe this vesicular eruption on the hands and feet.^{15,33} Although strict criteria have been suggested as to how these two definitions are to be used, these criteria are rarely adhered to.³³ Therefore, recently, authors have proposed

FIGURE 10-3 Atopic hand dermatitis, with prominent lichenification, in a 3-year-old Somali girl.

the use of "*acute and recurrent vesicular hand dermatitis*" to replace the terms *dyshidrosis* and *pompholyx*.^{28,33}

This text, in keeping with the classifications described by Warshaw et al.¹⁴ differentiates acute or recurrent vesicular hand dermatitis (RVHD) from chronic vesicular hand dermatitis (CVHD). Recurrent vesicular hand dermatitis (RVHD) is defined as a relapsing dermatitis in which recurrent, intensely pruritic crops of clear sterile vesicles or bullae, without surrounding erythema, appear on the sides of the fingers, palms, or plantar surface of the feet (Figure 10-4).³³ The absence of erythema associated with vesicles helps differentiate this diagnosis from ICD or ACD.³³ Hands are more commonly involved than the feet (80% and 12% of cases, respectively).²⁷ An acute attack usually begins with burning and itching, followed by deeply-seated vesicles that appear within 12-24 hours. These vesicles may persist for a period of 2 to 3 weeks and then resolve with associated desquamation.²⁶ They generally recur at unpredictable intervals.³³ Rarely, severe, noninflamed, symmetric, bullous eruptions may be present on the palmar or plantar surfaces; the term pompholyx is classically used to describe this more dramatic presentation.^{28,31} When the distal phalanx is involved, an attack of RVHD can cause a transverse ridge in the nail. Assessing the number of ridges can clue the practitioner into the number and frequency of RVHD attacks.²⁶

FIGURE 10-4 Vesicular hand dermatitis of the palm.

Chronic Vesicular Hand Dermatitis

The lesions of chronic vesicular hand dermatitis (CVHD) are constant (unlike RVHD which wax and wane), pruritic, vesicular, and mostly palmar, frequently stopping at the wrist and sparing the dorsal hand or involving only the fingertips.³⁴ Additionally, vesicles of CVHD have an erythematous base, unlike those in RVHD.^{33,34}

Hyperkeratotic Dermatitis

Hyperkeratotic hand dermatitis is characterized by symmetric circumscribed areas of dense, dry, scaly, hyperkeratotic skin, often with painful fissures, located on the proximal or middle of the palms; vesicles or pustular lesions are generally absent (Figure 10-5).^{25,29} It occurs commonly in men aged 40 to 60, who have a history of manual labor, although

FIGURE 10-5 Hyperkeratotic hand dermatitis with fissures in a middle aged female.

FIGURE 10-6 Nummular hand dermatitis.

it is also present in women.²⁹ Hyperkeratotic hand dermatitis generally has a constant chronic course.²⁹

Nummular (Discoid) Hand Dermatitis

The clinical manifestations of nummular hand dermatitis are round or oval (“coin-shaped”) eczematous plaques on an erythematous base that begin as grouped papules or papulovesicles that then coalesce into plaques, often with areas of central clearing.^{35,36} The lesions have an asymmetric distribution on the hands, distinct border, some scaling, and are intensely pruritic (Figure 10-6).^{35,36} Lesions are more common on the extremities during the winter months, favoring the dorsum of the hand and distal fingers.^{14,31} Chronic nummular dermatitis lesions are often difficult to treat and recur at the same sites.^{35,36}

DIAGNOSIS

Although distribution on the hand and physical characteristics may hint to a diagnosis, it is often difficult to translate the morphologic characteristics of hand dermatitis into a definite subtype classification. Additionally, there are no standardized diagnostic criteria for diagnosing hand dermatitis. Therefore, a thorough history, diagnostic examination, and work-up, including patch testing, are needed.¹⁹ Dermatoses of hand, such as tinea mannum, photosensitivity reactions, and infections should be excluded. Diagnostic questioning should evaluate the pathogenesis of the lesions (Figure 10-7), and physical examination should localize the lesions and describe their morphology.²

There is no diagnostic test available for ICD; it is a diagnosis of exclusion after ACD and AD have been ruled out.¹⁵ Almost any of the 85,000 known chemicals in the world environment can be irritative if given the right circumstances, however there are only about 3,000 substances identified as contact allergens.^{2,21} Patch testing for these allergens is the gold standard for diagnosing ACD and an essential part of the diagnostic work-up for hand dermatitis.¹⁸

<ul style="list-style-type: none"> • History of any medical problems, especially atopic dermatitis • Any previous episodes of hand dermatitis • Onset, location, and progression of current symptoms • Description of morphology • History of remissions • Exacerbating and relieving factors • Related non-cutaneous symptoms 	<ul style="list-style-type: none"> • Work history • Hobbies • Exposure to animals or fur • Household activities and cleaning products • Personal care products used • Treatments tried and/or medications taken or applied to the affected areas • Any friends, family, or co-workers similarly affected • Family history of atopy or skin disease

FIGURE 10-7 Pertinent history questions*.

As described by Bourke et al.¹⁸ patch testing involves the application of allergens to the skin at standardized concentrations via standardized vehicles. Allergens are placed in an area free of dermatitis, and attempts should be made to control dermatitis elsewhere on the body. The back is commonly used for convenience. Allergens are placed on Day 1, then kept under occlusion and assessed between Day 3 and 5. Later additional readings may reveal more positives.¹⁸ Standard screening series are used as ‘baseline’; in addition to the screening series, additional patch tests should be performed with the patient’s own materials and personal products. Once a positive allergen is identified through patch testing, it must be determined whether this substance is clinically relevant. Textbooks on contact dermatitis may help in this endeavor.¹⁸

Patch testing is also helpful in confirming suspected recurrent vesicular hand dermatitis (RVHD). Although this diagnosis is generally made clinically, patch testing can not only exclude ACD, but may also reveal sensitivities to certain agents which predispose the patient to RVHD eruptions.²⁶ If a patient has sensitivity to nickel, cobalt, or chromate, an oral challenge with these substances may reproduce the vesicular flare,²⁸ although this theory is controversial.³³ When diagnosing RVHD, it is important to exclude a dermatophytid ‘id’ reaction by assessing for fungal infection of the feet and intertriginous areas through skin scrapings and cultures.²⁸

Atopic dermatitis can be diagnosed in a patient with a history of itchy skin who has three or more of the following: (1) a history of rash in the skin creases, (2) a history of generally dry skin within the last year, (3) a personal history of asthma or hay fever, (4) onset under the age of 2, and (5) visible flexural dermatitis.³⁷ These five criteria were found to diagnose atopic dermatitis with a sensitivity and specificity of 80 and 97%, respectively.³⁷

Hyperkeratotic hand dermatitis, nummular hand dermatitis, and chronic vesicular hand dermatitis are all diagnosed based on their clinical morphology.^{14,29,34,36}

It is important to not delay when making a diagnosis of hand dermatitis because if the diagnosis is postponed for

more than twelve months, there is an increased likelihood that the dermatitis will become chronic.³⁸ Currently, 5-7% of patients with hand dermatitis are classified with chronic or severe symptoms, and of these, 2-4% are resistant to traditional topical treatments.²⁵

TREATMENT

The goal of treatment is to reduce clinical symptoms, improve the patient’s quality of life, and minimize relapses.

While acute flares of hand dermatitis can often be managed with avoidance of the inciting agents and topical corticosteroids, as hand dermatitis becomes chronic, it becomes more difficult to treat, even though many treatment options are available.^{30,38} Despite the high prevalence of hand dermatitis in the population and great burden the disease has on both the individual and society, few well-designed randomized controlled trials that have been performed to guide clinical practice. In fact, van Coevorden et al.³⁹ attempted to assess the quality of studies pertaining to treatment of hand dermatitis and determined that the studies were of such poor quality that their overall recommendation was to have researchers “start again”. Thus, the treatment of chronic hand dermatitis is rarely evidence based.

Lifestyle changes

Lifestyle changes are the foundation of treatment for hand dermatitis and can be summarized as: prevention, avoidance, protection, and substitution.

Although it is impossible to predict who will develop hand dermatitis, certain people have an increased tendency to develop the disease: Atopics, women, and people in ‘wet-work’ occupations are all at increased risk.^{12,24,25} Preventing hand dermatitis through education regarding lifestyle modification practices (Figure 10-8), workplace evaluations, and the prescreening of workers for atopy or allergen sensitivity in high risk occupations can help minimize development of the disease.^{40,41}

Avoidance is the hallmark of both ICD and ACD, where identified irritants and/or allergens are directly involved in the dermatitis. Complete avoidance of triggers is ideal but not always possible; as such, certain individuals may need to change jobs in order to control their dermatitis.²⁵ Additionally, avoidance of exacerbating factors, such as water (‘wet-work’), sweating, humidity, dryness, friction, cold, or heat as it pertains to the patient, can help control symptoms.⁴²

In the case where an irritant/allergen cannot be easily avoided, or when performing ‘wet work’, protection of the hands is necessary. For household work polyvinyl chloride (PVC) gloves are recommended.¹⁴ These should either have a cotton liner or be worn over cotton gloves to maximize protection because the gloves themselves

Hand washing and moisturizing

- Use lukewarm or cool water and mild cleansers without perfume, coloring, or antibacterial agents and with minimal preservatives. In general, bar soaps tend to have fewer preservatives than liquid soaps (Cetaphil or Aquanil liquid cleansers or generic equivalents are exceptions).
- Pat hands dry, especially between fingers.
- Immediately following partial drying of hands (e.g., within 3 minutes), apply a generous amount of a heavy cream or ointment (not lotion); petroleum jelly, a one-ingredient lubricant, works well.
- It is helpful to have containers of creams or ointments next to every sink in your home, as well as next to the bed, next to the TV, in the car, and in multiple places at work.
- Moisturizing should be repeated as often as possible throughout the day, ideally, 15 times per day.
- Avoid rubbing and scrubbing, the use of washcloths, and the overuse of soap or water.

Occlusive therapy at night for intensive therapy

- Apply a generous amount of your doctor's recommended emollient or prescribed medicine to your hands, then, put on cotton gloves, and wear overnight.

When performing 'wet-work'

- wear cotton gloves under vinyl or other nonlatex gloves;
- try not to use hot water, and decrease the exposure to water to less than 15 minutes at a time if possible;
- if possible, use running water rather than immersing hands; and
- remove rings before work (wet or dry).

Wear protective gloves in cold weather and for dusty work.* For frictional exposures, wear tight-fitting leather gloves (e.g., baseball, riding, or golfing gloves).

Avoid contact to the following, if possible:

Shampoos
 Fruits and vegetables' peelings, especially those from citrus fruits
 Polishes of all kinds
 Solvents (e.g., white spirit, thinners, turpentine)
 Hair lotions, creams, and dyes
 Detergents and strong cleansing agents
 Fragranced chemicals
 "Unknown" chemicals

* Heavy-duty vinyl gloves are better than rubber, nitrile, or other synthetic gloves because vinyl is less likely to cause allergic reactions.

FIGURE 10-8 Sample handout on lifestyle management for patients with hand dermatitis. (Reprinted with permission from Warshaw, et al.¹⁴)

may exacerbate the dermatitis.¹⁵ Gloves may need to be removed frequently because sweating can cause symptom exacerbations.¹⁸ In the occupational setting, a variety of chemicals may be encountered. To determine the most appropriate protective glove for a specific chemical, it may be necessary to consult with workplace management or visit <http://www.ansellpro.com/specware> for guidance and more information regarding which gloves are appropriate for certain occupational chemicals.¹⁵ Antiimpaction gloves have been shown to help patients with frictional hand dermatitis return to work.⁴³ Barrier creams, which place a physical barrier between the skin and potential irritants, may also be of use in occupations with chemical exposures.⁴⁴

The most basic substitution involves using mild soaps or soap substitutes and bland emollients. The aggressive use of emollients is critical to improving the skin's barrier function and providing the skin with adequate hydration.^{31,45} Simple petroleum-based emollients are generally as effective as newer emollients that contain skin-related lipids.⁴⁵

Medical therapy

Although lifestyle changes help in many instances to ameliorate the symptoms of hand dermatitis, medical treatment is generally necessary to gain further symptomatic control.

TREATMENTS THAT HAVE BEEN SHOWN TO BE EFFECTIVE FOR CHRONIC HAND DERMATITIS

Methods

Search Methodology

The electronic databases (Medline, Embase, and PubMed) were searched from January 1980 to December 2009 using the terms "hand dermatitis"/"hand eczema" and treatment. Additional papers cited by major articles written on hand dermatitis that pertained to the search criteria were included for screening.

Study Selection and Inclusion/ Exclusion Criteria

Titles, abstracts, and where necessary, full texts were read by one researcher and included if they dealt with hand dermatitis and the results of a therapeutic intervention. Single case reports and reviews were excluded, but case series and open-label studies were considered alongside randomized controlled studies. Studies that focused more on lifestyle changes, preventative measures, and emollients were excluded, along with studies that focused solely on the treatment of nickel-related hand dermatitis. Full texts were then reviewed.

Main outcome measures

Primary outcome measure assessed was the reduction in hand dermatitis symptoms. Additional measures assessed were rates of relapse and the severity and frequency of therapy-related adverse events.

Results

Included studies

48 studies specific to the treatment of hand dermatitis were identified. These studies involved a total of 3036 subjects. Of these 48 studies, 27 were open-label, 19 were double-blinded, one was single blinded, and one was a case-series. Placebo-control was included in the methods of 13 papers. Assessment periods ranged from two weeks to 1 year. Thirty papers evaluated patients with chronic hand dermatitis, 11 papers studied vesicular hand dermatitis, two papers assessed occupational-related hand dermatitis, two evaluated hyperkeratotic hand dermatitis, two studied exclusively atopic hand dermatitis, and one studied allergic contact hand dermatitis. (Chronic hand dermatitis [CHD] is generally defined as hand dermatitis symptoms lasting longer than 6 months).⁴²

TOPICAL AGENTS

Topical Steroids

Topical steroids are generally the first treatment tried for hand dermatitis. Four papers evaluated topical corticosteroids, two studied steroids in the primary reduction of hand dermatitis symptoms, and another two assessed intermittent steroid use for maintaining symptom remission. Additionally, one paper evaluated using zinc sulphate to augment corticosteroids' effect (Table 10-1).

Efficacy

One study of 61 patients with CHD found that continuous treatment with clobetasol propionate (group I steroid) for

a period of 1 to 3 weeks brought about healing in 90% of patients (mean time to healing was 11 days).⁴⁶

Two studies, with a total of 165 patients, compared the efficacy of various topical steroid strengths (group II to group V) for the primary reduction of hand dermatitis symptoms.^{47,48} Both studies revealed no difference in therapeutic effect between the topical steroids evaluated ($p>0.06$ as reported by Fowler et al.⁴⁷).

One paper performed a double-blind, left/right comparison study of 47 patients and found that the addition of 2.5% zinc sulphate to 0.05% clobetasol significantly decreased hand dermatitis symptoms and recurrence rates ($p<0.05$).⁴⁹

Adverse Events

Only minor effects, such as burning sensations, reversible skin atrophy, and brittle skin were noted with treatment.⁴⁶ Systemically, headache and jitteriness were recorded.⁴⁷ Side effects occurred with similar frequency between very strong potency and medium potency topical steroids.⁴⁶

Relapse

Two papers assessed the intermittent use of topical steroids for maintaining symptom remission. Veien et al.⁵⁰ found that clearance persisted in 83% and 68% when mometasone furoate was applied 3 times/week or 2 times/week, respectively, compared to 26% of the control ($p=0.001$). Moller et al.⁴⁶ found intermittent use of a very strong topical corticosteroid (clobetasol propionate) kept a higher percentage (70%) of patients in remission than a medium potency corticosteroid (fluprednidene acetate) (30%).

Nonsteroidal Immunomodulators

Six studies were found that evaluated the topical calcineurin inhibitors, tacrolimus and pimecrolimus, in patients with hand dermatitis (Table 10-2).

Efficacy

Two open, noncontrolled studies assessed the use of tacrolimus ointment 0.1%. In the first study, 29 patients with occupational hand dermatitis who applied tacrolimus twice daily had a significant reduction in severity after 12 weeks, with 44% achieving clear skin ($p<0.001$).⁵¹ The second study assessed thrice daily application of tacrolimus for 8 weeks in patients with CHD and found that except for vascularization, there were significant improvements in composite severity, erythema, scaling, induration, fissuring, and pruritus ($p<0.007$).⁵²

Pimecrolimus cream 1% was assessed in one open, noncontrolled study in 13 patients with CHD who applied the cream twice daily. Results showed that 85% of the

Krejci-Manwaring, 2008 ⁵⁶	Double-blind, randomized, placebo-controlled	Topical Tacrolimus 0.1% ointment vs. vehicle control	BID application	12 weeks	32	CHD	Treatment significantly improved induration and scaling ($p=0.003$ for both), but did not significantly prolong time to recurrence ($p=0.78$).	—	69% of responders relapsed.
Thelmo, 2003 ⁵²	Open, not controlled	Topical Tacrolimus 0.1%	TID application	8 weeks	25	CHD	Significant improvement in severity from baseline ($p<0.007$).	Mild transient burning at application site (5/25, 20%)	—
Belsito, 2004 ⁵⁵	Double-blind, randomized, placebo-controlled	Pimecrolimus 1% cream vs. vehicle control	BID application	22 days	294	CHD	Trend toward clearance with treatment ($p=0.068$)	Application site burning (0.7%)	—
Thaci, 2003 ⁵³	Open, not controlled	Pimecrolimus 1% cream	BID application	22 days	13	CHD	85% improved from baseline (11/13)	Application site burning (4/13, 31%), pruritus (2/13, 15%)	—
Baskan, 2007 ⁵⁴	Double-blind, randomized, L/R comparison, placebo-controlled	Pimecrolimus 1% cream vs. control	BID application	8 weeks	25	CHD	Significant improvement with treatment over placebo ($p=0.04$).	None observed.	—

*Please refer to methods in main text regarding search criteria and how papers were selected.
CHD—chronic hand dermatitis; ACD—allergic contact dermatitis; ICD—irritant contact dermatitis; AD—atopic dermatitis

patients improved from baseline.⁵³ Two double-blind, randomized, controlled trials also assessed the twice daily application of pimecrolimus. Baskan et al.⁵⁴ performed a left versus right comparison study of 25 patients with CHD and found that the treated hand improved significantly over the controlled hand ($p=0.04$), with symptoms of erythema, desquamation, lichenification, edema, and fissuring improving; the treatment did not appear to be effective for vascularization. However, Belsito and colleagues⁵⁵ performed a larger vehicle-controlled study of 294 patients treated over 3 weeks with pimecrolimus and failed to find significance with treatment ($p=0.068$).

Adverse Effects

Topical tacrolimus most commonly caused transient burning, itching, and redness at the application site, which decreased with use.^{51,52} Reactivation of herpes labialis was seen in two patients.⁵¹ Topical pimecrolimus most commonly caused application site burning and pruritus.^{53,55}

Relapse

Krejci-Manwaring and colleagues⁵⁶ assessed the use of topical tacrolimus 0.1% in 32 subjects with CHD who had received a 3-week prednisone taper and found that 69% of patients relapsed. The time to relapse was 48 days with tacrolimus compared to 39 days with vehicle ($p=0.78$).⁵⁶ Relapse was not assessed with pimecrolimus.

Topical Retinoids

One study, a phase I-II trial, was found, which assessed the efficacy of topical retinoids in patients with hand dermatitis (Table 10-3).

Efficacy

Hanifin and colleagues⁵⁷ studied the efficacy and safety of bexarotene gel in 55 patients with severe CHD. Patients

were randomized to either bexarotene gel 1% alone, or bexarotene gel 1% in combination with one of two topical steroids. Overall, 36% of patients achieved >90% clearance of hand dermatitis, and 71% achieved >50% clearance. Response rates did not improve with topical steroid use. Monotherapy seemed to be particularly effective for patients with irritant dermatitis.⁵⁷

Adverse Events

Irritation, moderate stinging, and burning with application were the most common complaints. Flaring of the dermatitis occurred in several patients (most commonly in patients with atopic dermatitis).⁵⁷

Relapse

Few patients relapsed once response was achieved, with responses persisting after discontinuation of the medication through 4 weeks of follow-up.⁵⁷

Ionizing Radiation

Two forms of radiation are most frequently used in the treatment of hand dermatitis, conventional superficial x-rays and Grenz rays (ultra-soft x-rays or Bucky rays). Seven papers were found which assessed ionizing radiation on a total of 148 patients (Table 10-4).

Efficacy

CONVENTIONAL SUPERFICIAL X-RAYS

Farris et al.⁵⁸ studied superficial x-ray therapy compared to a placebo-control in a double-blind study of 24 patients with hand dermatitis and found therapy led to a significant reduction in symptoms as assessed by both the patient and the observer. King and Chalmers,⁵⁹ however, found that patients with hyperkeratotic hand dermatitis or pompholyx who were treated with superficial radiotherapy

TABLE 10-3—Selected* Study of a Topical Retinoid for Hand Dermatitis

Lead Author, Date	Study Type	Treatment	Dose	Treatment Duration	N	Hand Dermatitis Type	Efficacy	Adverse Events Related to Treatment	Relapse
Hanifin, 2004 ⁵⁷	Open, randomized	Bexarotene gel 1% alone vs. bexarotene gel 1% + mometasone furoate ointment 0.1% vs. bexarotene gel 1% + topical hydrocortisone ointment 1%	TID application, as tolerated	22 weeks, as tolerated	55	CHD	36% of patients achieved > 90% clearance of hand dermatitis; 71% achieved > 50% clearance	Irritation at application site (16/55, 29%), stinging/burning (8/55, 15%), dermatitis flare (9/55, 16%)	'few'

TABLE 10-4—Selected* Studies of Ionizing Radiation for Hand Dermatitis

Lead Author, Date	Study Type	Treatment	Dose	Treatment Duration	N	Hand Dermatitis Type	Efficacy	Adverse Events Related to Treatment	Relapse
Farris, 1984 ⁵⁸	Double-blind, randomized, placebo-controlled, L/R comparison	Superficial radiotherapy vs. control	100 rad at 50kV at 3 week intervals	3 treatments	24	CHD	Significant reduction in symptoms as reported by both the patient and observer.	—	—
King, 1984 ⁵⁹	Double-blind, randomized, placebo-controlled, L/R comparison	Superficial radiotherapy vs. control	100 rad given 1 week apart	3 treatments	15	Hyperkeratotic hand dermatitis, pompholyx	At one month 7/15 (46%) of treated hands improved vs. none of control ($p<0.01$). At 3 and 6 months, no difference between treatment and placebo.	—	3/7 (43%) of initial responders relapsed within 2 months.
Sheehan-Dare, 1989 ⁶⁰	Single-blinded, randomized L/R, controlled	PUVA + mock-radiotherapy vs. superficial radiotherapy + mock PUVA	Radiotherapy: 3 treatments (0.9 Gy at 600kV) at 21 day intervals; PUVA: 1% 8-methoxysoralen + UVA 15 J/cm(2) 3x/week	Radiotherapy: 9 weeks; PUVA: 6 weeks	21	CHD	At 18 weeks, both therapies had led to improvement in the dermatitis; superficial radiotherapy produced a significant drop in symptom severity scores ($p=0.013$), but no difference between the two therapies was noted clinically.	—	—
Cartwright, 1987 ⁶¹	Double-blind, L/R, placebo-controlled	Grenz ray vs. control	300 rad (3 Gy) of Grenz rays: 3 treatments at 3 week intervals	18 weeks	30	CHD	No difference between treatment and placebo ($p>0.05$)	Pigmentation of treated hand (1/30, 3%)	—
Lindelof, 1987 ⁶²	Double-blind, placebo-controlled, L/R comparison	Grenz ray vs. control	300 rad (3Gy) given at 1 week intervals	6 treatments	24	CHD	Significant improvement with Grenz ray therapy ($p<0.001$ at 10 weeks).	Slight pigmentation (5/24, 21%)	—
Farris, 1985 ⁶³	Double-blind, randomized, L/R comparison	Conventional superficial X-ray vs. Grenz ray	100 rad (1Gy) conventional superficial X-ray on one hand, 300 rad (3 Gy) Grenz ray on the other. Treatments given 3 weeks apart.	3 treatments	25	CHD	Mean grade of eczema was significantly better at all stages with superficial x-rays ($p<0.05$).	None observed	—
Duff, 2006 ⁶⁴	Open, not controlled	Megavoltage radiation	900-1200 cGy	varied	9	Chronic vesicular hand dermatitis	All patients improved from baseline. 73% resolved completely.	—	20% recurred after complete resolution; 47% remained completely resolved.

*Please refer to methods in main text regarding search criteria and how papers were selected.
CHD—chronic hand dermatitis; ACD—allergic contact dermatitis; ICD—irritant contact dermatitis; AD—atopic dermatitis

showed significant improvement at one month over control ($p<0.01$), but at 3 and 6 months, significance was not maintained. Sheehan-Dare and colleagues⁶⁰ compared superficial radiotherapy to topical PUVA in a double-blind study of 21 CHD patients, and found that superficial radiotherapy led to more rapid improvement and a significant decrease in symptom severity scores ($p=0.013$ at 18 weeks). Both modalities led to improvement from baseline, but no difference between the two was clinically apparent at 18 weeks.⁶⁰

GRENZ RAYS

One double-blind trial compared Grenz ray therapy (300 rad given every 3 weeks) to placebo in 30 patients, and found Grenz ray therapy to be no more effective than placebo for CHD.⁶¹ However, Lindelof et al.⁶² used weekly Grenz ray therapy (300 rad) in 24 patients with CHD therapy and found it led to significant improvement over control ($p<0.01$ at 10 weeks).

Farris et al.⁶³ compared 300 rad of conventional superficial x-rays to 900 rads of Grenz rays in a double-blind trial with 25 hand dermatitis patients and found treatment with superficial x-rays led to better outcomes ($p<0.05$).

MEGAVOLTAGE RADIATION

One open, noncontrolled study assessed megavoltage radiation therapy in 9 patients with chronic vesicular hand dermatitis. All patients improved during the course of the radiation, with 47% of the sites irradiated completely clearing.⁶⁴

Adverse Events

Only skin pigmentation was noted with Grenz ray treatment.^{61,62}

Relapse

43% of patients who initially responded to superficial x-rays relapsed within 2 months.⁵⁹ Twenty percent of patients treated with megavoltage radiation relapsed after completely clearing.⁶⁴

Phototherapy

Both UVA and UVB have been used in the treatment of hand dermatitis. Twenty papers were found which evaluated phototherapy in the treatment of hand dermatitis (Table 10-5).

UVA

UVA-1 phototherapy utilizes long-wave UVA radiation (340-400nm) and has been shown to be effective in treating several inflammatory skin diseases.⁶⁵

Efficacy

One open, noncontrolled study evaluated the effectiveness of local UVA-1 irradiation in the treatment of 12 patients with chronic vesicular hand dermatitis. Patients received 40 J/cm² of UVA-1 daily to their hands for 3 weeks. Ten of the twelve patients significantly improved from pretreatment levels with therapy ($p=0.002$).⁶⁶ These results were supported by a double-blind, randomized study of 28 patients with vesicular hand dermatitis who received either UVA-1 or placebo. Treatment with UVA-1 was found to be significantly more effective than placebo in reducing symptoms ($P=0.005$).⁶⁷

Adverse Events

Mild erythema was the only adverse event observed.⁶⁷

Relapse

Three month post-treatment assessments revealed no relapse in patients that responded to UVA-1 therapy.⁶⁶

PUVA

Psoralen plus UVA (PUVA) combines a photosensitizer (psoralen) with UVA phototherapy. Psoralen can be given topically or orally.

Efficacy

Three open, noncontrolled studies assessed oral PUVA in a total of 54 patients with hand dermatitis. One study of 38 CHD patients found 20 cleared with treatment (53%),⁶⁸ while another study found six of nine (67%) achieved clearance after an average of 23 treatments (150 J/cm²).⁶⁹ The third paper studied oral PUVA in seven patients with severe recurrent vesicular (dyshidrotic) dermatitis and reported 100% clearance with their treatment and maintenance regimen.⁷⁰

Additionally, four open, noncontrolled studies assessed topical PUVA. Two studies, by Schempp et al.⁷¹ and Davis et al.⁷² evaluated bath PUVA with 8-MOP and found improvement in 93% and 70%, with 64% and 41% clearing, respectively. One study assessed PUVA with directly applied 0.1% 8-methoxysoralen in 17 CHD patients and found clinical improvement of at least moderate quality was observed in 82% of patients, with 29% having significant improvement.⁷³ The last study compared the use of paint PUVA with a cream to bath PUVA and found that a greater percentage of patients with hyperkeratotic hand dermatitis responded to the cream than the bath (75% versus 50%, respectively).⁷⁴

Oral PUVA therapy was compared to topical PUVA in two papers. Hawk and Grice⁷⁵ found that oral PUVA led to similar clearance rates in patients with dermatitis: 60% for

TABLE 10-5—Selected* Studies of Phototherapy for Hand Dermatitis

Lead Author, Date	Study Type	Treatment	Dose	Treatment Duration	Hand Dermatitis Type	Efficacy	Adverse Events Related to Treatment	Relapse	
Rosen, 1987 ⁷⁸	Randomized, L/R controlled	PUVA + control vs. UVB + control	PUVA: 8-methoxypсорален 0.6 mg/kg p.o. + UVA (initial dose 2 J/cm ²) increased by 0.5-1.0 J/cm ² as tolerated to a max of 15 J/cm ²). Mean total dose: 100 J/cm ² UVB: Initial dose 30 mJ/cm ² increased to 840 mJ/cm ² as tolerated. Mean total dose: 11,000 mJ/cm ² . Treatments given 3x/week.	Until clearance or a maximum 3 months	35	CHD	PUVA treated hands improved significantly over UVB ($p<0.001$). PUVA: All treated hands cleared and were significantly improved over untreated hands ($p<0.001$). UVB: Treated hand significantly more improved than untreated ($p<0.05$); no hands cleared.	PUVA: Nausea (29%), edema, pain, pruritis (21%), flare of dermatitis (21%), reversible hyperpigmentation (7%) UVB: Palmar bullae (12.5%), Staph. Aureus infection (6%) Significantly more adverse effects with PUVA than UVB ($p<0.0001$).	9/14 (64%) who cleared with PUVA relapsed within 3 months.
Sezer, 2007 ⁷⁷	Open, L/R comparison	UVB vs. topical paint PUVA	UVB: initial 150 mJ/cm ² , increasing to 2000 mJ/cm ² , 3x/week; PUVA: 0.1% 8-methoxypсорален gel + UVA 1.0 J/cm ² increasing to 7.5 J/cm ² 3x/week	9 weeks	12	CHD	Both topical paint PUVA and UVB led to significant improvements from baseline ($p=0.002$ in both), but there was no significant difference between the two treatments ($p=0.552$).	Mild xerosis responsive to emollients was seen in both groups, hyperpigmentation with PUVA (3/15, 2%), exacerbation of dermatitis (1/15, 7%)	UVB: 33% relapsed; paint PUVA: 50% relapsed
Kuhl, 2008 ⁸¹	Open, not randomized	Narrowband UVB	Initial 60-200 mJ/cm ² NB-UVB increased as patient tolerated. Mean total dose: 28,848 mJ/cm ² . 2-3 treatments per week.	Mean treatment duration: 3.25 months	8	CHD	7/8 (88%) showed a clinical response, with 2/8 (25%) having disease clearance	1/8 (13%) photoerythema, 1/8 (13%) pruritus & tingling.	
Bayerl, 1999 ⁸³	Open, randomized, controlled	Home UVB vs. control	UVB: back of hands 0.1 mW/m ² , palms 0.13 mW/m ²	2 months	48	Occupational hand dermatitis	Improvement with UVB was not significant	Stinging & burning; exacerbation of dermatitis (2/48, 42%)	

Sjovall, 1987 ⁸²	Open-label	Home UVB vs. Clinic UVB	Palms: 380 mJ/cm(2) increased to a max of 2900 mJ/cm(2). Dorsal hand: 100 mJ/cm(2) increased to a max of 1200 mJ/cm (2). Treatments were 4-5x/week.	10-15 weeks	26	CHD	18/26 (69%) were improved; a parallel and significant drop in both groups ($p<0.01$); none cleared	Burning and stinging (6/26, 23%)
Sjovall, 1994 ⁸⁴	Double-blind, randomized, placebo-controlled	Hand UVB vs. Whole body + Hand UVB vs. control	Palmar Hand: initially 100 mJ/cm(2) increased to 1300 mJ/cm(2) (cumulative dose ~ 19,000 mJ/cm(2)); Dorsal Hand & Whole Body: initially 25 mJ/cm(2) increased to 1000 mJ/cm (2) (cumulative dose ~ 13,000 mJ/cm(2)); Treatments 4x/week	8 weeks	18	CHD	Significant improvement is found only between whole body + hand UVB & placebo ($p<0.05$)	—

*Please refer to methods in main text regarding search criteria and how papers were selected.

CHD-chronic hand dermatitis; ACD-allergic contact dermatitis; ICD-irritant contact dermatitis; AD-atopic dermatitis

oral PUVA versus 50% for topical PUVA. Van Coevorden and colleagues⁷⁶ compared oral PUVA at home to topical bath PUVA administered in a hospital in 158 patients, and after 10 weeks of treatment, both groups showed equally substantial clinical improvement in their hand dermatitis ($p<0.001$), and there was no significant difference between the treatment modalities ($p=0.15$).

Adverse Effects

Oral PUVA commonly caused nausea.^{68,69} Topical PUVA was associated with stinging, burning, erythema, blistering, flaring of the dermatitis, and reversible hyperpigmentation.^{72-74,76}

Relapse

Once weekly maintenance therapy was generally necessary to remain asymptomatic after treatment with oral PUVA.⁷⁰ If patients discontinued treatment, remission continued for roughly 3 to 6 months,^{69,70} although one study reported a mean remission time of 11 months.⁶⁸ Relapse rates with topical PUVA were approximately 50-65%,^{77,78} with time to relapses varying from 2 to 6 months.^{71,74,78}

Comparative efficacy

Two studies compared topical PUVA to UVA therapy in patients with chronic vesicular hand dermatitis. In one open-label, left/right comparison study, both PUVA and UVA led to significant improvements from baseline ($p=0.0039$ and 0.049 , respectively), but there was no significant difference between the two treatments ($p=0.31$).⁷⁹ This data is supported by a double-blind study where 12 patients were randomized to receive either PUVA or UVA. Again, both treatment modalities led to significant symptom reductions from baseline ($p<0.005$), but there was no statistical difference between the two treatments.⁸⁰

UVB

Efficacy

One open-label study assessed narrowband-UVB in the treatment of eight CHD patients who were unresponsive to other forms of therapy. Results showed 88% improved, with 25% achieving complete clearance of lesions.⁸¹ Local (hand) versus whole-body UVB therapy was assessed in one double-blind, randomized, placebo-controlled trial with 18 CHD patients. Results revealed significant improvement only with whole-body UVB therapy compared to placebo, not with local hand UVB therapy.⁸²

Two open-label studies assessed home-UVB therapy. Bayer et al.⁸³ randomized 48 patients to either receive home UVB radiation or a placebo-control. Clinical

improvement with therapy was not found to be significant over control. However, Sjovall et al.⁸⁴ in their open-label study found home Hydrolux UVB units were as effective in the treatment of hand dermatitis as clinic units, with both significantly improving symptoms from baseline ($p<0.01$ in both).

Adverse Effects

Mild xerosis, stinging/burning, pruritus, erythema, palmar bullae, and exacerbation of dermatitis were reported with UVB use.^{78,81,83,84}

Relapse

One study reported that 33% of patients relapsed after treatment with UVB.⁷⁷

Comparative efficacy

UVB was compared to topical PUVA in three left versus right open-label studies. All three studies found that both UVB and PUVA led to significant improvements in disease severity from baseline ($p=0.002$ for both treatments, as reported by Sezer and Etikan⁷⁷). When comparing the efficacy of the two treatment modalities, two studies^{77,85} found there to be no significant difference between PUVA and UVB ($p=0.552$, p-values as reported by Sezer and Etikan⁷⁷), while the third study found PUVA led to significantly better outcomes than UVB ($p<0.001$).⁷⁸

SYSTEMIC THERAPIES

Cyclosporine

Cyclosporine is an immunosuppressant drug and potent T-cell inhibitor. One paper assessed cyclosporine for use in hand dermatitis (Table 10-6).

Efficacy

In a double blind trial, 41 patients with hand dermatitis were treated with either cyclosporine (3 mg/kg/day) or a potent topical corticosteroid for 6 weeks. Both treatments significantly improved the dermatitis from baseline ($p<0.001$ for both groups), and there was no significant difference in efficacy between the two treatment groups.⁸⁶

Adverse Events

Adverse events occurred in 68% of patients receiving cyclosporine compared to 56% of patients receiving the topical steroid. Cyclosporine led to an increased creatinine 30% above baseline in 5% of patients. There were no occurrences of hypertension.⁸⁶

TABLE 10-6—Selected* Studies of Cyclosporine, Methotrexate, and Oral Retinoids for Hand Dermatitis

Lead Author, Date	Study Type	Treatment	Dose	Treatment Duration	N	Hand Dermatitis Type	Efficacy	Adverse Events Related to Treatment	Relapse
Granlund, 1996 ⁸⁶	Double-blind, randomized, comparison trial	Oral cyclosporine vs. topical betamethasone-17,21-dipropionate 0.05%	Cyclosporine 3 mg/kg/day	6 weeks	41	CHD	Both treatment arms led to improvement from baseline ($p<0.001$ in both), but there was no significant difference between treatment modalities.	19/28 (68%) of patients on cyclosporine had some kind of adverse event (non-specific); increased creatinine 30% above baseline, but normalized with decreased dose in 2/41, 5%	50% relapsed within 2 weeks
Egan, 1999 ⁸⁷	Case series	Methotrexate	12.5-22.5 mg/week	varied	5	Vesicular Hand Dermatitis	All five patients cleared with treatment.	—	—
Bollag, 1999 ⁸⁸	Open, not controlled	Alitretinoin (9-cis-retinoic acid)	20 or 40 mg daily	1-5 months (mean: 2.3 months)	38	CHD	95% of patients showed clinical improvement, 55% with a very good response. All forms of HD responded similarly.	Transient headache (4/38, 11%), cheilitis (1/138, 29%), transient flushing (4/38, 11%), conjunctivitis (1/38, 3%)	Relapse occurred 1 month to 1 year later
Ruzicka, 2004 ⁸⁹	Double-blind, randomized, placebo-controlled	Alitretinoin vs. control	10 mg/day, 20 mg/day, or 40 mg/day	12 weeks	319	CHD	Alitretinoin led to significant improvement in all types and severities of CHD over placebo ($p<0.001$)	Headache (34/241, 14%); dry mouth/lips/mucosa (15/241, 6%); one patient developed erysipelas requiring hospitalization	26% relapsed
Ruzicka, 2008 ⁹⁰	Double-blind, randomized, placebo-controlled	Alitretinoin vs. control	10 gm/day or 30 mg/day	24 weeks	1032	CHD	48% of patients treated with alitretinoin had clear or almost clear hands, compared to 17% of placebo ($p<0.001$)	Headache (96/827, 11%), dry mouth/lips/skin (59/827, 7%), hyperlipidemia (9%), decreased TSH (6%)	Mean time to relapse: 5.5-6.2 months

CHD=chronic hand dermatitis; ACD-allergic contact dermatitis; ICD-irritant contact dermatitis; AD-atopic dermatitis

Relapse

After 2 weeks, relapse rates were roughly 50% in both groups.⁸⁶

Methotrexate

Methotrexate is a cytotoxic drug commonly used to control severe recalcitrant inflammatory dermatoses. One paper assessed methotrexate in hand dermatitis (Table 10-6).

Efficacy

In one case series, Eagan et al.⁸⁷ used low-dose methotrexate (12.5 to 22.5 mg per week) in five patients with severe vesicular hand dermatitis and found that all five patients either partially or completely cleared.

Adverse Events & Relapse

Neither adverse events nor relapses were documented in this case series.

Oral Retinoids

One oral retinoid, alitretinoin (9-cis-retinoic acid), was evaluated in three papers for use in hand dermatitis (Table 10-6).

Efficacy

In an initial non-controlled pilot study, 38 CHD patients were treated with alitretinoin (either 20 mg or 40 mg). 95% of patients clinically improved with therapy, 55% achieving a very good response.⁸⁸

Two randomized, double-blind, placebo controlled studies were performed by Ruzicka et al.^{89,90} with oral alitretinoin. In the first study, 319 patients with refractory moderate-to-severe hand dermatitis were randomized to receive either alitretinoin at doses of 10 mg/day, 20 mg/day, or 40 mg/day, or placebo for 12 weeks. Alitretinoin led to a significant and dose-dependent improvement in all types and severities of chronic hand dermatitis ($p<0.001$).⁸⁹ The second study assessed alitretinoin at 10 mg or 30 mg daily versus placebo for up to 24 weeks in 1032 patients. Significant dose-dependent improvement was seen, with 48% of the 30 mg/day treatment group achieving clear to almost clear hands compared to 17% for placebo ($p<0.001$).⁹⁰

Adverse Events

The most common adverse events reported were headache or dryness of the mucosa and/or lips; one patient developed erysipelas that required hospitalization. A dose-dependent

increase in triglyceride levels, slightly decreased hemoglobin level, and a decreased free thyroxin level and thyroid-stimulating hormone level were also observed.^{89,90}

Relapse

Relapse rate was calculated at 26%⁸⁹ with an average time to relapse being 5.5-6.2 months in the absence of antidermatitis medications.⁹⁰

OTHER THERAPIES

Botulinum Toxin Injections

Hyperhidrosis is known to be an exacerbating factor in patients with vesicular hand dermatitis. Botulinum toxin is a potent inhibitor of acetylcholine, which is involved in the production and release of sweat from eccrine sweat glands.⁹¹ Two papers assessed using botulinum toxin injections to control symptoms of vesicular hand dermatitis (Table 10-7).

Swartling et al.⁹² performed an open-label study of 10 patients with recurrent vesicular hand dermatitis. Patients received intradermal injections with botulinum toxin in one hand, while the other hand served as the control. Seven out of ten (70%) reported good to very good effects 5-to-6 weeks post-injection; six of the responders had a history of hyperhidrosis.⁹² Wollina and Karamfilov⁹¹ performed a similarly designed study and found significant improvement of dermatitis symptoms in the hand injected with botulinum toxin over control ($p<0.01$). No adverse events were reported.

Iontophoresis

Iontophoresis is the noninvasive transdermal transfer of ions by direct current that has been shown to be effective in treating hyperhydrosis.⁹³ In one open-label study (Table 10-7), 20 patients with recurrent vesicular (dyshidrotic) hand dermatitis were treated with pulsed direct current iontophoresis, which led to a significant improvement in symptoms ($p<0.001$). No adverse effects were reported.⁹³

Ranitidine

Ranitidine is a histamine type-2 receptor antagonist with immunomodulating properties.⁹⁴ After observing improvement in CHD patients who were on ranitidine for gastric ulcers, Veien et al.⁹⁴ randomized 47 patients with chronic atopic hand dermatitis to receive either oral ranitidine 300 mg twice daily or placebo for 16 weeks. Overall, there was a trend toward symptom reduction in patients on ranitidine ($p=0.07$). No side effects were observed (Table 10-7).

TABLE 10-7—Selected* Studies of Botulinum Toxin, Iontophoresis, and Ranitidine for Hand Dermatitis

Lead Author, Date	Study Type	Treatment	Dose	Treatment Duration	Hand Dermatitis Type	N	Efficacy	Adverse Events Related to Treatment	Relapse
Wollina, 2002 ³¹	Open, L/R controlled	Intradermal botulinum A injection vs. control	100 units of botulinum toxin A diluted in 2 mL physiologic sodium chloride solution were injected intradermally in 0.1mL aliquots.	1 series of injections; patients then followed for 8 weeks	Vesicular Hand Dermatitis	8	Treated hands showed significant improvement over control ($p<0.01$)	—	—
Swartling, 2002 ³²	Open, L/R controlled	Intradermal botulinum A injection (Botox) vs. control	2 units of Botox injected intradermally every 15 mm on the palm.	1 series of injections; patients then followed for 5-6 weeks	Vesicular Hand Dermatitis	10	Self-assessment showed good to very good effect in 7/10 (70%); disease activity scores decreased by 54% with treatment vs 29% with control.	—	—
Odia, 1996 ³³	Open, randomized, L/R controlled	Tap water iontophoresis	Pulse directed current: 9V, 9.8 kHz high-frequency phase direct current; Direct current: 18V ripple voltage. Amperage varied according to individual skin resistance, but this variation was small.	3 weeks	Vesicular Hand Dermatitis	20	Total severity significantly improved with treatment ($p<0.001$).	—	—
Veien, 1995 ³⁴	Double-blind, randomized, placebo-controlled	Oral ranitidine vs. control	300 mg BID	16 weeks	AD	47	Trend towards symptom reduction with treatment ($p=0.07$).	—	—

DISCUSSION

Lifestyle changes are vital for the treatment of hand dermatitis (Figure 10-8). However, lifestyle changes alone often fail to control chronic disease, and medical interventions are frequently necessary. Medical therapy is generally initiated in a step-wise fashion: first-line therapy includes treatment with topical steroids, topical immune modulators, or topical retinoids. Second-line therapy comprises phototherapy, ionizing radiation, or systemic therapy with oral steroids, oral retinoids, methotrexate, cyclosporine, or other systemic immunomodulators or antimetabolites.⁴²

TOPICAL AGENTS

Topical Steroids

Topical steroids are the mainstay of hand dermatitis treatment; however, there are no standard recommendations available as to how they should be used. The studies that met the search criteria showed that corticosteroid creams of various strengths were equally efficacious in treating hand dermatitis.^{47,48} The choice of corticosteroid can thus be guided by the drug's side effect profile, cost, as well as the severity and chronicity of the dermatitis. Intermittent-long-term use of high potency topical steroids may help control symptoms of chronic hand-dermatitis with minimal side effects.^{46,50} Adding zinc sulphate may additionally help to decrease symptoms and recurrence rates.⁴⁹ Warshaw³¹ states that in general, ointments are more effective than creams and contain fewer preservatives. In her opinion, generic triamcinolone ointment 0.1% in a petroleum base is the preferred topical ointment.³¹ Both the 'soak and smear' technique, where patients soak hands in water for 20 minutes prior to applying a topical steroid, and using occlusion to enhance drug delivery, can improve clearance rates.^{25,30,95}

Local adverse reactions with topical corticosteroids are common and include: epidermal and dermal atrophy, striae, and purpura.⁹⁶ Absorption of the steroid can lead to systemic complications, such as: suppression of the hypothalamic-pituitary-adrenal axis, Cushing's syndrome, osteoporosis, and hyperglycemia, or diabetes.⁹⁶ These adverse effects limit corticosteroid use for long-term treatment. High-potency topical steroids, especially when used for a long duration, over a large portion of the body, or with occlusion, increase the risk of systemic effects.⁹⁶ Although rare, corticosteroids may also act as contact allergens. Consider this when topical therapy fails to relieve a dermatitis.⁹⁷

Topical Immunomodulators

Topical immunomodulators tacrolimus (FK 506) and pimecrolimus (SDZ ASM 981) work by inhibiting the release of inflammatory cytokines from T lymphocytes and mast

cells, thus down-regulating T-cell activity.^{98,99} When applied topically, the systemic absorption of both tacrolimus and pimecrolimus is low.^{53,100} The most commonly reported adverse events are burning and pruritus at the application site.^{51,53} Additionally, unlike topical steroids, neither tacrolimus nor pimecrolimus induce skin atrophy.^{98,101} The studies of this search generally found that tacrolimus and pimecrolimus are effective for all symptoms of chronic hand dermatitis, except for vesicularization.^{52,54} Due to their low systemic absorption and favorable side effect profiles, tacrolimus and pimecrolimus can be effective steroid-sparing agents, useful when lengthy treatment is necessary.

Topical Retinoids

Retinoids activate the retinoid X (RXR) nuclear receptor, which then in turn activates a cascade of other receptors that collectively affect skin physiology.⁵⁷ Bexarotene has been used in the treatment of cutaneous T-cell lymphoma since 1999 in the United States.⁵⁷ Hanifin et al.⁵⁷ demonstrated that bexarotene gel can be effective and safe for use in hand dermatitis as well. Adverse events, such as stinging and burning at the application sites can be minimized if the gel is confined only to the areas of dermatitis.⁵⁷

IONIZING RADIATION

Ionizing radiation, both superficial x-ray therapy and Grenz ray therapy, has been used for the treatment of dermatoses in dermatology for more than 50 years. Two studies in this search,^{58,60} found that superficial radiotherapy led to significant improvement in the symptoms of hand dermatitis, comparable to that of PUVA.⁶⁰ However, one study failed to find superficial radiotherapy to be superior to placebo in the long term.⁵⁹ Regarding adverse effects related to superficial radiation therapy, Rowell¹⁰² performed a follow-up study of 100 patients treated with 1500-1600 rad of superficial radiotherapy for various dermatoses and found that four had developed basal cell carcinoma and one had developed squamous cell carcinoma. It is therefore recommended that no more than 1200 rad of therapy is given to an area of skin over a patient's lifetime.¹⁰²

Grenz rays, also called ultra-soft x-rays or Bucky rays, are x-rays with a longer wave length such that most of the energy is absorbed in the epidermis or upper layers of the dermis.¹⁰³ Grenz rays are associated with fewer cases of radiodermatitis than x-rays, but can cause skin hyperpigmentation or hypopigmentation, atrophy, and telangiectasias.¹⁰³ An association with cancer cannot be ruled out.¹⁰³ Data regarding the efficacy of Grenz rays for use in hand dermatitis is conflicted: one paper shows that Grenz ray therapy leads to significant therapeutic improvement,⁶² while another fails to show the therapy to be superior to placebo.⁶¹ One case report by Walling et al.¹⁶ describes the use of Grenz ray therapy in a 48-year-old man with recalcitrant frictional hyperkeratotic hand dermatitis. After six

sessions, the dermatitis cleared completely without recurrence. However, Farris et al.⁶³ compared conventional superficial x-rays to Grenz rays and found treatment with superficial x-rays led to significantly better outcomes. A common dosing regimen for the treatment of hand dermatitis is 300 rad (3 Gy) given every 1 to 3 weeks for up to six sessions.^{61–63} This is generally followed by a 6 month treatment-free interval.³¹

Duff et al.⁶⁴ assessed megavoltage radiation therapy in the treatment of hand dermatitis, and found six of the nine patients improved with treatment, with only 20% relapsing. Adverse effects were not reported, but megavoltage radiation to an extremity can cause subcutaneous fibrosis, joint stiffness, and edema after treatment.⁶⁴ Duff et al.⁶⁴ used maximum dose of 1200 cGy dose to treat hand dermatitis. Skin, lymphatics, vasculature, and adult cartilage and bone have been safely irradiated with doses greater than 5000 cGy, although cases of radiation-induced cancer do exist.⁶⁴

PHOTOTHERAPY

Phototherapy is the most studied treatment for hand dermatitis. UVA-1, Psoralen and UVA-1 (PUVA), and UVB have all been used and shown to be effective. No one treatment has proven to be vastly superior, although one paper suggests PUVA may lead to better outcomes than UVB.⁷⁸ Phototherapy treatment, therefore, may be driven by availability and side-effect profiles.

UVA-1 irradiated skin histologically demonstrates a reduction in mast cells and an induction in collagenase activity.⁶⁵ Long-term effects of this treatment therapy are not well known, and therefore, it is recommended that patients not be treated more than twice yearly with 15 irradiations per treatment cycle, be at least 18 years of age, and regularly monitored for adverse skin sequelae, such as skin cancer.⁶⁵

The addition of psoralen, a photosensitizer, to UVA therapy is advantageous because less UVA dose is needed in order to achieve an effect.¹⁰⁴ Although the mechanism of action for PUVA in the treatment of hand dermatitis is not well understood, the impairment of DNA synthesis in peripheral blood lymphocytes and inactivation of Langerhans cells may play a role.⁶⁹ Additionally, PUVA is known to thicken the stratum corneum, which can protect from irritant and allergen exposure.⁶⁹ Psoralen can be administered either topically or orally when used in combination with UVA, and both routes of administration are effective in the treatment of hand dermatitis.^{75,76} Topical PUVA utilizes either 8-methoxysoralen (8-MOP) or 5-methoxysoralen (5-MOP). These can be applied either by painting on an ointment, cream, emulsion, or gel ('paint' PUVA), or soaking the hands in a solution of diluted psoralen photosensitizers ('bath' PUVA).¹⁰⁴ Hand dermatitis patients respond well to both bath-PUVA and paint-PUVA modalities.⁷⁴ Additionally, 8-MOP and 5-MOP have similar efficacy, but 5-MOP is associated with greater

phototoxicity and pigmentary changes.¹⁰⁴ To avoid phototoxic side effects with PUVA (topical 1% psoralen), such as painful erythema and pruritus, the recommended starting dose is 0.25 J/cm² with subsequent incremental increases of 0.25 J/cm²; therapy should be given no more than three times per week.¹⁰⁵ Topical PUVA is more favorable than oral PUVA because it avoids systemic adverse effects such as nausea, vomiting, generalized sunburn, photoaging, and elevated liver transaminases. Bath PUVA allows a more uniform absorption of the photosensitizer into the skin,^{65,104} but paint PUVA allows the photosensitizer to be limited only to diseased areas.⁷⁴ Photosensitivity is lost more rapidly with topical PUVA than oral PUVA, meaning prolonged protection of the skin and eyes is not necessary, and ocular photo-damage can be avoided.⁶⁵ Topical PUVA is preferable to oral PUVA in patients with hepatic dysfunction, gastrointestinal issues, cataracts, and when shorter irradiation times are needed or drug interactions are anticipated, as with patients receiving anticoagulation.^{104,106} Multiple treatments with oral PUVA are associated with an eleven to thirteen-fold increased risk for basal cell carcinomas and three to seven-fold increased risk for squamous cell carcinomas. There is insufficient evidence to conclude that topical PUVA would decrease the risk of carcinogenesis.¹⁰⁴

Narrowband UVB (311-312 nm) has greatly replaced broadband UVB as it has been found that these wavelengths improve therapeutic results.¹⁰⁷ Acute adverse effects associated with UVB therapy are erythema and burning, local blisters, folliculitis, and pruritus; long-term effects include photoaging and carcinogenesis.¹⁰⁶ Two studies revealed less risk adverse events with UVB therapy than PUVA.^{77,78}

One major downfall of phototherapy is the inconvenience of having to take time to go to a center and receive treatments. Therefore, home phototherapy units, which have been shown to be as effective in the treatment of hand dermatitis as clinic or hospital units, may be beneficial.^{76,84}

SYSTEMIC THERAPIES

Oral Corticosteroids

No studies could be found that evaluated oral steroids specifically for use in hand dermatitis. Despite this, they remain important in treatment and should be considered when rapid control is needed.⁴² Warshaw et al.¹⁴ comment in their hand dermatitis review that "short bursts of prednisone at 60 mg as a single dose in the morning for 3 to 4 days and repeated every 2 to 4 months as needed have been helpful." Although oral steroids can considerably improve patients' symptoms, side effects limit their use. These side effects can range from mild to life-threatening. Acutely, they include skin atrophy, striae, and telangiectasias; hypertension; hyperglycemia; pancreatitis; and

hematologic, immunologic, and neuropsychotic effects.¹⁰⁸ Chronic use can lead to osteoporosis, aseptic joint necrosis, hypothalamic-pituitary-adrenal axis insufficiency, glaucoma, hyperlipidemia, growth suppression, gastrointestinal and hepatic effects, and possibly congenital malformations.¹⁰⁸

Cyclosporine

Cyclosporine is an immunosuppressant drug and potent T-cell inhibitor that acts by interrupting intracellular transduction pathways in lymphocytes.¹⁰⁹ Nephrotoxicity, hypertension, and carcinogenesis are adverse effects associated with cyclosporine use. Cyclosporine is eliminated by hepatic metabolism. The recommended starting dose is 2.5 mg/kg/day, and if improvement is not noted, the dose may be increased in increments of 0.5 to 1.0 mg/kg/day, until a maximum of 5 mg/kg/day is reached.¹⁰⁹

Cyclosporine is as effective as topical steroids in the treatment of hand dermatitis and can be used if initial topical treatments fail to improve symptoms.⁸⁶ Although the study found in the literature search reported that 50% of patients treated with cyclosporine relapsed,⁸⁶ long-term remission is possible with cyclosporine treatment. A study by Granlund et al.¹¹⁰ evaluated the long-term efficacy of cyclosporine in 27 patients with CHD and found that 1 year after completing therapy, 78% were still in remission.

Methotrexate

Methotrexate is a synthetic analog to folic acid that irreversibly inhibits dihydrofolate reductase and is cytotoxic.¹⁰⁹ Nausea, vomiting, and diarrhea are the most common major side effects. Major toxicities include: hepatotoxicity, bone marrow suppression, and carcinogenesis; it is an abortifacient and teratogen.¹⁰⁹ Methotrexate can be taken either orally or injected. It is eliminated by renal excretion.¹⁰⁹ Common doses are 7.5 to 25 mg/week.¹⁰⁹ Methotrexate has long been used in other dermatoses, one case series reports that low doses are effective in resolving recalcitrant hand dermatitis.⁸⁷

Oral Retinoids

Alitretinoin is an endogenous retinoid and pan-agonist of the retinoid receptor, binding to both retinoic acid receptors and retinoid X receptors.¹¹¹ Retinoids are known to affect cell proliferation, differentiation, and apoptosis.¹¹¹ Although the exact mechanism of alitretinoin's connection with hand dermatitis is not well understood, it has been shown in mice to have immunomodulating and anti-inflammatory effects, as well as the ability to downregulate keratinocytes and dermal endothelial cells.¹¹¹ Alitretinoin is metabolized by the cytochrome P450 system of the liver and is mainly excreted in the urine.¹¹¹ Overall, alitretinoin

is well tolerated, with headache being the most common adverse event.^{89,90} Abnormal laboratory test results, such as low thyroid-stimulating hormone levels, and high cholesterol and triglyceride levels, appear to be dose dependent, and may be reversible if the dose is reduced.¹¹¹ Doses used in the treatment of CHD are 10-30 mg daily, although the 30 mg dose may be preferable since efficacy is dose dependent.⁹⁰ Treatment lasts 12-24 weeks, depending on the response.^{90,111} Women of child-bearing age must undergo pregnancy testing, and pregnancy is an absolute contraindication to alitretinoin use as the drug is teratogenic.¹¹¹ Other contraindications include hepatic or severe renal insufficiency and breast-feeding.¹¹¹ Alitretinoin should not be given with tetracyclines because of reports of benign intracranial hypertension occurring with concomitant use.¹¹¹ Overall, oral alitretinoin can produce clinical responses in patients with moderate-to-severe hand dermatitis that have failed other therapies. It is generally well tolerated, but attention should be paid to fasting lipid levels and thyroid hormones.

OTHER THERAPIES

Botulinum Toxin & Iontophoresis

Both botulinum toxin injections and iontophoresis have been shown to improve the symptoms of chronic vesicular hand dermatitis by controlling hyperhidrosis, a common exacerbating factor.

Botulinum toxin, from the gram-positive bacillus *Clostridium botulinum*, is the most poisonous substance known.¹¹² Regarding hyperhidrosis, the toxin blocks the presynaptic release of acetylcholine and causes denervation of sweat glands, leading to a long-lasting inhibition of sweating (approximately seven months).¹¹² Injections of botulinum toxin A are given intradermally and are preceded by some form of analgesia or sedation to reduce pain.¹¹² Adverse events include potential toxin spread into nearby neuromuscular junctions, leading to intrinsic hand muscle weakness.¹¹² Despite this risk, botulinum toxin injections provide significant improvement to patients with hand dermatitis exacerbated by hyperhidrosis.^{91,92}

Iontophoresis has been studied for more than a century and uses a continuous low-voltage current to provide an electrical driving force to transport ions or charged drugs across the stratum corneum, without changing the skin barrier itself.¹¹³ Tap water iontophoresis is used to treat hyperhidrosis and is thought to improve symptoms by post-synaptically inhibiting sweat gland secretions.⁹³ Commercial iontophoresis devices are available for home use.¹¹² Treatment regimens have patients increasing the amperage to the maximum tolerated, and then treating each site for 30 minutes, twice daily, for up to 2 weeks.¹¹² Adverse effects include pain and small skin burns.¹¹²

Ranitidine

Ranitidine is a histamine type-2 receptor antagonist, commonly used to suppress acid production in the treatment of peptic ulcer disease and gastroesophageal reflux disease.¹¹⁴ Ranitidine is associated with a low incidence of adverse effects; headache, tiredness, and gastrointestinal disturbances are most common.¹¹⁵ A few case reports have described cases of anaphylaxis to ranitidine.¹¹⁴ An initial study by Veien et al.⁹⁴ showed a trend towards symptom reduction in patients with atopic hand dermatitis with treatment, but more studies are needed.

ADDITIONAL THERAPIES

Other treatments that have been shown in case reports to be effective for recalcitrant chronic hand dermatitis include mycophenolate mofetil,¹¹⁶ alefacept,¹¹⁷ and vitamin E.¹¹⁸ (It should be noted, though, that there is one report in the literature where mycophenolate mofetil induced a case of acute vesicular hand dermatitis.¹¹⁹) Additionally, azathioprine has been shown to be effective in the treatment of

atopic dermatitis and may prove to be helpful in the treatment of hand dermatitis as well.¹²⁰

CONCLUSION

Hand dermatitis is a common disease, especially prevalent in people who participate in ‘wet-work’. The disease often has a relapsing-and-remitting course that is chronic, debilitating, and frustrating. The etiologies and clinical manifestations of the disease are numerous, and no universally accepted guidelines are available for the classification, diagnosis, and treatment of hand dermatitis. Lifestyle factors, including the avoidance of any identified irritants, allergens, and exacerbating factors, along with the aggressive use of emollients and topical steroids are the mainstay of treatment and can be effective in mild or acute cases. In cases where hand dermatitis becomes chronic, though, additional interventions are necessary, and no one intervention has proven to be vastly superior to the others. Since there are few well-designed studies to guide clinical practice for the treatment of hand dermatitis, more randomized controlled trials are needed that adhere to modern quality criteria.

What We Know

- Hand dermatitis prevalence ~ 10%, incidence ~ 8%, although this is increased in certain populations, especially those associated with ‘wet-work’.
- Hand dermatitis affects all age groups.
- Etiology is multifactorial but frequently involves disruption of the normal skin barrier.
- ICD is direct skin damage caused by irritants and can occur in anyone. ACD is the result of a type IV immune reaction because of contact with an allergen to which a person has been previously sensitized. AD is an inherited endogenous dermatitis.
- Morphologies of hand dermatitis vary based on etiology, chronicity, and severity.
- Diagnosis involves a thorough history, physical examination, and patch testing.
- Lifestyle modifications involving avoiding known irritant/allergens, protecting hands while performing wet-work, and using emollients aggressively are essential in treatment.
- Group I-V topical steroids can improve symptoms of hand dermatitis with similar efficacy. Adding zinc sulphate may augment the effects. Side effects, such as skin atrophy, striae, and telangiectasias, limit long-term use. Intermittent use may help prevent relapse.
- Topical tacrolimus and pimecrolimus are of use in reducing all symptoms of hand dermatitis except vesicles. Skin side-effects are mild. Tacrolimus alone may not effectively prevent relapses.
- Topical bexarotene gel leads to durable responses with minimal side effects.
- UVA-1, Psoralen and UVA-1 (PUVA), and UVB have all been used and shown to be effective, with no one treatment proven to be superior. In general, bath PUVA has fewer side effects than oral PUVA is more practical for the treatment of hand dermatitis.
- Ionizing radiation treatments may prove to be helpful in patients that have failed other therapies.
- Cyclosporine can significantly reduce symptoms of hand dermatitis, but relapse rates are generally high.
- The oral retinoid, alitretinoin, can lead to a significant and dose-dependent improvement in all types and severities of chronic hand dermatitis with generally mild side effects and low relapse rates.
- Methotrexate cleared symptoms in five patients, but more randomized controlled trials are needed.
- Vesicular hand dermatitis exacerbated by hyperhidrosis may benefit from intradermal botulinum toxin injections or tap water iontophoresis.
- Few well-designed studies to guide clinical practice for the treatment of hand dermatitis, and more randomized controlled trials are needed that adhere to modern quality criteria.

Treatment of Acute Urticaria and Angioedema

Farzam Gorouhi, M.D., and Howard I. Maibach, M.D.

Urticaria was first documented by the Chinese in the 10th century BCE and it was named as “Feng Yin Zheng”.¹ William Cullen was probably the first to use the term “urticaria” in 1769.² It was recognized as a distinct nosological entity by Hippocrates.

Urticaria commonly known as hives is a cutaneous syndrome characterized by upper dermal edema (wheal) and erythema (flare) that blanches on pressure.

Essentially, urticaria corresponds to the activation of dermal mast cells. Mast cell activation induces inflammatory reactions by secreting chemical mediators stored in pre-formed granules (histamine, tryptase, or chymotrypsin) and by synthesizing and secreting leukotrienes, prostaglandins, chemokines, and cytokines.³

Acute urticaria may be accompanied by angioedema. Angioedema is defined as rapid edema involving the dermis, subcutaneous tissue,¹ mucosa, and submucosal tissue. Acute urticaria is usually pruritic. It completely resolves within 6 weeks but mostly lasts less than 2 days.¹ The epidermis is generally unscathed, and scratch marks are relatively uncommon despite the severe itching of urticaria. Thus, desquamation does not occur in urticaria or angioedema. Although pruritus is the main symptom of the disease, pain and tenderness can occasionally occur. Further, acute urticaria is more common in children than in adults.⁴ Urticaria usually becomes evident a few minutes after exposure to the trigger. As acute urticaria lasts for a short period and, in many cases, is not severe, it often does not come to the attention of dermatologists or allergologists. However, angioedema without urticaria should raise suspicion of a hereditary form of angioedema (particularly complement [C]-1-inhibitor deficiency (C1-INH)), which can be often more severe with laryngeal involvement.

As acute urticaria lasts for a short period of time and in many cases may not be severe, it often does not come to the attention of dermatologists or allergologists.

ETIOLOGY

Urticaria may be caused by a state of hypersensitivity to foods or drugs, foci of infection, physical agents (heat, cold, light, friction), or psychological stimuli.³ The majority of drugs available today are capable of causing acute

urticaria. Angioedema, on the other hand, can be hereditary or acquired. The hereditary form has three subtypes as follows. Type I is characterized by low plasma levels of normal C1 esterase inhibitor protein. Type II patients are antigenically intact, and this type is defined by the presence of normal or elevated levels of dysfunctional C1-esterase inhibitor. Type III has been identified as a new subtype of angioedema that occurs mainly in women with normal functional and quantitative complement levels and does not have any specific laboratory marker. Some type III patients are characterized by X-linked dominant inheritance. Both estrogen-dependent and estrogen-independent forms have been recognized in hereditary angioedema type III;⁵ these may be caused by mutations in the factor XII gene.^{6,7} Non-hereditary angioedema is the most common form of angioedema and can be caused by different triggers mainly via an immunologic response. ACE inhibitor- and NSAID-induced angioedemas comprise the most common drug-induced angioedemas.⁴ Table-1 summarizes all the known causes of acute urticaria and angioedema.

EPIDEMIOLOGY

The published reports on the prevalence of urticaria differ widely. The available literature shows that 0.05–23.2% of the general population experience urticaria in their lifetime. Gaig et al. reported a cumulative incidence of 18.72% for acute urticaria in the Spanish population.⁸ There is no doubt that urticaria and angioedema affects women more than men.^{8–14} Acute urticaria tends to affect younger individuals, while chronic urticaria is typically a disease affecting middle-aged individuals. The coexistence of acute urticaria and angioedema is more frequent in younger patients.^{15,16}

METHODS

Pubmed, Scopus, and ISI Web of Science were searched to find published randomized-controlled trials (RCT) of treatments for acute urticaria and/or acute attacks of hereditary or nonhereditary angioedema. References of selected papers were reviewed to find any other relevant study.

TABLE 11-1—Etiologic Factors for Urticaria/Angioedema

Etiologic factor	Examples	Etiologic factor	Examples
Food and food additives	<ul style="list-style-type: none"> • Saccharine • Asparagus, cow's milk protein, nuts, fish, chocolate, fruits (berries), eggs, peanut, tomatoes, shellfish • Sodium disulfite • Sodium benzoate 	Lymphoproliferative disorders	<ul style="list-style-type: none"> • B cell type (Main cause of acquired angioedema)
Medications	<ul style="list-style-type: none"> • Biologicals (Infliximab) • Antibiotics: beta lactams (penicillins, ampicillin, amoxicillin, cephalosporins), aminoglycosides, Sorbitol complexes • Tetracyclines, roxithromycin, sulphonamides • Nonsteroidal anti-inflammatory agents: piroxicam, aspirin, other salicylates • Enzymes: streptokinase, trypsin, chymopapain • Antifungal agents: fluconazole, ketoconazole • Steroids • Angiotensin-converting enzyme inhibitors • Theophylline • Hormones: insulin, corticotrophin, vasopressin • Radiographic contrast media • Tetrazine • Hydralazine • Hyoscine butylbromide • Narcotic analgesics • Bupropion • Quinidine • Cimetidine • Tripelennamine • Opiates • Anesthetic agents (local and general) • Anticancer drugs • Muscle myorelaxants (curare) • Alcohol • Vaccines • Dextrans • Vitamins • Hyaluronidase • Mannitol • Protamine • Eugenol • Blood transfusions 	Toxicity	<ul style="list-style-type: none"> • Insect bites/venom (bee, ant, flea) • Plants (Grevillea juniperina) • Sea animals
Contact urticaria allergens	<ul style="list-style-type: none"> • Nickel 	Physiological changes	<ul style="list-style-type: none"> • Menstruation, pregnancy • Anxiety, stress
		Parasitic infection	<ul style="list-style-type: none"> • Dicrocoelium dendriticum infestation • Anisakis simplex • Blastocystis • Schistosomiasis • Giardiasis • Pigeon tick (<i>Argas reflexus</i>) • Toxoplasmosis • Malaria
		Viral infections (the most common)	<ul style="list-style-type: none"> • Hepatitis A • Hepatitis B • Infectious mononucleosis • Parvovirus B19 • <i>Haemophilus influenzae</i> b
		Bacterial infection	<ul style="list-style-type: none"> • <i>Mycoplasma pneumonia</i> • <i>Streptococcal</i> infection • <i>Shigellosis</i> • <i>Ehrlichiosis</i> • <i>Brevibacterium iodonium</i> • <i>Yersinia enterocolitica</i> • <i>Helicobacter pylori</i>
		Fungal infection	<ul style="list-style-type: none"> • <i>Aspergillus</i>
		Hormonal disorders	<ul style="list-style-type: none"> • Decrease in TSH
		Neoplasm	<ul style="list-style-type: none"> • Acute myeloid leukemia • Acute lymphoblastic leukemia
		Physical stimuli	<ul style="list-style-type: none"> • Mechanical: dermatographism, pressure, vibration • Thermic: heat, cold • Cholinergic: sweat • X ray
		Enzyme deficiency	<ul style="list-style-type: none"> • C1 inhibitors deficiency: hereditary, acquired
		Mastocytosis	<ul style="list-style-type: none"> • Cutaneous and systemic
		Autoimmune disorders	<ul style="list-style-type: none"> • Urticaria vasculitis • Systemic lupus erythematosus • Cryoglobulinemia • Wissler-Fanconi syndrome
		Autoimmune idiopathic	<ul style="list-style-type: none"> • Antibody to IGE receptor or IGE

THERAPY

Antihistamines

Antihistamines (H1 or H2 receptor blockers) remain the therapy of choice for acute urticaria. H1 receptor antagonists are mainly used; these include first (e.g., diphenhydramine)

and second generations (e.g., loratadine, and cetirizine) of the drug. Second-generation H1 antihistamines are less toxic. H2 receptor blockers (e.g., ranitidine, cimetidine, and famotidine) are a class of drugs used to block the action of histamine, especially on parietal cells in the stomach, decreasing the production of acid by these cells.

Is cimetidine or Famotidine more effective than diphenhydramine in the treatment of acute urticaria?

Cimetidine

Efficacy and Safety

In a small trial, the effects of intravenous administration of cimetidine 300 mg and diphenhydramine 50 mg in acute urticaria were compared with each other. Although cimetidine relieved urticaria more than diphenhydramine (80% vs. 45%), there was no significant difference between the two drugs.¹⁷ In another RCT, cimetidine, 300 mg and diphenhydramine, 50 mg were compared as intramuscular treatments. Cimetidine was comparable but not superior to diphenhydramine. The sedation level was significantly higher in the diphenhydramine-treated patients.

Comments and Limitations

There is no randomized placebo-controlled trial to prove the efficacy of either cimetidine or diphenhydramine. Cimetidine is comparable to diphenhydramine.

Famotidine

Efficacy and Safety

In an RCT, two intramuscular injections of 20 mg famotidine did not change the intensity of urticaria and pruritus more than single dose intramuscular administration of 50 mg diphenhydramine (Table 11-2).¹⁸ No major side effect was mentioned. No significant difference between famotidine and diphenhydramine was noted in terms of sedation.¹⁸

Comments and Limitations

Famotidine is as effective as diphenhydramine. The efficacy of neither drug has been confirmed by placebo-controlled trials yet.

Is addition of cimetidine to diphenhydramine beneficial in the treatment of acute urticaria?

Efficacy and Safety

Runge et al.¹⁷ compared cimetidine 300 mg plus diphenhydramine 50 mg intravenously with diphenhydramine 50 mg plus placebo intravenously. Eleven out of twelve patients (91.6%) vs. 5/11 (45.4%) obtained relief from urticaria, respectively. Side effects included burning sensation

at the injection site in one patient per group in addition to lightheadedness and nausea in three patients treated with cimetidine plus diphenhydramine. Lin et al.¹⁹ investigated the additive effects of intravenous ranitidine 50 mg to intravenous diphenhydramine 50 mg. Acute urticaria persisted after 2 h in 4/29 (13.8%) of patients in the combination therapy group vs. 11/24 (45.8%) in diphenhydramine group. In a similar randomized trial, Knight et al. compared the efficacy of intravenous ranitidine 50 mg plus diphenhydramine 50 mg versus diphenhydramine alone. The addition of ranitidine relieved acute urticaria in 44/49 (89.8%) of patients after 2 h, while diphenhydramine alleviated urticaria in 33/43 (76.7%) of patients. In both trials, there was a mild decrease in the heart rate, particularly in the combination treatment group patients. No bradycardia was reported in any of these trials.

Comments and Limitations

Ranitidine and cimetidine may have some additive effects to diphenhydramine in the treatment of acute urticaria or other acute allergic reactions.

Can cetirizine prevent acute urticaria formation in atopic dermatitis patients?

Cetirizine is the active carboxylated metabolite of the first-generation antihistamine, hydroxyzine. It is a potent H1 blocker in addition to its anti-inflammatory properties, which include the inhibition of eosinophil chemotaxis.²⁰

Efficacy and Safety

In the only preventive trial involving cetirizine for preventing acute urticaria in atopic dermatitis patients, oral cetirizine (0.5 mg/kg/day) was compared to placebo administration. Acute urticaria occurred in 5.6% of cetirizine-treated patients and in 15.7% of placebo-treated patients after 18 months. Such a significant difference was not noted at an earlier time point (6 months). Moreover, patients under cetirizine therapy suffered a lower number of episodes during the 18-month therapy period. No side effects were reported in this RCT.²¹

Comments and Limitations

Second-generation H1 antihistamines such as cetirizine may be considered effective prophylactic agents.

Corticosteroids

Short-term oral corticosteroid therapy has been considered as an alternative for severe acute urticaria.

TABLE 11-2—Summary of Published Studies on Acute Urticaria Treatments

Study	Treatments	No. of patients	Efficacy	Safety	Notes
Runge et al., 1992 ¹⁷	Cimetidine 300 mg plus placebo IV vs. DPH 50 mg plus placebo IV vs. combined	10 vs. 11 vs. 12	Urticaria relief: 8/10 (80%) vs. 5/11 (45.4%) vs. 11/12 (91.6%), p<0.05 for DPH vs. combination therapy; Treatment failure: 3/10 (30%) vs. 4/11 (36.3%) vs. 2/12 (16.6%), p>0.05	Burning sensation in IV injection site: 0/10 (0%) vs. 1/11 (9%) vs. 1/12 (8.3%); superficial thrombophlebitis: 2/10 (20%) vs. 0/11 (0%) vs. 0/12 (0%); lightheadedness or dizziness: 2/10 (20%) vs. 0/11 (0%) vs. 2/12 (16.6%); nausea and chills: 0/10 (0%) vs. 0/11 (0%) vs. 1/12 (8.3%), p>0.05 for all	Short follow-up (30 minutes)
Moscati and Moore, 1990 ⁴³	300 mg cimetidine IM vs. 50 mg DPH IM	46 vs. 47	Overall improvement: 2.870 ± 0.341 vs. 2.723 ± 0.452 (p>0.05); Itching: –1.174 ± 0.996 vs. –1.489 ± 1.019 (p>0.05); Wheal intensity: –0.935 ± 0.646 vs. –0.915 ± 0.654, p>0.05	Sedation (change from baseline): 0.37 ± 0.61 vs. 1.085 ± 0.855, p<0.0001	Short follow-up (30 minutes)
Knight et al., 1999	50 mg ranitidine IV plus 50 mg DPH IV vs. placebo plus 50 mg DPH IV	49 vs. 43	Urticaria (hour 2): 5/49 (10.2%) vs. 10/43 (23.2%), p<0.05	Heart rate: 85 vs 86 (baseline), 76 vs. 82 (hour 1) (p=?), 75.6 vs. 79 (hour 2) (p=?)	Abstract only, significances of safety comparisons are not clear.
Lin et al., 2000 ¹⁹	50 mg ranitidine IV plus 50 mg DPH IV vs. placebo plus 50 mg DPH IV	29 vs. 24	Urticaria (hour 2): 4/29 (13.8%) vs. 11/24 (45.8%), p<0.05	Heart rate: 86.0 vs. 86.0 (baseline), 76 vs. 82 (1 hour) (p=?), 76 vs. 80 (2 hour) (p=?)	Both acute urticaria and angioedema patients were included. Significances of safety comparisons are not clear.
Watson et al., 2000 ¹⁸	Two doses of 20 mg famotidine IM vs. 50 mg DPH IM	15 vs. 10	Change in pruritus (VAS): 36 mm vs. 54 mm, p>0.05; Intensity of urticaria (VAS): 34 mm vs. 34 mm, p>0.05; Change in body surface area involved: 20% vs. 8%, p>0.05	Change in sedation (VAS): 0 mm vs. 20 mm, p>0.05	Acute urticaria of less than 72 hours duration, Short follow-up (30 minutes)
Pollack and Romano, 1995 ²²	50 mg DPH IM, and 25 mg hydroxyzine orally TDS, plus either prednisone, 20 mg, or placebo orally BD for 4 days	24 vs. 19	Pruritus (0–10 VAS): 1.3 ± 1.3 vs. 4.4 ± 2.2 for 2 days follow-up and 0.0 ± 0.0 vs. 1.6 ± 1.0 for 5 days follow-up, p<0.0001 for both	0/24 (0%) vs. 0/19 (0%) for prednisolone vs. placebo; Occasional sedation with hydroxyzine treatment in both groups p>0.05	Acute urticaria of less than 24 hours duration; drug adherence was evaluated.
Preventive evidence					
Simons et al., 2001 ²¹	0.25 mg/kg cetirizine orally BD for 18 months vs. 0.25 mg/kg placebo orally BD for 18 months	411 vs. 406	Acute urticaria in 18 months post-treatment: 23/411 (5.6%) vs. 64/406 (15.7%), p<0.01 Acute urticaria event in 6 months post-treatment: 12/411 (2.9%) vs. 18/406 (4.4%), p>0.05 Two or more episodes of urticaria 3/411 (0.7%) vs. 18/406 (4.4%), p=0.001	Not reported	Target population was young children with atopic dermatitis.

DPH, diphenhydramine; IV, intravenous; IM, intramuscular; BD, twice daily; TDS, three times a day

*All of included studies in this table were randomized double-blind studies (Level of evidence IB). Intention to treat analyses were calculated wherever possible.

[†]defined as more than 25% improvement in VAS score.

Is addition of Oral prednisone to antihistamines helpful in the treatment of acute urticaria?

Efficacy and Safety

One randomized trial was found. A combination therapy of intramuscular diphenhydramine 50 mg, and oral hydroxyzine 25 mg thrice daily was considered as the control and was compared to the same regimen, plus oral prednisone 20 mg twice daily for 4 days. Mean pruritus scores were significantly lower for the prednisone group (1.3 ± 1.3 vs. 4.4 ± 2.2 for 2-day follow-up and 0.0 ± 0.0 vs. 1.6 ± 1.0 for 5-day follow-up). Four days treatment of 20 mg oral prednisone did not induce any side effects. Occasional sedation has been observed in both groups.²² In a pseudorandomized trial, 3 days treatment with oral prednisone 50 mg/day was more effective than loratadine 10 mg/day (93.8% vs. 65.9%).²³

Comments and limitations

Short term and low dose oral corticosteroid therapy may be helpful as an adjuvant therapy in acute urticaria.

ANGIOEDEMA (ACUTE ATTACKS)

Table 11-3 includes a detailed description of all relevant studies concerning angioedema.

Is C1 esterase inhibitor more effective than placebo in the treatment or prevention of acute hereditary angioedema?

Pasteurized plasma-derived C1-INH concentrate (Berinert®)

Berinert is the first FDA-approved treatment for acute attacks of hereditary angioedema.

Nanofiltered plasma-derived C1-INH (Cinryze®)

Cinryze® is a C1 esterase inhibitor that is used to prevent attacks in teenagers and adults with hereditary angioedema. It is a lipophilized intravenous preparation. During manufacturing, it undergoes an extra step of nanofiltration for eliminating small-size particles, such as small viruses and prions.

Recombinant human C1-INH (Rhucin®)

Recombinant human C1-INH (rhC1-INH) production is induced in the milk of transgenic rabbits. The main pharmacologic difference between plasma-derived and recombinant C1-INH is the seven times shorter half-life of the latter (<3 h vs. >20 h for plasma-derived C1-INH).^{24,25}

Efficacy and Safety

Craig et al. compared the intravenous administration of 10 mg/kg vs. 20 mg/kg Berinert with a placebo in a double-blind randomized trial. Patients receiving the higher dose had faster time to onset of relief (0.5 h vs. 1.2 h) when compared to the placebo group (1.5 h). There was no serious adverse event, and the frequency of side effects was similar to the placebo group.²⁶ Another placebo-controlled trial evaluated the efficacy and safety of human plasma-derived nanofiltered C1-INH (Cinryze). The median time to complete resolution of symptoms was 12.3 h in the Cinryze group vs. 25 h in placebo group. In a randomized prophylaxis phase trial, Zuraw et al. assessed intravenous application of Cinryze (1000 units) every 3 to 4 days; the attack rate, severity of attacks, and total duration of attacks were all significantly lower in the Cinryze-treated patients. The side effects included lightheadedness, pruritus, rash, and fever.²⁷ Two different doses (100 U/kg and 50 U/kg) of intravenous recombinant human C1-INH were compared to placebo administration in two randomized trials performed in USA and Europe.²⁸ The pooled data of these trials showed that recombinant C1-INH (Rhucin) can reduce the time to onset of symptom relief from 495 minutes in the placebo group to 122 minutes in the group treated with Rhucin 50 U/kg and to 66 minutes in the group treated with Rhucin 100 U/kg. The median times to minimal symptoms were 266, 247, and 1210 minutes in the 100 U/kg Rhucin, 50 U/kg Rhucin, and placebo groups, respectively. Treatment-emergent side effects occurred more frequently in the placebo group.

Comments and limitations

Pasteurized plasma-derived C1-INH concentrate is recommended for acute attacks of hereditary angioedema. The recommended Berinert dosage is 20 units (U) per kilogram of body weight. The safety and efficacy of Berinert for prophylactic therapy have not been established. On the other hand, Cinryze has a definitive effect in preventing future attacks and a modest effect in the treatment of acute attacks. Recombinant human C1-INH at doses of 50–100 U/kg is an effective and safe therapy for acute attacks of hereditary angioedema. However, due to the unique carbohydrate additions (glycosylation) to rhC1-INH, there is a possibility that anaphylaxis may occur,²⁹ although no case of anaphylaxis has been reported due to the administration of rhC1-INH thus far.

Is icatibant more effective than placebo in the treatment of acute hereditary angioedema?

Bradykinin plays a key role in edema formation, and angioedema can be induced by elevated bradykinin

TABLE 11-3—Summary of Published Randomized Studies on Angioedema

Study	Treatments	No. of patients*	Efficacy	Safety	Notes
Craig et al., 2009 ²⁶ (I.M.P.A.C.T.1)	20 U/kg vs. 10 U/kg pasteurized C1 esterase inhibitor concentrate IV vs. placebo	43 vs. 40 vs. 42	Time to onset of symptom relief (hours): 3.89 (\pm 8.20) vs. 7.47 (\pm 10.51) vs. 10.27 (\pm 11.48), $p=0.002$; Time to complete resolution of all HAE symptoms including pain (h): 81.84 (\pm 314.34) vs. 216.06 (\pm 494.23) vs. 125.08 (\pm 382.81), $p=0.02$; Patients with worsened intensity of symptoms between 2 and 4 hours: 2 (4.7%) vs. 8 (20.5%) vs. 13 (31.0%), $p=0.001$; Number of vomiting episodes within 4 hours: 0.1 (\pm 0.41) vs. 0.2 (\pm 0.77) vs. 0.8 (\pm 2.59), $p=0.03$	Adverse events: 9/46 (19.6%) vs. 10/39 (25.6%) vs. 18/41 (43.9%); $p<0.05$ for 20 U/kg vs. placebo Drug-related adverse event: 5% (10.9%) vs. 8 p>0.05 for all (20.5%) vs. 8/41 (19.5%). Severe adverse event was zero in all groups.	Only Hereditary angioedema cases were included. I.M.P.A.C.T.2 is an ongoing open label extension of this trial to further investigate this drug.
Zuraw et al., 2010 ^{a,27}	One or two intravenous injections of nanofiltered C1 inhibitor concentrate (1000 U each) vs. placebo	36 vs. 35 (35 vs. 33)	The onset of unequivocal relief (4 hours): 21/35 (60.0%) vs. 14/33 (42.4%), $p=0.06$; Median time to the onset of unequivocal relief (hours): 2 vs. more than 4, $p<0.05$; Median time to complete resolution of symptoms (hours), 12.3 vs. 25, $p<0.05$	Adverse events: 6/36 (16.6%) vs. 7/35 (20.0%), $p>0.05$ Drug related adverse events: 1/36 (rash at the site of injection, 2.8%) vs. 2/35 (5.7%), $p>0.05$	Only hereditary angioedema cases were included.
Zuraw et al., 2010 ^{b,28}	Recombinant human C1-inhibitor 100 U/kg vs. 50 U/kg vs. saline	30 vs. 13 vs. 30 (29 vs. 12 vs. 29)	Median time to onset of symptom relief (minutes): 66 vs. 122 vs. 495, $p<0.05$; Median time to minimal symptoms (minutes): 266 vs. 247 vs. 1210, $p<0.05$	Drug-emergent adverse events: 7/29 (24.1%) vs. 4/12 (33.3%), vs. 14/29 (48.3%), $p>0.05$ for all; Drug related adverse events: 1/29 (3.4%) vs. 0/12 (0%) vs. 3/29 (10.3%)	Pooled results of two randomized trials. Only hereditary angioedema cases were included.
Reidel et al., 2008 and Cicardi 2010 ^{a,44} (FAST 1)	Icatibant 30 mg SC vs. placebo	27 vs. 29	Time to clinically significant relief (hours): 2.5 vs. 4.6, $p>0.05$; Time to onset of relief (hours): 0.8 vs. 16.9, $p<0.05$, Rescue medication needed 6/27 (22%) vs. 14/29 (48%), $p=0.04$; Time to almost complete relief (hours): 8.5 vs. 23.3, $p>0.05$	Adverse events: 12/27 (44.4%) vs. 19/29 (65.5%) Drug-related adverse events: 4/27 (15%) vs. 1/29 (3%)	Only hereditary angioedema cases were included.
Reidel et al., 2008 and Cicardi 2010a ^{34,44} (FAST 2)	Icatibant 30 mg SC vs. oral tranexamic acid 1 g TDS for 2 days	36 vs. 38	Time to clinically significant relief (hours): 2.0 vs. 12.0, $p<0.001$; Time to onset of relief (hours): 0.8 vs. 7.9, $p<0.05$, Rescue medication needed 5/36 vs. 11/38, $p=0.1$; Time to almost complete relief (hours): 10.0 vs. 51.0, $p<0.05$	Averse events: 19/36 (53%) vs. 16/38 (42%); Drug related adverse events: 5/36 (14%) vs. 4/38 (11%), $p>0.05$ for all	Only hereditary angioedema cases were included.
Lin et al., 2000 ¹⁹	50 mg ranitidine IV plus 50 mg DPH IV vs. placebo plus 50 mg DPH IV	22 vs. 27	No angioedema (hour 1): 7/22 (31.8%) vs. 3/27 (11.1%), $p=0.09$ (hour 2): 11/22 (50%) vs. 13/27 (48.1%), $p>0.05$	Heart rate: 86.0 vs. 86.0 (baseline), 76 vs. 82 (hour 1), 76 vs. 80 (hour 2), $p=?$	Both acute urticaria and non-hereditary angioedema patients were included.
Schneider et al., 2007 ⁴⁵ (EDEMA 1 study)	Single dose of 5, 10, 20, or 40 mg/m ² IV ecballantide vs. placebo	10 (each dose) vs. 8 (placebo)	Significant improvement at the primary attack site: 29/40: (72.5%) vs. 2/8 (25%), $p=0.01$; Time to significant improvement (minutes): 75.0 vs. 303.0, $p<0.05$ Symptom improvement: 8/10 (80%) vs. 5/10 (50%) vs. 7/10 (70%) vs. 9/10 (90%) vs. 2/8 (25%). 5 mg/m ² vs. placebo and 20 mg/m ² vs. placebo were significant.	32/41 (78.0%) vs. 7/8 (87.5%), $p>0.05$	Low sample size; Only hereditary cases were included.

Levy et al., 2008 ³⁶ and Cicardi 2010 ^{b,38} (EDEMA3 study)	30 mg SC ecallantide vs. placebo	36 vs. 36	Median treatment outcome score (4 hours): 50 vs. 0, p = 0.004; Median change from baseline in mean symptom complex severity Score: -1.00 (IQR, -1.50 to 0.00) vs. -0.50 (IQR, -1.00 to 0.00), p=0.01; Estimated time to significant improvement (min): 165 vs. 240, p>0.05	Adverse events 20/36 (56%) vs. 12/36 (33%), p>0.05; Drug related adverse events: 4/36 (11%) vs. 5/36 (14%), p>0.05	Only hereditary cases were included.
Levy et al., 2008 ³⁶ (EDEMA4 study)	30 mg SC ecallantide vs. placebo	48 vs. 48	Treatment outcome score (4 hours): 53.0 (95%CI, 39 to 68) vs. 8.0 (95%CI, -12 to 28), p = 0.003; Change from baseline in mean symptom complex severity score (4 hours): -0.8 (95%CI, -1.0 to -0.6) vs. -0.4 (95%CI, -0.6 to -0.1), p = 0.01	Treatment related adverse events: 4/48 (8.3%) vs. 5/48 (10.4%), p>0.05	Only hereditary cases were included.
Preventive evidence					
Munch and Weeke, 1985 ⁴⁰	Oral tranexamic acid 1.5 g vs. placebo three times daily for 3 months.	12 vs. 12	Days with edema: 36/854 (4.2%) vs. 88/403 (21.8%); Days with itching: 45/854 (5.2%) vs. 104/401 (25.9%), p<0.05 for both	Diarrhea: 5/10 vs. 2/10; abdominal discomfort: 6/10 vs. 2/10, p>0.05 for both	Crossover study; Only nonhereditary angioedema patients were included. Patients were allowed to use other medications such as antihistamines during attacks.
Zuraw et al., 2010 ²⁷	Nanofiltered C1 inhibitor concentrate (1000 units in 10 mL sterile water) vs. placebo (10 mL of saline) every 3 to 4 days.	12 vs. 12	Mean attack rates: 6.26 vs. 12.73 (p<0.001); Mean severity score: 1.3±0.85 vs. 1.9±0.36, p<0.001; Total duration of attacks: 2.1±1.13 vs. 3.4±1.39 days, p=0.002	Adverse events: 3/12 (25%) vs. 3/12 (25%), p>0.05	Cross over study; Two 12-week prophylaxis periods; Only hereditary cases were included.
Weiler et al., 2002 ⁴²	Calcium heparin (200 U/kg; maximum of 10,000 units) or matching placebo SC every 12 hours vs. Inhaled saline vs. heparin (200 U/kg) administered slowly over 5 minutes.	Roughly 17 per group (unclear)	Median flare intensities in inhaled heparin, placebo, and injected heparin groups were 9.2, 8.0, and 5.1, respectively: Transformed estimates: -0.12 (injected heparin vs. inhaled heparin), p=0.02, -0.09 (injected heparin vs. placebo), p=0.1, -0.03 (placebo vs. inhaled heparin), p=0.75	The most common adverse events: injection site reactions, headache, upper respiratory tract infections, knee pain or stiffness, sore throat, and bruising of various body parts. The injection treatments had	

DPH, diphenhydramine; IV, intravenous; SC, subcutaneous; TDS, 3 times a day.
All of included studies in this table were randomized double-blind studies (Level of evidence 1B). *The numbers in the parenthesis denote the number of the patients per group who finished the study.

concentrations,³⁰ which can be caused by either increased bradykinin production or reduced bradykinin inactivation. Icatibant (Jerini, Berlin, Germany) is a selective bradykinin type 2 receptor antagonist with a similar structure and affinity to bradykinin itself. It is a synthetic decapeptide (H-d-Arg-Arg-Pro-Hyp-Gly-Thi-Ser-d-Tic-Oic-Arg-OH). It has only been approved in the European Union, and the US Food and Drug Administration (FDA) approval is pending. Icatibant has been shown to antagonize bradykinin effects such as vasodilation, hypotension, reflex tachycardia, tissue plasminogen activator release, and smooth muscle contractions *in vitro*, *in vivo*, and human studies.³¹⁻³³ It can be administered subcutaneously. Its most common adverse events include erythema, swelling, warm sensation, burning, itching, and cutaneous pain.

Efficacy and Safety

“For Angioedema Subcutaneous Treatment” (FAST)-1 and FAST-2 studies are two double-blind, randomized, multicenter trials that have investigated the efficacy of icatibant against acute attacks of hereditary angioedema.³⁴ In the FAST-1 study, patients received either icatibant (single dose, 30 mg subcutaneously) or placebo, while in FAST-2, patients received either icatibant (single dose, 30 mg subcutaneously) or oral tranexamic acid (3 g daily for 2 days). In FAST-1, the time to onset of relief was 0.8 h vs. 16.9 h for icatibant and placebo, respectively; there were no significant differences between the two groups in terms of the primary outcome measure (Time to clinically significant relief) and other outcomes. In FAST-2, the time to onset of symptom relief was 0.8 h versus 7.9 h in the icatibant and tranexamic acid groups, respectively. No serious drug related adverse events were reported in the FAST-1 and FAST-2 trials.³⁵

Comments and limitations

Icatibant is more effective than oral tranexamic acid in treating acute attacks of hereditary angioedema. Cicardi et al. mentioned the non-superior efficacy of icatibant as compared with placebo; however, the early use of rescue medication may have masked the benefit of icatibant in the FAST-1 trial.³⁴

Is addition of ranitidine to diphenhydramine helpful in the treatment of acute non-hereditary angioedema?

Efficacy and Safety

In the only randomized trial for immunologic angioedema, intravenous combination therapy of ranitidine 50 mg plus diphenhydramine 50 mg was compared to diphenhydramine 50 mg alone. There was no angioedema in 11/22 (50%) of patients in the H1 plus H2 blocker group

as compared to 13/27 (48.1%) patients in the H1 blocker group. Combination therapy decreased the heart rate largely than did treatment with the H1 blocker.¹⁹

Comments and Limitations

The addition of ranitidine did not add any benefits to diphenhydramine treatment of acquired angioedema.

Is ecallantide more effective than placebo in the treatment of acute hereditary angioedema?

Ecballantide (Kalbitor/Dx-88; Dyax, Cambridge, MA) is a potent and specific recombinant protein inhibitor of plasma kallikrein. It is a clear and colorless, sterile, and non-pyrogenic solution. By directly inhibiting plasma kallikrein, it reduces the conversion of HMW kininogen to bradykinin. Ecballantide has no significant effect on the QTc interval, heart rate, or any other components of the ECG. A maximum plasma concentration of 586 ± 106 ng/mL was observed approximately 2–3 h after single 30 mg subcutaneous injection. Its mean elimination half-life is 2.0 ± 0.5 h. In December 2009, the US FDA approved ecballantide for the treatment of acute attacks of hereditary angioedema in patients aged 16 years and older after a clinical trial (Evaluation of DX-88_s Effect in Mitigating AngioedemaSM 4 or EDEMA4 study).³⁶ Side effects include dizziness, fatigue, headache, nausea, vomiting, increased liver function tests, and prolonged partial thromboplastin time.

Efficacy and Safety

In the EDEMA1 trial, Schneider and colleagues sought the best dose for ecallantide. They compared intravenous injections of ecallantide 5, 10, 20, and 40 mg/m² with placebo administration. Twenty-nine out of 40 patients responded to ecallantide (72.5%) whereas the response in the placebo group was 25%. The frequency of side effects was similar in the ecallantide and placebo groups.³⁷ In the EDEMA3 study, 72 patients were randomized to receive either 30 mg of subcutaneous ecallantide or placebo. The mean treatment outcome score was significantly better in the ecallantide group both after 4 h and 24 h. The same trend was noted for the mean symptom complex severity scores. Patients under ecallantide therapy experienced headache, diarrhea, pyrexia, and nasal congestion more often than the patients receiving the placebo. Drug-related adverse events occurred in both groups with no significant difference in frequency or severity.^{38, 39} EDEMA4 had a similar study design to EDEMA3. The sample size, however, was higher (96 patients), with the results being similar to those of the EDEMA3 study (Figure 11-1).^{36, 39}

B. Forest plot, ecallantide vs. placebo, Outcome: drug related Adverse Events.

Comments and limitations

Ecallantide may be considered as a first-line therapy for acute attacks of hereditary angioedema. It is well tolerated by the majority of patients; its most common side effects include nausea, fatigue, headache, and upper respiratory infections. Its only serious complication is anaphylaxis. This limits its self-administered application.

Is tranexamic acid more effective than placebo as a prophylaxis agent of nonhereditary angioedema?

Efficacy and Safety

In a preventive crossover study, patients were randomly assigned to receive either oral tranexamic acid (4.5 gm/day) or placebo for 3 months. After completion of the treatment

period, the total number of days with edema in the tranexamic acid and placebo patients were 36/854 (4.2%) and 88/403 (21.8%), respectively. After 4 years of follow up, the patients in the tranexamic acid group continued to show a good response. Side effects in the tranexamic acid group included frequent diarrhea and abdominal discomfort as compared to that in the placebo group.⁴⁰

Comments and Limitations

Oral tranexamic acid appears to be a good therapeutic agent for preventing acute attacks of non-hereditary angioedema.

Can heparin injection or inhalation prevent acute angioedema attacks in hereditary angioedema patients?

Since the 1970s, it has been suggested that heparin can change the dynamics of complement cascade.⁴¹

Efficacy and Safety

In one crossover RCT, the effects of subcutaneously injected calcium heparin (200 U/kg) were compared with those of inhaled calcium heparin and placebo. Subcutaneous injection of heparin did not prevent the attacks better than the placebo. Further, importantly, the patients who were received inhaled heparin responded worse than the placebo group. The main side effects included injection site reactions, headache, upper respiratory tract infections, knee pain or stiffness, sore throat, and bruising of various body parts. Injection site reactions were the only drug-related adverse effects. There were no serious drug-related adverse events due to the short duration of the heparin therapy.⁴²

What We Know: Acute Urticaria

- The exact pathophysiology of acute urticaria is unclear. Several different triggers can induce it. (see Table 11-1)
- There is no placebo-controlled trial to prove the efficacy of H1 or H2 antihistamines in the treatment of acute urticaria.
- H2 antihistamines are as effective as H1 antihistamines and the combination therapy of H1 and H2 can be beneficial.
- Short-term (less than 4 days) low dose oral corticosteroid therapy can be useful in severe acute urticaria cases.

What We Know: Angioedema

- For non-hereditary angioedema, the first step is to remove any potential trigger.
- Evidence for acute attacks of nonhereditary angioedema is extremely weak. The only relevant randomized trial showed no benefit for addition of ranitidine to diphenhydramine in the treatment of allergic angioedema.
- Evidence for prophylactic therapy of acquired angioedema is weak too. In the only trial, tranexamic acid was proven to be a good prophylactic agent for nonhereditary angioedema.
- Although it has not been supported by RCTs, it is highly recommended to develop training programs for angioedema patients to self administer the drugs to either prevent or quickly treat acute attacks.
- Although attenuated androgens are the first prophylaxis choice for hereditary angioedema, there is no strong evidence to support it.
- C1-INH can be prescribed to prevent attacks of hereditary angioedema (in nano-filtered form) and also to treat the acute form of it (all types including recombinant form).
- Two new drugs of Icatibant and Ecallantide are effective and safe for the treatment of acute attacks of hereditary angioedema.

Treatment of Chronic Urticaria

David A. Khan, M.D.

INTRODUCTION

Chronic urticaria (CU) is a common condition faced by both dermatologists and allergists alike. Numerous therapies have been used to treat CU with antihistamines being the best studied. However, many patients with CU are only partially responsive to antihistamines. The intent of this chapter is to review the evidence for both antihistamine and alternative, nonantihistamine therapies in the treatment of CU.

EPIDEMIOLOGY

The epidemiology of urticaria has not been adequately studied and data are especially lacking for the United States. In the United States, anecdotally there appears to be an increase in CU patients within many practices. Approximately 20% of the population may have acute urticaria at some point in their lives. This statistic has not changed much from a study conducted in 1969 in England¹ to a more recent telephone survey in Spain from 2004.² The prevalence of CU in the general population has not been adequately studied. In the aforementioned Spanish telephone survey, 0.6% of respondents gave a history consistent with CU. Anecdotally, many allergists in the U.S. feel there has been an increase in the number of patients they are seeing with CU, but whether this is indeed fact or perception remains to be proven. One German study found that ~3% of both a general practitioner's patients as well as a dermatologist's patients had some form of urticaria.³

ETIOLOGY

While numerous etiologies for CU exist, in the majority of cases, no cause can be found and hence a diagnosis of chronic idiopathic urticaria (CIU) is made. Approximately 30–40% of patients with CU have evidence of autoantibodies, including autoantibodies to the high-affinity IgE receptor (Fc ϵ RI) and rarely anti-IgE antibodies.⁴ These patients may be classified as having chronic autoimmune urticaria.^{5,6} Physical urticarias may often be distinguished by historical features of not only the triggering physical stimulus, but also the duration of the urticarial lesion itself. Individual physical urticaria lesions typically last between

30 minutes to 2 hours. In contrast, lesions of other types of CU, typically last most of the day. Other etiologies of CU are less common including urticarial vasculitis and rarely other systemic diseases.

SEARCH METHODOLOGY

A search of the medical literature was performed using the electronic databases of MEDLINE (OVID) and PubMed from 1966–2009, using search terms of urticaria, therapy, as well as individual names of different therapeutic agents or classes. Reference lists from the already identified studies were reviewed for additional, appropriate studies. Articles not published in English were excluded. Therapies available in the U.S. are the focus of this chapter.

THERAPIES

Avoidance Measures

Many patients with CU may have nonspecific triggers that aggravate their urticaria. Nonsteroidal anti-inflammatory drugs (NSAID) may exacerbate urticaria in 20–30% of CU patients.^{7–9} Avoidance of aspirin and other NSAIDs is recommended for patients with a history of NSAID-induced exacerbation of their CU and may be considered in other patients where this history is less clear. However, studies to evaluate the efficacy of NSAID avoidance on outcomes in CU are lacking. Heat is another common trigger for CU patients as is tight clothing, the latter more of a problem for patients with DPU. Opiates are known to cause non-IgE mediated reactions and have the potential to exacerbate urticaria in some CU patients. A small study of 25 CU patients showed very rare reactions to challenges with codeine.¹⁰ While avoidance of these factors is often recommended, no evidence exists as to the efficacy of avoiding these potential triggers.

DIETARY MANIPULATION

IgE-mediated food reactions are not a cause of CU and testing for food allergy is not necessary.¹¹ Although chronic urticaria is not a manifestation of IgE-mediated food allergy, some authorities have suggested that certain substances

in food may exacerbate or even be the cause of CU. This is believed to be caused by the presence of “pseudoallergens,” which are substances in food that exacerbate CU. Pseudoallergens include artificial preservatives and dyes in processed foods, as well as naturally-occurring aromatic compounds in certain foods (many fruits and vegetables, seafood, others). Aromatic compounds in wine, tomatoes, and spices as well as phenols such as p-hydroxybenzoic acid, citrus and orange oil, and salicylates have all been identified as pseudoallergens.¹² The evidence for pseudoallergen-free diets in CU has been evaluated in uncontrolled studies.^{13,14} One study concluded that adherence to a diet low in pseudoallergens was helpful, since 73% of 64 CU patients had either cessation or a significant reduction of symptoms within two weeks of adopting a pseudoallergen-free diet.¹³ However, only 19% of those who improved developed symptoms when subsequently challenged with individual pseudoallergens on provocation tests. In contrast to the high rates of response in this study, a subsequent larger study of 140 patients placed on a pseudoallergen-free diet found that only 28 percent had a strong or partial response.¹⁴ The largest study on this topic studied 838 patients with chronic urticaria and all underwent a food-additive-free diet. Thirty-one percent of subjects noted improvement in CU but none had complete remission. Double-blind placebo-controlled challenges were performed to both mixes of additives and individual additives in all subjects with a favorable response to diet, as well as a subset of those with no improvement on the diet. Overall, only 1–3% of patients had confirmatory double-blind challenges. Overall, the evidence is weak that pseudoallergen-free diets improve CU and given the difficulty of adhering to these diets, their use in all CU patients is not recommended.

TOPICAL THERAPIES

Potent topical corticosteroids have been shown to reduce mast cell numbers and response to stroking the skin in a study of six patients with dermographism.¹⁵ Other relatively small studies have shown clinical improvement in patients with localized delayed pressure urticaria treated with different preparations of potent topical corticosteroids.^{16,17} An open trial in CIU patients with topical corticosteroids showed only short-term improvement in symptoms.¹⁸ These studies suggest that topical corticosteroids may be beneficial in patients with localized delayed pressure urticaria but have limited utility and long-term efficacy for treating diffuse urticaria and are not recommended for chronic idiopathic urticaria.

SYSTEMIC THERAPIES

While numerous systemic therapies have been used to treat patients with chronic urticaria, the majority of systemic therapies have not been extensively studied with the exception of H1 antihistamines. There is a wide range of levels

of evidence as well as quantity and quality of evidence for these therapies. In addition, the safety of these therapies varies widely as does cost. Table 12-1 summarizes the evidence, potential adverse effects, and cost for several therapies in chronic urticaria.

H1 ANTIHISTAMINES

H1 antihistamines are widely considered the cornerstone of pharmacotherapy for CU.^{19,20} Most symptoms of urticaria are primarily mediated by H1-receptors located on nerves and endothelial cells and therefore H1-antagonists are logical mainstays of therapy for urticaria. Both first and second-generation antihistamines have been used in the treatment of urticaria. Patients with CU show variable responsiveness to antihistamines. In a study involving 390 patients with urticaria, the majority of which had CU, 44% of patients reported a good response to H1-antagonists.²¹ A cross-sectional survey of 98 CU patients treated with antihistamines (mostly first-generation) reported that 94% experienced short or long-term control of pruritus.²²

A number of large, double-blind, placebo-controlled, randomized studies have demonstrated the safety and efficacy of second-generation antihistamines in improving symptoms of chronic urticaria, as well as disruption of sleep and daily activities. Each of the currently available 2nd generation antihistamines in the United States has been shown to be effective in these types of studies in CU including loratadine,²³ cetirizine,^{24,25} fexofenadine,^{26,27} desloratadine,²⁸⁻³¹ and levocetirizine^{32,33} Amongst agents used to treat CU, 2nd generation antihistamines have the most robust evidence for safety and efficacy and are widely endorsed by international guidelines as first-line agents to treat CU.^{19,20,34}

Relatively few studies have compared the efficacy amongst the currently available 2nd generation agents. An open label study treated 50 CU patients consecutively with cetirizine and found 45 who achieved complete symptomatic control.³⁵ Thirty of these 45 complete cetirizine responders completed a 6-week open-label trial with levocetirizine. Similar control was achieved for wheal and flare but significantly less control of itch than with cetirizine. A large, randomized, double-blind, multi-center study compared levocetirizine 5 mg with desloratadine daily for 4 weeks in 886 patients with CIU.³⁶ While both agents showed clinically significant improvement in the Dermatology Life Quality Index, levocetirizine showed greater improvement in pruritus scores and CIU composite scores than desloratadine. A randomized double-blind study compared cetirizine 10 mg versus fexofenadine 180 mg daily for 6 weeks in 116 patients with CU.³⁷ A higher percentage of patients were symptom free with cetirizine (52%) than with fexofenadine (4%) with similar rates of adverse effects. Overall, the evidence favors cetirizine and levocetirizine; however, more well-designed clinical trials are required to confirm this.

Many patients with CU may not respond adequately to typically recommended doses of second-generation

TABLE 12-1—Evidence for Therapies in Chronic Urticaria

Drug	Level of Evidence	Quality & Amount of Evidence	Potential for Serious Adverse Effects	Cost
H1 antihistamines	Ia	High	Low	Low
H2 antihistamines	Ib	Low	Low	Low
doxepin	Ib	Moderate	Low	Low
Systemic corticosteroids	IV	Low	High	Low
Leukotriene modifiers	Ib	Moderate	Low	Moderate

Category of evidence (modified from Shekelle et al.(280)): Ia = evidence for meta-analysis of randomized controlled trials or systematic reviews of randomized controlled trials; Ib = evidence from at least one randomized controlled trial; IIa = evidence from at least one controlled study without randomization; IIb = evidence from at least one other type of quasi-experimental study; III: evidence from nonexperimental descriptive studies, such as comparative studies, correlation studies, and case-control studies; IV = evidence from expert committee reports or opinions or clinical experience of respected authorities, or both.

Quality and Amount of Evidence stratified based on both number of studies as well as quality of studies.

* = require laboratory monitoring which would increase cost

antihistamines. Limited data are available on dosing second-generation antihistamines at higher than the recommended amounts. Studies evaluating cetirizine in doses ranging from 20 to 30 mg/day showed conflicting results. An open study of 21 CU patients with inadequate response after 1-2 weeks of cetirizine 10 mg daily were treated with cetirizine 10 mg twice daily for 1-2 weeks.³⁸ The subjects were randomized to continue either cetirizine 20 mg daily or reduce to 10 mg daily for an additional 1-2 weeks. Both groups had improved urticarial scores on cetirizine 20 mg daily with continued improvement in the group that remained on the higher dosage but worsening symptoms in the group whose cetirizine dosage was reduced to 10 mg daily. In contrast, a similarly sized study evaluated 22 CIU patients with histories of failing two or more 2nd generation antihistamines who were treated with cetirizine 10 mg daily for 1 week, then the dosage was increased to 10 mg three times daily.³⁹ Only one of the 22 patients had benefit with increased doses of cetirizine, while the others were eventually treated with systemic steroids, cyclosporine,

or cyclophosphamide in one case. A multicenter trial of 418 patients treated with fexofenadine at doses of 20 mg, 60 mg, 120 mg, or 240 mg twice daily found that the three higher doses provided better disease control than the lowest dose, but there were no significant differences in effectiveness among the higher doses.²⁷ Recently a study of 30 patients with acquired cold urticaria evaluated patients in a randomized, placebo-controlled, cross-over study comparing desloratadine 5 mg daily with desloratadine 20 mg daily versus placebo using cold provocation testing and objective outcomes.⁴ While both doses of desloratadine showed efficacy, the 20 mg dosage showed greater efficacy than the 5 mg dosage. Finally, a recent study enrolled 80 patients who had histories of failing antihistamine therapies into a double-blind randomized trial of levocetirizine or desloratadine.⁴¹ Daily doses were increased weekly from 5 mg to 10 mg then 20 mg at weekly intervals. Subjects left the study when they became symptom free. At the end of 3 weeks if subjects failed 20 mg of either levocetirizine or desloratadine, they were crossed over to receive the other

medication. Interestingly 13 patients became symptom free on standard 5 mg doses of either medication raising issues of prior adherence with therapy. In comparison, 28 subjects became symptom free on the higher doses of 10 mg (8 levocetirizine vs. 7 desloratadine) and 20 mg (5 levocetirizine vs. 1 desloratadine). Of the 28 patients nonresponsive to 20 mg desloratadine, seven became symptom-free with 20 mg levocetirizine. None of the 18 levocetirizine nonresponders benefited with 20 mg desloratadine. Interestingly, there were no reports of increased somnolence with these higher doses in either treatment group. Recent international guidelines for CU have recommended using second-generation antihistamines in doses up to four-fold higher than recommended¹⁹, though the evidence for this approach is limited.

First-generation antihistamines have also been used to treat urticaria. Double-blind placebo-controlled studies have demonstrated efficacy for several first-generation antihistamines in CU with overall similar efficacy to second-generation antihistamines.^{24,42,43} First-generation antihistamines have been recommended as add-on therapy to CU patients who have had inadequate control on second-generation antihistamines, however studies to demonstrate efficacy of this approach are lacking.^{44,45} Sedation and impairment are well documented with first-generation antihistamines. While the degree of impairment varies amongst first-generation antihistamines, as a group they cause significantly greater impairment of cognition and psychomotor function than second-generation antihistamines.⁴⁶ Sedating antihistamines are often recommended to be dosed as a single nocturnal dose in an attempt to reduce daytime impairment.⁴⁷ Data are lacking regarding whether this approach does reduce daytime somnolence especially when given chronically to patients with CU. Studies evaluating subacute use of first generation antihistamines have shown tolerance to performance impairment after 3-5 days of therapy.⁴⁸⁻⁵⁰ In addition to sedation and cognitive impairment, anticholinergic side effects including dry mouth and urinary retention are more common with first-generation antihistamines.

H2 ANTIHISTAMINES

H2-receptor antagonists have also been used to treat urticaria in conjunction with H1-receptor antagonists. Most studies demonstrating efficacy of H2-antagonists added to H1-antagonists in CU have been performed with cimetidine.⁵¹⁻⁵³ Cimetidine is an inhibitor of a number of cytochrome p 450 isoenzymes including those that are involved with metabolism of first-generation antihistamines. Plasma concentrations of hydroxyzine are higher in combination with cimetidine than with hydroxyzine alone.^{54,55} The increased serum hydroxyzine levels seen with concomitant cimetidine therapy also show enhanced suppression of histamine induced wheal and flare responses.⁵⁵ These effects were not seen with cimetidine and cetirizine. This

pharmacologic interaction may explain the perceived additional benefit of H2-antagonists in CU. Studies evaluating the combination of H1-antagonists and ranitidine in CU have yielded conflicting results in regards to an additive effect.^{56,57} A recent single-blind comparative trial using famotidine (which does not affect p-450 metabolism) in combination with hydroxyzine showed improvement compared to hydroxyzine plus cetirizine but was limited by the small and disproportionate number of evaluable subjects at the end of the study (19 in famotidine group and 7 in cetirizine group).⁵⁸ Overall, the evidence is weak supporting additional efficacy of adding H2 antihistamines to H1 antihistamines in CU therapy.

DOXEPIN

Doxepin is a tricyclic antidepressant with both H1 and H2 receptor antagonist properties. It has particularly potent H1 antagonist activity with in vitro studies showing 800 times more potent antagonism for the H1 receptor than diphenhydramine.⁵⁹ A double-blind cross-over study of 50 CIU subjects randomized to doxepin 10 mg three times daily or diphenhydramine 25 mg three times daily demonstrated superiority of doxepin with partial or total control achieved in 74% of subjects on doxepin versus only 10% treated with diphenhydramine.⁶⁰ Doxepin was noted to be half as sedating as diphenhydramine. Another small study in idiopathic cold urticaria patients comparing doxepin 10 mg with cyproheptadine 4 mg and hydroxyzine 10 mg (all administered three times daily) showed similar efficacy in regards to suppression of the ice cube test but less adverse effects with doxepin.⁶¹ Since doxepin has a half-life of 13 hours⁶² it may be dosed once a day, and because of its potential for sedation is often recommended at bedtime.⁶³ Data are lacking in regards to the addition of doxepin with other 2nd generation antihistamines although this strategy is often used.⁶⁴

SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids are frequently used in patients with CU refractory to antihistamine therapy. Nonetheless, no controlled trials have demonstrated the efficacy of systemic corticosteroids in CU. One study evaluated the role of a steroid taper but not compared to placebo. This study of 40 patients with delayed pressure urticaria (DPU) compared a combination of nimesulide and ketotifen with a 7 week taper of prednisone and found similar results.⁶⁵ Thirty percent of subjects withdrew from the prednisone treatment group due to adverse effects. A prospective study of 17 patients with various types of CU who were taking systemic corticosteroids (3-30 days per month) evaluated the impact of corticosteroid withdrawal and ability to sustain control off corticosteroids.⁶⁶ They noted that 47% had a short relapse or worsening of their urticaria upon withdrawal of corticosteroids. The majority of patients

were able to remain off corticosteroids with either complete or partial remission with addition of H1-antagonists. Expert opinion varies on the role of systemic corticosteroids with some suggesting alternate day use for refractory patients,⁴⁴ and others including international consensus groups that systemic corticosteroids should be avoided for long-term treatment of CU, since dosages necessary to suppress symptoms are usually high with significant adverse effects.^{19,47} Given the predictable and significant side effects of systemic glucocorticoids, these drugs should be avoided for long-term use but may be needed as rescue therapy to gain control of severe symptoms.

ALTERNATIVE THERAPIES FOR CU

While antihistamines are the mainstay of therapy in CU, as many as 50% of CU patients may not achieve satisfactory control with antihistamine therapy.²¹ Systemic corticosteroids have predictable systemic toxicities that occur frequently in patients on chronic therapy. A number of therapeutic alternatives have been evaluated to treat anti-histamine refractory urticaria in order to reduce the need for systemic corticosteroids.^{67,68} The term alternative therapies are used to describe these various agents. While some of these therapies possess immunosuppressant, immunomodulatory, or corticosteroid-sparing activity, these properties do not apply to all of these therapeutic options and therefore these terms are not recommended to use to describe alternative therapies as a whole. Overall, the evidence for these alternative agents is limited, and large, well-designed studies are lacking. Special considerations for the use of these alternative agents include potential toxicity (both acute and long-term), cost, need for laboratory monitoring, and patient preferences.

Leukotriene Modifiers

Leukotrienes may have a role in the pathogenesis of some patients with urticaria. Leukotriene D₄ when injected into the skin is more potent than histamine in causing a wheal and flare.⁶⁹ Serum from patients with autoimmune CU has been shown to induce release of histamine and leukotriene production.⁷⁰ Leukotriene modifiers are one of the best studied groups of alternative agents for treatment of CU and are generally well-tolerated with rare significant adverse effects. Leukotriene receptor antagonists have shown efficacy in the treatment of CU in single and double-blind studies for zafirlukast and montelukast either as single agents or in combination with antihistamines.⁷¹⁻⁷⁷ Most of these studies had relatively small numbers of subjects ranging from 27-86 subjects with only one study involving 160 subjects.⁷⁷ However, a double-blind placebo controlled crossover trial with zafirlukast in 52 patients with CIU showed no benefit.⁷⁸ Most studies showing beneficial effects of leukotriene receptor antagonists have shown improvement within weeks of initiation. Studies

comparing the efficacy of leukotriene receptor antagonists with antihistamines have shown mixed results with some studies showing greater efficacy^{73,74} and others showing less efficacy⁷⁷ than second-generation antihistamines. In contrast to leukotriene receptor antagonists, 5-lipoxygenase inhibitors have not been studied in the treatment of CU with only rare anecdotes of success reported.^{79,80}

Several factors have been suggested to predict clinical response to leukotriene modifiers. The pathogenesis of aspirin/NSAID-exacerbated urticaria is linked to systemic overproduction of prostaglandin D₂ and cysteinyl leukotriene production.⁸¹ Initial case reports followed by randomized controlled trials have shown efficacy of montelukast in NSAID-exacerbated CIU patients with one study showing efficacy of montelukast greater than cetirizine.⁷⁴ An open study of 10 subjects with proven NSAID-induced urticaria underwent premedication with montelukast prior to ibuprofen challenge with three showing complete blockade and 6 with partial blockade of urticaria.⁸² Two randomized-controlled studies involving 27 and 95 CIU patients reported ASST positivity a predictor of better response to leukotriene modifiers.^{72,73} In contrast, an open trial suggested that shorter duration of CU and younger age were more predictive of response to leukotriene modifiers than either a history of NSAID exacerbation or positive ASST.⁸³ Montelukast has also been reported to be beneficial in three of five patients with urticaria that was induced or aggravated by antihistamines.⁸⁴

Leukotriene modifiers have been reported to have benefit in some physical urticarias. Case reports of leukotriene receptor antagonists either alone or in combination with antihistamines have suggested benefit in cold urticaria.^{85,86} Two randomized controlled trials have demonstrated superiority of a leukotriene receptor antagonist in combination with antihistamines over antihistamine monotherapy in patients with DPU.^{71,87}

Overall, while several controlled studies indicate efficacy of leukotriene receptor antagonists in CU, most studies are relatively small. Nonetheless, given the benign side effect profile of these agents and general tolerability, they may be considered in patients with unsatisfactory responses to antihistamine therapy.

Dapsone

Dapsone produces a variety of effects of potential relevance to both vasculitic and nonvasculitic urticaria. These effects include suppression of prostaglandin and leukotriene activity, interference with release or function of lysosomal enzymes⁸⁸ and myeloperoxidase generation of toxic halides,⁸⁹ disruption of integrin-mediated neutrophil adhesiveness,⁹⁰ inhibition of signals to recruit and activate neutrophils,⁹¹ and scavenging of oxygen free radical intermediates.⁹² Many of these activities may affect neutrophil function, however it is unclear whether dapsone has preferential response in neutrophil-rich urticaria.

Several case reports and case series have suggested benefit of dapsone in CIU, idiopathic angioedema, DPU, and urticarial vasculitis.⁹³⁻¹⁰⁰ A series of 11 patients with antihistamine unresponsive CU (3 with DPU) were treated with dapsone 25 mg daily in addition to cetirizine and instructed to withdraw cetirizine when satisfactory control of symptoms was achieved.⁹⁵ Nine patients (including the three DPU patients) had a complete response to the 25 mg dosage with another patient requiring 50 mg of dapsone for complete control. The majority of patients had a sustained remission of urticaria. Recently a randomized, unblinded study of 65 CIU patients compared dapsone and desloratadine versus desloratadine alone during 3 months of treatment with an additional 3 month post-treatment observational period.¹⁰¹ While the dapsone treated group had similar reductions in urticaria scores compared to the desloratadine monotherapy group, nine patients treated with dapsone had complete responses, whereas none of the control subjects did. Additionally, five of nine responders remained urticaria free 3 months after discontinuing dapsone suggesting that dapsone may induce remission of CU as has been suggested in some other reports.^{93,95}

Dapsone is usually well-tolerated but has predictable side effects including dose-related anemia. Less common adverse effects include peripheral neuropathy, rash, gastrointestinal complaints, hepatotoxicity, and rarely methemoglobinemia, blood dyscrasias or the syndrome of drug rash with eosinophilia and systemic symptoms.¹⁰² Prior to initiation of dapsone therapy, it is recommended to determine the level of glucose-6-phosphate dehydrogenase (G6PD) as dapsone should be avoided in G6PD-deficient patients due to risk of severe hemolysis. Ongoing laboratory monitoring for anemia and hepatotoxicity is recommended.¹⁰³

Overall, the evidence for the efficacy of dapsone in CU is limited. Case series and reports suggest efficacy and possibly remission. While generally well-tolerated, laboratory monitoring is required. My own experience with dapsone in CU has been favorable and I believe it is a reasonable alternative agent in antihistamine refractory patients.

Sulfasalazine

Sulfasalazine produces a variety of anti-inflammatory effects with potential relevance to urticaria pathogenesis including decreased prostaglandin D2 synthesis and histamine release from activated mast cells,¹⁰⁴ attenuation of the respiratory burst of polymorphonuclear leukocytes,¹⁰⁵ and inhibition of proliferation of B-lymphocytes.¹⁰⁶ Case reports and case series have suggested efficacy of sulfasalazine in patients with CU and DPU.¹⁰⁷⁻¹⁰⁹ A retrospective observational study of 19 CIU patients demonstrated significant improvement in 14 of 19 patients with more modest benefit in 4 additional patients.¹¹⁰ Therapeutic response occurred within 1 month and doses above 2 g/d had no additional benefit.

Gastrointestinal complaints including nausea, vomiting, dyspepsia and anorexia and headache are the most frequent complications of sulfasalazine therapy.¹¹¹ These symptoms typically occur early in therapy and are much more common in patients taking > 4 g/d (a dose usually not required for treatment of CU). Gradual escalation of dosing over several days may reduce the gastrointestinal effects. Hematologic abnormalities, proteinuria, and hepatotoxicity, are uncommon but laboratory monitoring for these adverse effects is recommended.¹¹² The potential for sulfasalazine to induce remission of urticaria is unknown.

Overall, the evidence for sulfasalazine in CU is very limited. It is typically a well-tolerated drug (other than gastrointestinal effects which are easily recognizable) and is inexpensive and therefore may be considered in patients with antihistamine refractory CU. My own personal experience with sulfasalazine in CU is that it may be occasionally effective and that serious adverse effects are rare with appropriate monitoring.

Hydroxychloroquine

Hydroxychloroquine is an anti-inflammatory agent that disrupts T-cell receptor crosslinking-dependent calcium signaling¹¹³ and disrupts antigen processing¹¹⁴ and therefore has potential benefit in CU. Limited data are available on the use of hydroxychloroquine in CU. A case report suggested efficacy in a patient with hypocomplementemic urticarial vasculitis.¹¹⁵ A randomized, blinded, placebo-controlled study of 21 subjects with CU demonstrated significant improvement in quality of life, but only trends towards improvement in urticaria activity scores or reduction in other medications.¹¹⁶ The study was underpowered to detect significant differences due to drop-outs.

Hydroxychloroquine is generally well-tolerated with the most worrisome adverse effect being retinopathy. The risk of retinopathy from hydroxychloroquine is exceedingly rare with less than 20 reported cases in over 1 million treated individuals.¹¹⁷ Almost all cases have occurred in individuals who have used the drug > 5 years. Many cases of toxicity involved dosages greater than 6.5 mg/kg/day. While recommendations vary, the most recent American Academy of Ophthalmology recommendations divide the type of evaluation based on low or high risk patients.¹¹⁷ High risk patients are identified as taking > 6.5 mg/kg/day, duration of use > 5 years, age > 60 years and presence of renal or liver disease or obesity. For low risk patients, a baseline examination during the first year is recommended with follow-up evaluations varying from every 2-4 years based on age.

Overall, evidence for hydroxychloroquine in CU is also very limited. It is typically well-tolerated and inexpensive but has a slow onset of action. My personal experience with hydroxychloroquine is that it is occasionally effective without serious adverse effects.

Colchicine

Amongst alternative agents, colchicine has been used relatively frequently to treat CU despite minimal evidence to support its use. Colchicine has some anti-inflammatory activities particularly as relates to neutrophils including suppression of neutrophil leukotriene B4 generation¹¹⁸ and expression of adhesion molecules on endothelium and neutrophils¹¹⁹ that could potentially play a role in CU. A single double-blind placebo controlled trial in 13 patients with DPU failed to show benefit of colchicine.¹²⁰ A recent open study treated CU patients according to histologic features of their CU and 8 of 9 colchicine treated patients with neutrophilic inflammation responded to colchicine.¹⁰⁰ Other case reports suggest efficacy in urticarial vasculitis patients.¹²¹⁻¹²³ Colchicine is generally well-tolerated with the most frequent adverse effect being diarrhea. High doses can cause bone marrow suppression and long-term use has rarely been associated with myopathy.¹²⁴

Overall, colchicine has very limited evidence supporting its use in CU. Other than diarrhea, it is typically well-tolerated and inexpensive. My personal experience with colchicine has been disappointing with rare beneficial effects in CU patients.

Calcineurin Inhibitors

Cyclosporine is another relatively well-studied alternative agent in CU. A wide spectrum of possible anti-urticularial

mechanisms has been described, including inhibition of calcium-dependent release of and responsiveness to histamine, leukotriene C4, and other mediators in various cell types, including mast cells.¹²⁵ Many of these hypothesized effects target the mast cell, but anti-T-lymphocyte activity with resultant disruption of autoantibodies and interaction with mast cells may be another mechanism of action in urticaria.¹²⁶ Cyclosporine may also disrupt TNF- α activity and secondarily inhibit neutrophil accumulation¹²⁷ as well as reducing levels of IL-2R and IL-5.¹²⁸ Tacrolimus has similar immunosuppressive activities as cyclosporine but binds to a different immunophilin, FK506 binding protein, and this complex inhibits calcineurin phosphatase.¹²⁹ Like cyclosporine, tacrolimus has been shown to inhibit mediator release from mast cells.¹³⁰

The first published experience described dramatic improvement in three patients (2 also with an angioedema component) but who discontinued therapy because of intolerance of the relatively high dose used (6 mg/kg daily), with relapse of their CIU.¹³¹ Subsequently, several other case reports and case series have used lower doses sometimes with downward titration of dosing to maintain efficacy and reduce adverse effects^{128,132,133} A recent case series suggests efficacy in pediatric patients with CU¹³⁴ Evidence on cyclosporine in physical urticarias is limited to single case reports for cold¹³⁵ and solar¹³⁶ urticaria.

Three randomized controlled studies have demonstrated the efficacy of cyclosporine in CU patients.¹³⁷⁻¹³⁹ Comparisons of these studies are shown in Table 12-2.

TABLE 12-2—Randomized, Controlled Studies on Cyclosporine in CU

	Grattan et al.(137)	DiGioachhino et al.(138)	Vena et al.(139)
Total subjects	30	40	99
# randomized to CSA	20	20	64
Dose of CSA	4 mg/kg/day	5 mg/kg/day for 8 weeks then 4 mg/kg/day for 8 weeks	5 mg/kg/day for 2 weeks then 4 mg/kg/day for 2 weeks then 3 mg/kg/day for 12 weeks
Duration of controlled study therapy	4 weeks	2 weeks	16 weeks
ASST only subjects	yes	yes	not stated
Primary outcome	Reduction of urticaria activity score to <25% of baseline at 4 weeks	Not stated	Change in urticaria severity score at 8 weeks
Primary Results	Responders CSA: 8/19 PBO: 0/10	"Responders" after 2 weeks: CSA: 20/20 Cetirizine: 4/20	Improved severity scores after 8 weeks: CSA: 62% PBO: 23%
Adverse effects	29/30 none stopped therapy	3 reversible rise in creatinine 4 other adverse effects	CSA: 44/64 PBO: 16/35 6 had rise in creatinine
Comments	7/10 nonresponders to placebo, responded to CSA in open label extension	Study severely limited due to crossing-over of control group after 2 weeks and most of data comparing data pre and post CSA	Statistical improvements in Dermatology Life Quality Index in CSA vs. PBO

CSA: cyclosporine; ASST: autologous serum skin test; PBO: placebo

Two studies randomized patients to either cyclosporine or placebo,^{137,139} while one study¹³⁸ used cetirizine as a comparator. Doses used varied from 3–5 mg/kg/day. The main limitation of these studies was the definition of refractory CU as poor response to antihistamines or modest doses of cetirizine. Often in clinical practice, measures that are more aggressive are used to treat CU patients prior to resorting to cyclosporine and it is unclear based on these controlled studies whether cyclosporine would be as effective. One study was limited by the comparator group being switched over to open label cyclosporine therapy after only 2 weeks.¹³⁸

The optimal duration of therapy with cyclosporine is unclear with some recommending longer therapy to sustain benefit,^{139,140} with follow-up in the literature extending out as far as a mean of 11 years, while others suggest most of the benefit is apparent by the initial month of treatment.¹⁴¹ Studies evaluating using a positive ASST as a predictor of response to cyclosporine have found no correlation.¹⁴¹ Advantageous properties of cyclosporine include rapid onset (sometimes within days),^{133,138,142} possibility of long-lasting remission,^{135,138} and degree of efficacy comparable to prednisone.¹⁴²

Tacrolimus is another calcineurin inhibitor that has been evaluated in CU. A pilot observational study of tacrolimus in 12 patients with CIU poorly responsive to antihistamines reported 70% of patients responded to tacrolimus with 3 patients having resolution of urticaria, including one who had not responded to cyclosporine.¹⁴³

A number of adverse effects have been associated with calcineurin inhibitors including hypertension, renal dysfunction, headache, hypertrichosis, gingival hyperplasia, paresthesias, gastrointestinal symptoms, and metabolic abnormalities.¹⁴⁴ Many of these adverse effects are dose and/or duration related. Malignancies have been rarely reported with calcineurin inhibitors. A prospective long-term cohort study of 1252 patients with psoriasis treated with cyclosporine were followed up to 5 years and found a higher incidence of skin malignancies but not other nonskin malignancies.¹⁴⁵ Monitoring of blood pressure, renal function, serum drug levels, and other metabolic factors are important in patients treated with calcineurin inhibitors.¹⁴⁴

Overall, calcineurin inhibitors have the most abundant literature of available alternative agents with several controlled studies showing efficacy. My own experience with these agents is consistent with the previously discussed findings that these agents are frequently effective (including patients refractory to other alternative agents), have a rapid onset of action, are capable of inducing long-lasting remission, and are generally well tolerated. Nevertheless, due to their frequency of adverse effects and potential for serious adverse effects, I personally do not typically recommend calcineurin inhibitors as first-line alternative agents.

Mycophenolate

Mycophenolate mofetil (MMF) is an immunosuppressant used in transplantation as well as a growing number of autoimmune diseases. The active metabolite of MMF is a competitive inhibitor of inosine-5'-monophosphate dehydrogenase, and kills activated lymphocytes through the activation of a caspase-independent necrotic signal.¹⁴⁶ In an open-label study of 9 patients with CU with positive ASST refractory to H1 and H2 antagonists, 12 weeks of MMF 1000 mg twice daily showed significant improvement in urticarial scores, reduction in antihistamines and steroid sparing activity.¹⁴⁷ The most common adverse effects with MMF include gastrointestinal disturbances occurring in up to 20% of patients at doses of 2 g daily.¹⁴⁸ Hematologic side effects including leukopenia are less common, usually mild, reversible and dose related.

Overall, the evidence for mycophenolate in CU remains minimal. While often used as an alternative to other immunosuppressants (due to its better tolerability) for other diseases, its role in the treatment of CU is unclear but likely can be considered when other immunosuppressants are being contemplated. My personal experience with this agent has been that it has been effective in some patients with minimal adverse effects.

Omalizumab

Omalizumab is a recombinant humanized monoclonal antibody that binds to free IgE and inhibits binding of IgE to Fc ϵ RI, the high-affinity IgE receptor. Omalizumab reduces the number of Fc ϵ RI receptors on the surface of mast cells and basophils.¹⁴⁹ Several case reports have suggested efficacy of omalizumab in a variety of types of CU including cold urticaria,¹⁵⁰ cholinergic urticaria,¹⁵¹ solar urticaria,¹⁵² urticarial vasculitis,¹⁵³ idiopathic,¹⁵⁴ and idiopathic angioedema.¹⁵⁵ Recently, a proof of concept study evaluated the efficacy of omalizumab in 12 patients with CAU.¹⁵⁶ This was a single-blind study that included a 4-week placebo phase followed by omalizumab every 2 or 4 weeks for 16 weeks. Seven patients had complete resolution, four had partial improvement and 1 had no response. Preliminary evidence from double-blind, placebo-controlled studies of omalizumab also indicate efficacy in CU patients.¹⁵⁷ The mechanism of action of omalizumab is not clear and reports of efficacy have included patients without detectable autoantibodies and low total IgE levels.¹⁵⁸ Omalizumab is generally well-tolerated with rare reports of anaphylactic reactions occurring.

While the current evidence for omalizumab in CU is limited, there appears to be a growing body of evidence suggesting efficacy. This may certainly lead to new discoveries on pathogenesis of CU. Omalizumab is typically well-tolerated but expensive and may not be covered for urticaria treatment by many third party payers. Its potential for

remission of CU is also unclear. My personal experience with omalizumab indicates a high degree of efficacy but with return of urticaria upon discontinuation.

Intravenous Immunoglobulin (IVIG)

Intravenous immunoglobulin has a variety of immunomodulatory activities that theoretically may be important in CU including modulation of adhesion, complement function, cytokine levels, autoantibodies and anti-idiotype networks.¹⁵⁹ The earliest report of use of IVIG in CU involved an open-label trial of 10 patients with positive ASST and basophil histamine release tests who had failed other therapies including alternative agents.¹⁶⁰ Patients were treated with an immunomodulatory dose of IVIG, 0.4 g/kg/day for 5 consecutive days. Benefit was noted in 9 of 10 patients with three patients experiencing prolonged remission with 3 years of follow-up. Other case reports have suggested benefit of IVIG with various dosing regimens,^{161–163} however there are other reports of IVIG failures, particularly in urticarial vasculitis.^{164,165} A low-dose regimen of .15 g/kg every 4 weeks was reported to be effective in an open label study of 29 patients with autoimmune CU.¹⁶⁶ IVIG has also been reported to be beneficial in DPUA,¹⁶⁷ solar urticaria,¹⁶⁸ and urticarial vasculitis.¹⁶⁹ IVIG is relatively safe with predictable infusion-related adverse reactions including headache, myalgias, and nausea and rarely anaphylactoid reactions, aseptic meningitis or renal failure.

Overall, data are limited on the efficacy of IVIG. While typically well-tolerated, it is expensive and requires prolonged infusions. My personal experience with IVIG in CU has been disappointing.

Other Biologic Therapies

In addition to omalizumab, other biologic therapies have been reported to be helpful in case reports of refractory CU patients. A patient with DPUA was noted to have a rapid response when treated with the tumor necrosis factor inhibitor, etanercept for psoriasis.¹⁷⁰ His response persisted when switched to infliximab due to inadequate control of psoriasis. Numerous case reports have shown efficacy of the interleukin-1 receptor antagonist, anakinra, for the autoinflammatory syndrome, Schnitzler syndrome characterized by urticaria, fever, bone pain and monoclonal IgM gammopathy.^{171–173} Anakinra has also been reported to be beneficial in urticarial vasculitis.¹⁷⁴ Rituximab is a monoclonal antibody targeted against CD20 transmembrane protein on the surface of mature B cells. Individual case reports of efficacy of rituximab have recently been reported in patients with CAU¹⁷⁵ and urticarial vasculitis.^{176,177} In contrast, a case report of a failure of rituximab was reported in a severe steroid dependent CU patient who was resistant to numerous other alternative agents.¹⁷⁸

While these case reports are interesting, data are severely limited on these biologic therapies and with the exception of the treatment of Schnitzler syndrome, they should mainly be considered for patients proven refractory to other alternative agents.

Beta-Agonists

Beta-agonists have well-known inhibitory effects *in vitro* on mast cells including inhibition of mediator release.¹⁷⁹ However, studies of their *in vivo* effects on the skin have shown variable, limited and dose-related inhibitory effects on wheal and flare responses when injected into the skin prior to challenge with allergen, histamine or compound 48/80.¹⁸⁰ A small double-blind cross-over study of the cutaneous effects of oral terbutaline showed attenuation of the wheal response to injected allergen, but no effect on response to injection of histamine in 8 horse-allergic individuals. This same study also found that 2.5 mg terbutaline three times a day for 1 week had no effect on cold provocation in five subjects with cold urticaria. A more recent double-blind, double-dummy study similarly found that orally administered terbutaline or its pro-drug bambuterol did not inhibit mast cell activation or allergic skin responses.¹⁸¹

Reports on the efficacy of beta-agonists in CU have been mixed. An observational study of 24 patients with various forms of CU resistant to antihistamine therapy found terbutaline dosed 25 mg three times daily was more effective than antihistamines.¹⁸² Other case reports suggested efficacy with terbutaline and ketotifen in combination, in cold and other forms of CU.^{183,184} However, two double-blind studies have not shown significant benefit of terbutaline in CU.^{52,185} One study evaluated 18 patients with CU and found terbutaline no different than placebo.¹⁸⁵ Another double-blind, multiarm, crossover study of 19 CU patients found terbutaline inferior to antihistamine therapy.⁵² The most common adverse effects associated with oral beta agonist therapy are agitation, insomnia, tremulousness and tachycardia.

Overall, small, placebo-controlled studies have not shown efficacy of beta-agonists in CU. Therefore, it is unlikely that oral beta-agonists have a significant impact on most patients with CU, nevertheless they may be considered in select patients with refractory CU. My personal experience with beta agonists has been disappointing.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Indomethacin is the main NSAID studied in CU and has been reported to be effective in an observational report of 10 patients with urticarial vasculitis.¹⁸⁶ In contrast, a double-blind, controlled, crossover trial of indomethacin therapy in 14 patients with delayed pressure urticaria revealed no

significant subjective improvement or reduction in area of induced wheals.¹⁸⁷ A study of topical indomethacin in 9 subjects with chronic dermatographia urticaria showed augmentation of dermatographia wheals.¹⁸⁸ The cyclooxygenase-2 inhibitor rofecoxib (withdrawn from the US market) showed efficacy in two small case series of CU patients,^{189,190} but no studies have been reported on the efficacy with the currently available cyclooxygenase-2 inhibitors in CU.

Overall, evidence for efficacy of NSAIDs in CU therapy is minimal. Since NSAIDs are a frequent cause of urticaria exacerbations, caution should be exercised when considering their use as alternative agents.

Methylxanthines

Few studies have evaluated the role of methylxanthines in CU. The earliest report of theophylline in 15 CU patients noted complete response in three, whereas six had no significant benefit.¹⁹¹ More recently, a larger double-blind, placebo-controlled study of 134 CU patients evaluated theophylline 200 mg twice a day for 6 months then 200 mg once a day for 6 months versus placebo as an add-on therapy to cetirizine.¹⁹² Both groups experienced large improvements in all symptoms assessed, however the treatment group had statistically significant improvement in overall urticaria scores but not pruritus. The clinical relevance of this statistical difference is unclear. These investigators also studied a group of 23 patients with DPUA using an open-label cross-over design and noted additional benefit over cetirizine during theophylline therapy.¹⁹³ An observational study of aminophylline plus terbutaline in 42 patients with cold urticaria showed overall improvement in the majority of subjects however 3 patients had to stop therapy due to cardiac events and 19 others had less severe adverse effects.¹⁹⁴

Overall, the evidence for the efficacy of theophylline in CU is modest at best. Nevertheless, it is usually well tolerated within its narrow therapeutic range and it is inexpensive. It certainly can be considered for antihistamine refractory CU patients, particularly as an add-on to antihistamines.

Phototherapy

Phototherapy includes ultraviolet-A (UVA) therapy with coadministration of psoralen (PUVA) or ultraviolet-B (UVB) therapy. Phototherapy may decrease histamine release from mast cells.¹⁹⁵ Phototherapy has been reported to be successful in various case reports of solar urticaria.¹⁹⁶⁻¹⁹⁹ Case series have reported benefit of phototherapy in other physical urticarias (cold, cholinergic, dermatographism) and CIU.²⁰⁰⁻²⁰² A relatively large retrospective study of 94 patients (88 with CIU) treated with narrow-band UVB (NB-UVB) demonstrated that 72% of treatment courses produced moderate improvement to

clearance of urticaria.²⁰³ Telephone follow-up years later revealed 33% of patients were clear of urticaria with 45% indicating improvement from NB-UVB therapy. Recently, an open-trial of 81 CU patients receiving levocetirizine with 48 randomized to additional NB-UVB therapy showed improvement in both groups but statistically larger treatment effects in the NB-UVB treated group.²⁰⁴ In addition, the NB-UVB treated group showed much lower scores 3 months later than those treated with levocetirizine alone. Adverse effects of phototherapy include erythema, pruritus, photodegenerative changes and increased risk for skin cancer.²⁰⁵

Overall, the evidence for phototherapy in CU is based on uncontrolled but relatively large case series and suggests efficacy in physical urticarias, especially solar urticaria in addition to CIU. Frequency of treatments and regional availability is a main obstacle of phototherapy but it certainly should be considered as an alternative agent.

Androgens

Androgens have an established role in the therapy for C1-esterase inhibitor deficiency syndromes. Danazol has immunosuppressive effects *in vitro* at physiologic concentrations showing inhibition of mitogen-induced lymphocyte proliferation.²⁰⁶ Several case reports suggest efficacy of androgens in physical urticaria including cholinergic urticaria^{207,208} and aquagenic urticaria.²⁰⁹ A randomized controlled trial found danazol effective in reducing exercise-induced wheals in 17 male patients with cholinergic urticaria.²¹⁰ Stanozolol was reported to be effective in a case series of five female patients with steroid-dependent CIU and was thought to induce remission in three of the patients. A relatively large, 12-week, randomized, double-blind, placebo-controlled study compared stanozolol 2 mg three times a day versus placebo in 58 CIU patients.²¹¹ The stanozolol group had a higher frequency of marked improvement (65% vs. 29%) and mean reduction in clinical scores. This study is limited by little information on prior therapy and the observation that both groups seemed to have a continued reduction in urticarial activity without a plateau by the end of the study. Androgens have a number of potential adverse effects including virilization, dysmenorrhea, weight gain, hypertension, hyperlipidemia, thrombotic complications, and rarely hepatotoxicity.

Overall, androgens have limited evidence to support their use. Since tolerability is generally better in males, these agents could be considered for refractory CU patients. My personal experience with androgens in CU has been disappointing.

Methotrexate

Methotrexate is an anti-inflammatory agent with unclear mechanisms of action that include increasing adenosine

levels, inducing apoptosis in activated CD4+ T-cells, and decreased neutrophil chemotaxis.²¹² Experience with methotrexate is limited with a few case reports and a case series the largest of which included 7 patients with CAU who noted benefit within 1-2 weeks of therapy.²¹³⁻²¹⁶ Methotrexate has potentially serious adverse effects including hepatotoxicity and pulmonary fibrosis and requires extensive laboratory monitoring. Given all of the above, its use should be restricted to CU patients who have failed numerous other safer alternative agents.

Anticoagulants

Recent studies have suggested that activation of the coagulation cascade via the tissue factor pathway leading to serum elevations in prothrombin fragments and D-dimer may have a role in the pathophysiology of CU.²¹⁷⁻²¹⁹ Therefore, anticoagulant therapy may have a therapeutic rationale in the treatment of CU. Warfarin has been reported in case reports to be efficacious in CU patients.²²⁰⁻²²² One study evaluated eight patients with CU treated in an open fashion with warfarin with a target International normalized ratio (INR) between 2.0-2.5.²²³ Six of eight patients showed improvement and three patients who had “dramatic” clinical improvement were treated in a double-blind manner and these subjects also showed efficacy during the periods on warfarin compared to placebo. A single case report found that three of four patients with concomitant angioedema had either no change or had worsening of their condition.²²⁴ One case report demonstrated that prophylactic subcutaneous heparin sodium dosed 5,000 IU twice daily was efficacious in a patient who failed warfarin.²²⁵ Treatment with warfarin carries the risk of hemorrhage, which can potentially be life-threatening and requires frequent monitoring of the INR.

Overall, the evidence for anticoagulants in CU therapy is minimal and primarily of theoretical benefit. Due to its risk for serious adverse effects, anticoagulant therapy should be reserved for CU patients who have failed numerous safer alternative agents.

Miscellaneous Alternative Agents

A number of other alternative therapies have been described in the treatment of CU including sirolimus,²²⁶ cyclophosphamide,²²⁷⁻²³⁰ gold,²³¹ plasmapheresis,²³²⁻²³⁷ cromolyn,^{238,239} and nifedipine²⁴⁰⁻²⁴³ and have been reviewed elsewhere.⁶⁸ Some agents have also been studied in CU with limited to no efficacy such as interferon alpha.^{244,245}

Choosing Alternative Agents for Treatment of Refractory Urticaria

There are several factors involved in selecting an alternative agent for refractory CU. First, it should be established

that the patient is indeed refractory to antihistamine therapy. Unfortunately, predictive factors for response to the vast majority of alternative agents are lacking. The presence of underlying comorbid factors may also play a role in determining an alternative agent. For example, in a patient with poorly controlled hypertension, a calcineurin inhibitor may have higher risk of exacerbating the hypertension. A patient's tolerability to other medications may also influence drug selection. Baseline laboratories may be required to determine if any agents are contraindicated, such as dapsone and hydroxychloroquine in a patient with G6PD deficiency. Frequency of treatment-related visits (e.g. frequent phototherapy sessions) should also be considered as this may be an impediment for certain patients. The cost of alternative agents varies considerably and their affordability is another important treatment consideration. Rapidity of response to an alternative agent is another factor that influences choice. In patients suffering significant adverse effects from glucocorticoid toxicity, agents with slow onset of action (e.g. hydroxychloroquine) may not be optimal. Finally, the potential risk of a given alternative agent is extremely important and needs to be weighed against the patient's current quality of life and any adverse effects from current therapy for their CU. While on alternative therapies, appropriate laboratory monitoring if indicated, is important. Recent guidelines for laboratory monitoring of many of the rheumatic agents used in the treatment of CU have been proposed and are available online as a supplement.¹¹²

Step-based Therapies for CU

Step-based therapies for many chronic diseases have been recommended by various expert panels and are often widely used. In regards to treatment of CU, a step-based approach has only recently been developed in guidelines.¹⁹ Unfortunately, no step-based approach in CU has been evaluated in any controlled study and evidence for these approaches are based largely on expert opinion. My own personal approach to patients with CU is shown in Table 12-3.

Therapies for Specific Conditions Associated with CU

Helicobacter pylori Infection

Helicobacter pylori has been reported in recent years to be associated with CU. Recently a study of 35 CU patients (57% were positive for *H. pylori*) found an association with heavy bacterial colonization and intense gastric inflammation and severity of CU.²⁴⁶ Several studies have evaluated whether treatment for eradication of *H. pylori* improves urticaria in CU patients. Overall the results are conflicting with several studies favoring that *H. pylori* eradication is beneficial²⁴⁶⁻²⁵² and many others indicating it is not

TABLE 12-3—Example of Step-Based Therapy in Chronic Urticaria

Step 1	2 nd gen antihistamine (e.g., cetirizine)
Step 2	Higher dose 2 nd gen antihistamine (e.g., cetirizine 20-40 mg daily)
Step 3	2 nd gen antihistamine + 1 st gen antihistamine (hydroxyzine or doxepin dosed at bedtime up to 150 mg qhs)
Step 4	Antihistamines + leukotriene receptor antagonist
Step 5	Anti-inflammatory alternative therapy (e.g., dapsone, sulfasalazine, hydroxychloroquine)
Step 6	Immunosuppressant alternative therapy (e.g., tacrolimus, cyclosporine, mycophenolate)
Step 7	Biologic therapy (e.g., omalizumab)
Step 8	Other alternative therapies (e.g., phototherapy, IVIG, etc)

helpful.²⁵³⁻²⁶⁰ Currently it is unclear whether treatment of eradication of *H. pylori* improves urticaria.

Thyroid autoimmunity

For several decades, an association with thyroid autoimmunity and CU has been described.²⁶¹⁻²⁶³ Several reports have described clinical benefits of CU with treatment of these patients with thyroid hormone at doses that suppress the TSH level.²⁶⁴⁻²⁶⁶ A recent survey of U.S. allergists showed that while the majority tested for thyroid autoantibodies, the minority treated euthyroid patients.²⁶⁷ Controlled studies proving the efficacy of treating euthyroid patients with thyroid hormone are currently lacking.

Herpes Infection

Rare cases of urticaria associated with genital herpes have been reported with successful treatment with acyclovir²⁶⁸ and valacyclovir.²⁶⁹ Another case series of 12 patients with CIU, idiopathic angioedema, and HAE found that 5 patients responded to acyclovir therapy with recurrence with discontinuation of acyclovir.²⁷⁰ None had genital herpes but they did have elevated antibody titers to herpes simplex or Ebstein-Barr virus. Controlled studies proving the efficacy of anti-herpetic therapy on CU are currently lacking.

Hormone Sensitivity

Autoimmune progesterone dermatitis is a rare cyclical disease associated with the luteal phase of the menstrual

cycle with a variety of dermatologic manifestations including urticaria and angioedema.²⁷¹ The diagnosis can be confirmed through intradermal skin testing or intramuscular or oral challenge with progesterone.²⁷²⁻²⁷⁴ Case reports of successful treatment with conjugated estrogen,²⁷² gonadotropin-releasing hormone agonists,²⁷⁵ tamoxifen,²⁷³ and bilateral oophorectomy²⁷⁴ suggest that hormonal manipulation may be efficacious in some cases. Another even more rare form of hormone sensitivity is estrogen dermatitis, which is associated with premenstrual flares of dermatosis including urticaria in some cases.^{276,277} Patients with urticaria due to estrogen are diagnosed with intradermal skin tests to estrogen. Treatment with tamoxifen,^{276,277} bilateral oophorectomy,²⁷⁸ and progestin²⁷⁹ has been reported successful in some cases.

CONCLUSION

Antihistamines are first-line therapy and effective in the majority of cases of CU. Nevertheless, some patients with CU are antihistamine resistant and may require alternative agents for adequate control of their CU. The ultimate goal should be to control urticaria to reduce its impact on the quality of life of the patient, minimize adverse effects of medications, and eliminate chronic or frequent oral corticosteroids. While the evidence is limited for non-antihistamine therapies in CU, a rationale patient-based approach can be developed based on levels and quality of evidence, potential for adverse effects, costs, and patient preferences.

What We Know

- Antihistamines are first-line therapy and effective in the majority of cases of chronic urticaria.
- Higher doses of some second generation antihistamines may be more effective at achieving control of chronic urticaria than typically recommended doses.
- A significant percentage of chronic urticaria patients

- are antihistamine resistant and may require alternative agents for adequate control of their urticaria.
- While the evidence is limited for non-antihistamine therapies in chronic urticaria, a rationale patient-based approach can be developed based on levels and quality of evidence, potential for adverse effects, costs, and patient preferences.

Atopic Dermatitis

Dina Farshidi, M.D., Ravneet Kaur, M.D.,
Jashin J. Wu, M.D., and David Peng, M.D.

BACKGROUND

Atopic dermatitis (AD), also known as atopic eczema, is a common inflammatory skin disease that frequently follows a chronic relapsing course. As part of the “atopic triad”, AD often occurs in patients with a personal or family history of asthma or atopic rhinitis. This disease can be lifelong, causing significant interference with school, work, and social interactions.

During the past decade, extraordinary progress has been made in our understanding of the pathogenesis and treatment of AD. Because AD is a complex disease with variable clinical manifestations and no laboratory procedure to provide an unequivocal diagnosis, different sets of criteria have been developed to provide guidance in its diagnosis.

In this chapter, we will review our most recent understanding of the pathogenesis, diagnosis, and treatment of AD.

INTRODUCTION

Atopic dermatitis is an inflammatory skin disease that primarily affects children and young adults. Its lifetime prevalence is approximately 5 to 15% in children from industrialized countries,¹ with approximately 80% of cases starting before the age of 5.² In the United States, the lifetime prevalence in school-aged children has been reported to be up to 17%,³ with prevalence rates increasing in parallel with the rising prevalence of other atopic disorders.⁴

Although the cardinal features of AD are cutaneous hyper-reactivity and hypo-reactivity, as well as intense pruritus that is worse at night, the presentation of AD is often variable because of the differences in age, genetic background, and environmental factors surrounding the individuals studied. One major difference involves the word used to describe the condition, “atopic”. Ironically, many patients do not test positive for common allergens in skin-prick testing or for specific circulating immunoglobulin E (IgE) antibodies in serum testing, and therefore do not present with an atopic form of the disease.⁵ Other subtypes and variations including irritant or allergic contact eczema also exist, but we categorize them all as one condition because the pathogenesis remains unclear.

At this point, there is no consensus on the etiology of atopic dermatitis, but it likely involves some complex interplay between strong genetic and environmental factors; there is only a partial consensus on the diagnosis and treatment of AD.

CLINICAL PICTURE

Atopic dermatitis can be classified into three forms: infantile, childhood, and adult or late-onset. The infantile form is predominantly characterized by acute inflammation with edema, vesicles, exudate and crusting favoring the face, scalp, and extensor surfaces (Figure 13-1). The childhood form tends to be characterized by subacute clinical features such as poorly demarcated erythema and scaling papules and thin plaques, which favor flexural surfaces of the extremities and skin folds including the antecubital fossa, the popliteal fossa, and the neck (Figure 13-2). Of note, periocular erythema, edema and scaling can produce infraorbital lines known as Dennie-Morgan folds (Figure 13-3). The adult, late-onset or chronic form also favors the flexor regions and lesions are typically morphologically characterized by lichenified or fissured plaques, and

FIGURE 13-2 Subacute atopic dermatitis. Characterized by poorly demarcated erythema and scaling papules and thin plaques. (From ledamod.wordpress.com)

fibrotic papules or nodules from chronic rubbing and scratching (Figure 13-4). Importantly, lesions from any of the three forms can coexist.

MORBIDITY AND COSTS

Compared to other dermatologic diseases, AD can be associated with serious effects on quality of life. Itch and associated sleep loss, social stigmatization from other children and parents, avoidance of activities involving baring of the skin such as swimming, the need for special clothing and bedding, and the need for multiple applications of topical treatments and visits to the dermatologist are just some of the potential causes for morbidity in this patient population.⁶

When direct costs are considered, AD treatment can total \$364 million to \$3.8 billion USD in the United States.⁷ While different study methodologies are responsible for deviations in cost, even the underestimated figures reveal a significant economic burden.^{8,9} For the individual patient, the annual cost is \$338 on average and is almost 1.5-fold higher (\$820) for patients with AD who develop atopic manifestations, such as food allergies, asthma, allergic rhinitis and allergic conjunctivitis.¹⁰ Unfortunately, the high cost of AD is unlikely to diminish in the years to come, especially in light of the increasing prevalence of the disease. To potentially address these costs, more emphasis should be placed on recognizing the disease earlier and implementing therapeutic and preventative measures that reduce the development of atopic manifestations.

FIGURE 13-4 Chronic atopic dermatitis. Characterized by Lichenified or fissured plaques and fibrotic papules or nodules from chronic rubbing and scratching. (From lookfordiagnosis.com).

GENETICS

The hereditary aspect of AD has long been established. In twin studies, concordance rates for monozygotic twins (23–86%) were higher than dizygotic twins (15–50%).^{11–16} Such a wide range can be explained, in part, by the heterogeneity of phenotypes across studies, and by the environment's role in influencing disease risk and manifestation.

Historically, our understanding of the genetic basis of AD was limited. Until recently, we believed AD to be related to any number of things, such as polymorphisms in the cutaneous mast cell chymase,¹⁷ *Rsal* polymorphisms in the genes coding for the β chain of the high affinity receptor for IgE,¹⁸ and gain of function mutations in the α subunit of the interleukin-4 receptor.¹⁹ Now, after extensive genome-wide linkage studies, association studies and high-throughput expression profiling studies, we better understand the role of skin barrier dysfunction candidate genes in conjunction with innate and adaptive immune response genes in the pathogenesis of AD. To date, more than 100 studies report genetic associations for 81 genes, of which more than half had at least one positive association with AD. Of these, the filaggrin (filament-aggregating protein) gene has been most consistently replicated.²⁰ By binding to keratin fibers in epithelial cells, filaggrin builds a defense matrix of cytoskeleton fibrils in the stratum corneum and a functional barrier at the skin surface. Present in up to 10% of Europeans and North Americans, filaggrin null mutations follow a recessive pattern of inheritance and are associated with mild-to-moderate AD that presents in childhood.^{21,22} Deficiency results in a compromised skin barrier that fails to protect against microbial insults and antigens, which in turn predisposes afflicted individuals to allergic sensitization, allergic rhinitis, and atopic dermatitis. AD patients with the filaggrin mutation also present with disease that is of earlier onset, more severe in nature, more persistent in course, and are more likely to develop asthma and allergic sensitizations.²³

Although recent research has argued that the primary defect in AD resides in the epidermal barrier,²⁴ it is important to recognize that a significant number of patients with AD do not have any known filaggrin gene mutation and approximately 40% of patients with the filaggrin null mutation do not have AD.²⁵ Thus, despite our progress in better understanding the genetics of AD, we have yet to discover the exact relationship between barrier dysfunction and immune dysregulation in patients with AD. Current research identifying other skin barrier proteins that are essential for normal barrier function as well as specific biomarkers for AD will likely further elucidate the drivers of this disease.

Also worth noting, parent-of-origin effects, or maternal hereditability, has also been linked to AD and supported by genetic association studies with maternally transmitted alleles in the kazal-type serine protease inhibitor 5 (SPINK5) gene.^{26–28}

ENVIRONMENT

There has been a large increase in the prevalence of atopic dermatitis over the past 30 years.²⁹ It has been shown that members of wealthier families are more frequently affected.³⁰ The implications of this are unclear but may be related to greater exposure to indoor allergens. According to the “hygiene hypothesis,” children born into larger families express less atopy because of frequent exposure to infections, presumably from their siblings.³¹ However, a population-based cross-sectional study of 12,601 children between the ages of 5–7 and 9–11 from Germany found that factors such as day-care attendance and the number of older siblings were not associated with a decreased risk of developing AD.³²

Exposure to allergens, such as dust-mites, is thought to play a role in AD.³³ Interestingly, despite popular belief that furry pets kept at home are responsible for the development of AD in children, a systematic review of cohort, case control and cross-sectional studies by Langan et al. found evidence to suggest protective effects from the exposure.³⁴ Exposure to other irritants, such as bacteria, is likely to be an equally important risk factor.³⁵

Other studies favoring the role of environmental factors in the pathogenesis of AD include studies involving migrants. One study showed that 14.9% of black Caribbean children living in London developed AD compared to only 5.6% of similar children living in Kingston, Jamaica.³⁶

Psychosocial factors early in life also appear to play a role. In a systematic review of 43 cohort studies, Chida et al. found evidence to suggest a positive correlation between adverse psychosocial factors and future atopic disorder. More notably, the subgroup meta-analysis on the healthy and atopic disorder patient populations showed psychosocial factors had both an etiologic and prognostic effect on atopic disorders.³⁷

Still, many of the environmental risk factors are not fully understood at this time and the fact that many cases of atopic dermatitis spontaneously improve around the time of puberty further complicates this issue.

IMMUNOBIOLOGY

As previously discussed, the fundamental lesion in AD is a defective skin barrier that results in dry skin. Entry of irritants and microbes stimulates both the innate and adaptive immune systems which in turn contribute to the overall inflammatory process in AD.

Any initiating stimulus such as mechanical trauma secondary to scratching can potentially stimulate the local production of proinflammatory cytokines including interleukin 1 (IL-1) and tumor necrosis factor alpha (TNF alpha) as well as chemokines that allow trafficking of leukocytes into the skin.^{38–42}

Overall, the dysregulated cytokine profile in AD patients favors a CD4+ Th2 response with the predominant production of Th2 cytokines IL-4, IL-5 and IL-13.⁴³ These cytokines,

specifically IL-4, are involved in IgE isotype switching in B cells which allows subsequent binding of allergens to IgE receptors on mast and dendritic cells and stimulation of a local immune response. Interestingly, recent observations seem to indicate that in contrast to acute AD lesion which contain a Th2 predominant subset of cells, chronic lesions may contain either both the Th2 and Th1 subset of cells or a predominantly Th1 subset of cells.^{44–46}

Patients with AD are also known to be more susceptible to microbial infections, particularly with *S. aureus*. Studies have shown that the presence of antimicrobial peptides is significantly decreased in acute and chronic AD lesions and this may contribute to the increased susceptibility of AD patients to skin colonization and infection. Exposure to microbial superantigens and toxins then allows worsening of skin inflammation.^{47,48}

Further research and a better understanding of the complex immunology behind AD may allow for improvements in treatment and care of patients with this disease.

DIAGNOSTIC CRITERIA

Atopic dermatitis has a wide spectrum of dermatologic manifestations. With no specific diagnostic tests available, the diagnosis of AD is clinical. Over the years, numerous sets of diagnostic criteria have been suggested. The first set introduced by Hanifin and Rajka in 1980 consisted of 4 major and 23 minor criteria.⁵⁵ Despite the criteria being quoted in hundreds of scientific studies, only two validation studies have been published, and these found the model to be of low specificity (78–94%), time consuming and unmanageable.⁵⁶ As a refinement of Hanifin and Rajka's diagnostic criteria, the UK diagnostic criteria was introduced by Williams et al. in 1997.⁵⁷

Based on a systematic review of 27 published validation studies of various diagnostic criteria for AD, the UK diagnostic criteria was found to be the most extensively validated, with a sensitivity ranging from 10 to 100% and a specificity ranging from 89 to 99%. The markedly low sensitivity of 10% was reported by an independent Iranian study by Firooz et al. and is likely due to international differences in clinical phenotype, environmental factors, and observation bias.⁵⁸

Although most healthcare professionals do not use diagnostic criteria in routine practice, the simplified UK Working Party criteria (Table 13-1) can be useful in difficult cases and for conducting clinical trials. The criteria are all noninvasive and consist of one mandatory criterion and five major criteria, of which three have to be present for diagnosis.

To date, 20 different scales have been identified to measure disease severity. Based on a systematic review conducted by Schmitt et al. only 3 scales, SCORing Atopic Dermatitis (SCORAD), the Eczema Area and Severity Index (EASI), and the Patient Oriented Eczema Measure (POEM) have been sufficiently tested and found to perform adequately.⁵⁹ Of the three, POEM is considered

TABLE 13-1—The UK Working Party Diagnostic Criteria for Atopic Dermatitis

Must have:

- An itchy skin condition in the past 12 months

Plus three or more of the following:

- Previous involvement of skin creases (i.e., bends of elbows)
- Personal history of asthma or hay fever (or history of atopic disease in first degree relative if child is >4 years)
- History of general dry skin in the past 12 months
- Onset before the age of 2 years (not used if child aged <4 years)
- Visible flexural dermatitis (including dermatitis affecting cheeks or forehead and outer areas of limbs in children aged <4 years)

Williams, HC, Burney, PGJ, Hay, RJ, et al: The U.K. Working Party's diagnostic criteria for atopic dermatitis I. derivation of a minimum set of discriminators for atopic dermatitis. *Br J Dermatol* 1994;131: 383–396.

the most practical measure of patient outcome in the clinic. It consists of seven questions on subjective symptoms and disease severity and can be easily filled out by the patient prior to being seen by the physician.

TREATMENT

Few clinical trials evaluate the management of AD beyond 6 weeks duration, which may not be sufficient time to gauge the long-term outcomes of modern treatment modalities.⁶⁰ Without long-term studies, it is difficult to determine whether modern treatments have any effect on the chronic nature of the disease. Thus, the general approach to treatment of AD has been to focus on short-term control of symptoms by using conservative measures that emphasize the elimination of exacerbating factors, provide symptomatic relief and minimize exposure to potentially toxic drugs (see Table 13-2). For cases of severe refractory disease that fail to respond to conventional therapy, second-line treatments such as phototherapy or immunosuppressive medications may be considered. In all cases, it is crucial to provide patients with information about their disease and to address their questions and concerns.

It is important to help patients eliminate factors that may be responsible for exacerbating their disease.⁶¹ Such factors may include excessive bathing, low humidity, emotional stress, xerosis, infections, and exposure to fragrances, solvents, detergents, house dust, and wool.⁶² For patients experiencing significant stress or psychosocial disturbances, psychologic services can be offered.³⁷

To address the issue of xerosis, skin hydration is critical. While lotions with high water and low oil content can induce evaporation, thick creams with low water content or ointments with zero water content, offer better protection against xerosis. Different preparations, including water-in-oil (e.g., Eucerin[®]), oil-in-water (e.g., Moisturel[®]), urea based (e.g., Laceran[®]) and glycerin based preparations, have been proven effective in improving clinical

TABLE 13-2—Major Treatment Modalities

	Indication(s)	Routine Dose(s)	Strength of Recommendation*	Level of Evidence**
Noninflamed Skin				
Emollients	Xerosis, Pruritus	Multiple times daily, especially after bathing	A	Good
Hydrogels	Xerosis, Pruritus	Twice daily	A	Fair
Antihistamines	Sedation, Pruritus	Nightly	B	Fair
Inflamed Skin				
Topical Corticosteroids	Irritation, Pruritus	Daily to twice daily	A	Good
Topical Calcineurin Inhibitors	Refractory to topical steroids; thin-sensitive, steroid sparing skin	Twice daily	A	Good
Systemic Steroids	Acute flare	Short burst with tapering over few weeks	A	Fair
Systemic Calcineurin Inhibitors	Refractory	Not available	D	Poor
Cyclosporine	Refractory	Short course of 3–4 mg/kg daily	B	Good
Other Immunosuppressants	Refractory	Not available	B	Poor
Biologics	Refractory	Not available	I	Poor
Phototherapy	Refractory	Average 3 times per week	B	Fair
Infected Skin				
Bleach Baths	Reduce colonization	Several times weekly to daily	B	Poor
Mupirocin	Local infection	2–3 times daily for 5 days	A	Good
Gentian violet	Local infection	Not available	D	Fair
Chlorhexidine	Local infection	Not available	D	Fair
Oral Antibiotics	Widespread Infection	Depends on pathogen and appropriate antibiotic	A	Good
Antivirals	Herpes Simplex Infection	Topical: 6 times daily for 7 days; oral: dosing depends on antiviral agent used	A	Good
Antifungals	Candida or Dermatophyte Infection	Twice daily	A	Good

*Strength of recommendations is based on the U.S. Preventative Services Task Force (USPSTF) criteria for grading recommendations. The five classifications (A, B, D, I) reflect the strength of evidence and magnitude of net benefit.

A- Strongly recommends that clinicians provide [the service] to eligible patients.

B- No recommendation for or against routine provision of (the service).

D- Recommends against routinely providing (the service) to asymptomatic patients.

I- Insufficient evidence to recommend for or against routinely providing (the service).

**Level of Evidence is based on the USPSTF criteria for grading the quality of evidence for a service and consists of a 3-point scale (good, fair, poor).

Good: Evidence includes consistent results from well-designed, well-conducted studies in representative populations that directly assess effects on health outcomes.

Fair: Evidence is sufficient to determine effects on health outcomes, but the strength of the evidence is limited by the number, quality, or consistency of the individual studies, generalizability to routine practice, or indirect nature of the evidence on health outcomes.

Poor: Evidence is insufficient to assess the effects on health outcomes because of limited number or power of studies, important flaws in their design or conduct, gaps in the chain of evidence, or lack of information on important health outcomes.

symptoms of AD as both primary and adjunctive therapy for AD; however, no systematic review comparing their efficacies is available.^{63–68} In general, emollients have been

associated with few adverse events and are limited to a few reports of burning upon application.⁶⁹ Alternatively, medical devices, known as hydrogels, can also be used to retain

moisture and provide a mechanical barrier to irritants. These FDA-approved, prescriptive treatments, including MimyX cream[®],⁷⁰ EpiCeram[®]⁷¹ and Atopiclair Nonsteroidal Cream[®],⁷² are indicated to improve xerosis and manage the burning and itching associated with AD. In a recent clinical trial involving 113 children with moderate to severe AD, EpiCeram was shown to be comparable to mid-strength topical corticosteroid in improving xerosis and managing the burning and itching associated with AD.⁷³ Furthermore, these agents are not associated with any of the undesirable side effects and usage restrictions associated with topical steroids. Drugs with antihistaminic effects can be tried to suppress pruritus, prevent exacerbation caused by scratching and improve sleep (especially if sedating) in patients with AD, however placebo-controlled studies concerning their antipruritic effects show conflicting results.⁷⁴⁻⁷⁹ One explanation for these variations is that histamine is only one of several mediators of pruritus^{86,87} and many different nociceptive mechanisms are involved in AD.^{88,89}

Another explanation is that most of these studies are limited to investigation of the role of histamine H1 antihistamines in the treatment of pruritus. In a more recent study conducted by Reese, et al.⁹² histamine was shown to generate itch in mice via the H1, H4, and possibly H3 receptors. Interestingly, the histamine H2 receptor does not seem to be involved in pruritus as the H2 receptor agonist Dimaprit did not induce dose-dependent scratching, and the H2 antagonist Cimetidine did not significantly reduce histamine-induced scratching. To further investigate the relative contribution of the four known histamine receptors, Thurmond et al.⁹³ used selective antagonists in mice models and found the H4 receptor blockers most effective in inhibiting itch. Similarly, Wolfgang Bäumer et al.⁹⁴ found that compared to administering the H1 receptor antagonist Cetirizine alone, a combination of H1 and H4 receptor antagonists resulted in greater inhibition of scratching behavior associated with allergic dermatitis in mice. Although preliminary, these studies suggest a new strategy using H4, and possibly H3, receptor blockers to treat pruritus in AD. However, before any recommendations can be made, further research supporting their efficacies and safety in humans must be conducted.

As previously mentioned, patients with AD have an increased risk for cutaneous bacterial, viral, and fungal infections. These secondary infections exacerbate the disease and should be treated if suspected. Infection with *Staphylococcus aureus* (*S. aureus*) is most common and presents with honey-colored crusting, folliculitis, and pyoderma (Figure 13-5). Local infections can be treated with topical mupirocin (Bactroban[®]) applied 2–3 times daily for 5 days, while more extensive disease may require oral antibiotics.⁹⁵ In any case, all infections should be cultured and treated with the appropriate antimicrobial agent.

Patients with AD also show higher rates of *S. aureus* colonization (76–100%) compared to healthy control subjects (2–25%).^{96,97} For this reason, many researchers

FIGURE 13-5 Secondary Infection with *Staphylococcus aureus* is characterized by honey-colored, crusting, folliculitis and pyoderma.

have investigated the role of bacterial growth suppression in the treatment for AD. Although two reports suggest that topical antibiotic application to all atopic areas could improve clinical severity,^{98,99} more recent studies do not show any improvement.^{100,101} These studies also show that adjunctive application of topical mupirocin or fusidic acid to corticosteroid therapy does not decrease clinical severity of atopic lesions more significantly than topical corticosteroid administration alone. In contrast, gentian violet and chlorohemin have been found to decrease *S. aureus* density and improve AD.^{102,103} However, the use of either agent is generally limited by the former's cosmetic side-effects and the latter's link to irritant contact dermatitis when used extensively. Alternatively, chronic use of diluted bleach baths with intermittent intranasal application of mupirocin ointment have activity against *S. aureus*, including MRSA, and have been shown to significantly improve the severity of AD and reduce the frequency of skin infections.¹⁰⁴

Secondary infection with herpes simplex, known as eczema herpeticum, also occurs commonly and is characterized by vesicles, punched out erosions and hemorrhagic crusting (Figure 13-6). Patients should be treated immediately with oral antiviral therapy. Likewise, dermatophyte infections are seen more commonly in patients with AD and can be treated with standard regimens of topical or oral antifungals.

Topical corticosteroids are the mainstay of therapy for AD. The strength and vehicle of choice depend on the severity of the disease. Most trials of topical steroids are short in duration and fail to address how long the patient should continue therapy. In addressing the issue of frequency of application, two systematic reviews suggested once rather than twice daily treatment as the first step in the management of all patients with atopic dermatitis.^{63,105}

Commonly reported adverse effects of topical corticosteroid use include stinging, burning, contact dermatitis, pruritus, dryness, folliculitis, excess hair growth

FIGURE 13-6 Secondary infection with herpes simplex is characterized by vesicles, punched out erosions and hemorrhagic crusting.

and pigment alteration. More concerning adverse events include skin atrophy and suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Suppression of the HPA axis is rare and tends to occur in patients receiving potent topical preparations in combination with inhaled glucocorticoids for their concurrent asthma.^{106,107} Again, most studies have been too short to sufficiently address the risk of long-term use of topical steroids.

Moreover, there are no trials that compare all contenders for the most effective and safe topical corticosteroid. However, two newer topical corticosteroids, desonide gel (0.05%) and fluticasone propionate (0.05%), have emerged with treatment efficacies comparable to other topical corticosteroids associated with greater side effects.^{108,109} In addition, fluticasone propionate cream (0.05%) has a unique quality of not being associated with skin thinning, which may in part be caused by its minimal subcutaneous penetration, rapid metabolism and/or its high binding capacity for the glucocorticoid receptor.^{110,111}

Systemic corticosteroids are rarely used to treat AD long-term, but their short-term use to treat severe flare-ups is of common practice.¹¹² Two randomized-controlled trials have evaluated the efficacy and safety of systemic corticosteroids. The first study evaluated the administration of 4 weeks daily oral beclomethasone 0.8 mg/kg plus nasal beclomethasone 0.4 mg/kg to 26 children suffering refractory AD, and found a 22% reduction in disease severity and reported no adverse events.¹¹³ Similarly, the second study treated patients with flunisolide at age-adjusted doses for 2 weeks and showed an average 39% decrease in clinical severity, no relapses for 3 weeks after discontinuation of the medication, and no adverse events.¹¹⁴ Unfortunately, data from these trials is insufficient to draw any definite conclusions regarding the safety of systemic corticosteroids. Thus, most guidelines, including the 2006 Practical Allergy (PRACTALL) consensus group guidelines,¹¹⁵ agree that in the case of acute flares, patients might benefit from a short

course of systemic corticosteroids, but that long-term use and administration to children should be avoided.

As a second-line therapy, topical calcineurin inhibitors (tacrolimus and pimecrolimus) have been shown to be as effective as low potency topical steroids in the treatment of moderate-to-severe AD.^{116,117} Moreover, unlike topical corticosteroids, topical calcineurin inhibitors do not cause skin atrophy and are therefore particularly useful in patients with facial, neck, and skin fold involvement. Tacrolimus and pimecrolimus both work by inhibiting cytokine production. In addition, tacrolimus causes an alteration in the epidermal antigen-presenting dendritic cells that decreases immunologic responses to antigens.¹¹⁸ Studies comparing these two calcineurin inhibitors found that tacrolimus ointment may be more effective than pimecrolimus cream but that it may also cause greater local irritation.¹¹⁹

In 2006, the FDA issued a public health warning and labeling change for topical calcineurin inhibitors to inform patients and providers about their potential malignancy risk.¹²⁰ Although data from several case reports and animal studies suggested a possible link between these agents and different lymphomas and skin cancers, a recent propensity-score-matched cohort study found no increase in the incidence of lymphoma among topical pimecrolimus or topical tacrolimus users relative to corticosteroid users at an average of 1.3 years follow-up. This study is useful in that immunosuppression-related lymphoma typically develops within 2 years of exposure. Unfortunately, this study does not address the potential risk that may be associated with longer-term exposures to these drugs and fails to draw any firm conclusions about the pediatric populations. Likewise, another recent retrospective cohort observational study showed no increase in the overall cancer rate of topical calcineurin users versus nonusers, but did associate the use of topical tacrolimus with an increased risk of T-cell lymphoma.¹²¹ Without long-term studies fully evaluating the safety of these topical agents, the FDA recommends limiting their use to patients unresponsive to or intolerant of other treatments, and prohibits their use in children less than 2 years of age. Similarly, oral calcineurin inhibitors have been shown to be effective in refractory cases of AD but are generally avoided because of their potentially toxic side effect profiles.¹²³

Immunosuppressants (e.g., cyclosporine, methotrexate, azathioprine, and mycophenolate mofetil) are other systemic agents that can be used conservatively in the treatment of refractory disease. In evaluating the use of cyclosporine in the treatment of severe AD, a randomized, open-label, 12-month study showed that treatment at a starting dose of 3 mg/kg/day was efficacious, well tolerated, and associated with only a few side effects such as an increase in serum creatinine and diastolic blood pressure.¹²⁴ Other studies have shown that patients typically demonstrate a clinical response within 10–20 days after beginning treatment,^{125,126} and that in most patients treatment can be tapered slowly after 8 weeks.¹²⁷ However, in a

randomized comparison in 40 children, Harper et al. found that relative to multiple short-term (12 weeks) courses of therapy, continuous therapy with cyclosporine for 1 year resulted in more consistent control of symptoms and more significant improvement of quality of life from baseline.¹²⁸ Based on these and similar studies, the American Academy of Dermatology recommends the use of cyclosporine for the treatment of severe and refractory AD even though it is not currently approved by the FDA for this indication.¹²⁹

Methotrexate, a very effective agent used in the treatment of chronic inflammatory conditions such as psoriasis and rheumatoid arthritis, has also been reported to be effective in the treatment of AD by a number of anecdotal reports and small retrospective studies.¹³⁰⁻¹³² In a three year prospective study conducted by Bergman et al. nine patients unresponsive to prolonged therapy with oral antihistamines and local corticosteroids were administered low dose (10–20 mg) methotrexate therapy once a week along with folic acid supplements. Of the nine participants, six patients achieved complete remission after 3 months of therapy and three showed significant improvement. Initial response was noted after 3 to 7 weeks and no serious adverse events were noted during treatment.¹³³

In addition, data from case reports, retrospective studies and a few small clinical trials support the use of mycophenolate mofetil, a purine biosynthesis inhibitor indicated for the prophylaxis of organ rejection, and azathioprine, a DNA and RNA biosynthesis inhibitor with immunosuppressant and cytotoxic actions, in refractory cases of AD.¹³⁴⁻¹³⁹ Like oral calcineurin inhibitors, systemic immunosuppressants can be used in cases of severe and refractory AD, but their long-term use should be avoided.

More recently, a few case reports and trials have documented the use of biologics in the treatment of AD. Omalizumab, rituximab, infliximab, alefacept, etanercept, efalizumab, interferon gamma and mepolizumab have all been administered to patients with AD but have shown inconsistent results. Of note, efalizumab was taken off the market because of reports associating its use with

progressive multifocal leukoencephalopathy. Given the side effect profiles of the remaining drugs, further studies are necessary before any of them can be routinely recommended for the treatment of AD.¹⁴¹⁻¹⁵⁶

Another second-line therapy is phototherapy with broadband UVB, UVA, narrowband UVB, or psoralen plus UVA (PUVA).¹⁵⁷⁻¹⁵⁹ Some studies suggest that narrowband UVB and UVA-1 may be more efficacious than the other modalities.¹⁶⁰⁻¹⁶² In a study of thirty-two patients receiving UVA1 irradiation 5 times per week for 3 consecutive weeks, Ring et al. validated the efficacy of UVA-1 phototherapy in decreasing disease severity but concluded that the effectiveness was short-term and unsustainable three months after discontinuation of treatment.¹⁶³ Furthermore, the general use of phototherapy is limited to severe and refractory cases because of its potential association with an increased risk of skin cancer.¹⁶⁴⁻¹⁷⁶

PROGNOSIS

Approximately 60% of childhood patients are disease free by early adolescence, however many of these cases are likely to see recurrence of their disease, often in the form of hand eczema, in adulthood.¹⁷⁷ Factors most consistently predicting persistent atopic dermatitis include early onset, severe widespread disease in infancy, concomitant asthma or hay fever and a family history of atopic dermatitis. Psychosocial factors also influence the prognosis of atopic disorder and should therefore be addressed in the management of the disease.³⁷

CONCLUSION

AD is a common inflammatory skin disease that negatively impacts the quality of life of those affected and produces a significant economic burden on society. This review has attempted to provide key features of our understanding of the etiology, diagnosis, and treatment of atopic dermatitis (Table 13-3). AD remains primarily a clinically based

What We Know

- Atopic Dermatitis (AD) is a common inflammatory skin disease that frequently follows a chronic relapsing course.
- It negatively impacts quality of life and produces a significant economic burden.
- As part of the “atopic triad”, AD often occurs in patients with a personal or family history of asthma or atopic rhinitis.
- There is no consensus on the etiology of AD, but it likely involves a relationship between skin barrier dysfunction and immune dysregulation caused by both genetic and environmental factors.
- Its presentations are variable and influenced by differences in age, genetic background, and environmental factors.

- With no specific diagnostic tests available, the diagnosis of AD is clinical.
- Topical corticosteroids are generally considered first line treatment of mild to moderate AD; there is only a partial consensus on the treatment of severe or recalcitrant AD.
- Patients with AD are known to be more susceptible to microbial infections, particularly with *S. aureus*, and should be treated accordingly.
- Preventive measures are recommended and include skin hydration as well as avoidance of triggers and exacerbating factors.

Treatment(s)		
Publication	Number of studies	Finding(s)
Fleischer AB, Boguniewicz M. An approach to pruritus in atopic dermatitis: a critical systematic review of the tacrolimus ointment literature. <i>J Drugs Dermatol.</i> 2010;9(5):488–98.	52	(1) Tacrolimus is more effective at reducing pruritus when compared with pimecrolimus and some topical corticosteroids. (2) It is safer for long term use when compared with topical corticosteroids.
El-Batawy MM, Bosseila MA, Mashaly HM, et al. Topical calcineurin inhibitors in atopic dermatitis: a systematic review and meta-analysis. <i>J Dermatolog Sci.</i> 2009;54(2):76–87.	19	(1) Topical calcineurin inhibitors (TCI) in AD are more effective than placebo. (2) Although less effective than topical corticosteroids (TCS), pimecrolimus has its value in long-term maintenance and as a steroid-sparing agent. (3) In treatment of moderate to severe AD, topical tacrolimus is as effective as moderately potent TCs, and more effective than mild preparations. (4) Chronic AD lesions of the face and flexures are the most justified indication for topical calcineurin inhibitors.
Meduri NB, Vandergriff T, Rasmussen H, et al. Phototherapy in the management of atopic dermatitis: a systematic review. <i>Photodermatology, Photoimmunology & Photomedicine.</i> 2007;23(4):106–12.	9	(1) Phototherapy with medium-dose (50 J/cm ²) UVA1, if available, should be used to control acute flares of AD. (2) UVB modalities, specifically narrow-band UVB, should be used for the management of chronic AD.
Chida Y, Steptoe A, Hirakawa N, et al. The effects of psychologic intervention on atopic dermatitis. A systematic review and meta-analysis. <i>Int Arch Allergy and Immunol.</i> 2007;144(1):1–9	8	(1) Meta-analysis revealed that psychologic interventions had a significant ameliorating effect on eczema severity, itching intensity and scratching in atopic dermatitis patients.
Schmitt J, Schmitt N, Meurer M. Cyclosporin in the treatment of patients with atopic eczema - a systematic review and meta-analysis. <i>J Eur Acad Dermatol Venereol.</i> 2007;21(5):606–19.	15	(1) Effectiveness of cyclosporin is similar in adults and children, but tolerability might be better in children. (2) As data to adequately evaluate the long-term effectiveness and safety of cyclosporin in patients with atopic eczema are unavailable, long-term registries are encouraged.
Schmitt J, Schkel K, Schmitt N, et al. Systemic treatment of severe atopic eczema: a systematic review. <i>Acta Dermato-Venereologica.</i> 2007;87(2):100–11.	27	(1) Cyclosporine is recommended as first option for patients with atopic eczema refractory to conventional treatment. (2) Evidence from randomized controlled trials also exists for interferon-? and azathioprine. (3) Systemic glucocorticosteroids have not been assessed adequately in studies. (4) Mycophenolate mofetil showed effectiveness in 2 small-uncontrolled studies. (5) Intravenous immunoglobulins and infliximab are not recommended based on published data.
Callen J, Chamlin S, Eichenfield L F, et al. A systematic review of the safety of topical therapies for atopic dermatitis. <i>Br J Dermatol.</i> 2007;156(2):203–21.	61	Physiological changes appear to be uncommon and systemic complications rare and have only been found with use of topical corticosteroids.
Langan SM, Thomas KS, Williams HC. What is meant by a “flare” in atopic dermatitis? A systematic review and proposal. <i>Arch Dermatol.</i> 2006;142(9):1190–6.	15	A flare of AD is defined as an episode requiring escalation of treatment or seeking additional medical advice. Consideration should also be given to totally controlled weeks and well-controlled weeks to assess overall disease activity in patients with AD.
Garside R, Stein K, Castelnovo E, et al. The effectiveness and cost-effectiveness of pimecrolimus and tacrolimus for atopic eczema: a systematic review and economic evaluation. <i>Health Technology Assessment.</i> 2005;9(29):iii, xi-xiii,1.	18	(1) Pimecrolimus is more effective than placebo treatment in controlling mild to moderate atopic eczema. (2) Tacrolimus is more effective than the placebo treatment and mild topical corticosteroids. (3) No significant difference shown when compared to topical corticosteroids. (4) Short-term adverse effects with both immunosuppressants are relatively common, but appear to be mild. (5) Experience of long-term use of the agents is lacking so the risk of rare but serious adverse effects remains unknown. (6) No conclusions can be confidently drawn about the cost-effectiveness of pimecrolimus or tacrolimus compared to active topical corticosteroid comparators.

Treatment(s)		
Publication	Number of studies	Finding(s)
Ashcroft DM, Dimmock P, Garside R, et al. Efficacy and tolerability of topical pimecrolimus and tacrolimus in the treatment of atopic dermatitis: meta-analysis of randomized-controlled trials. <i>BMJ</i> . 2005;330(7490):516.	25	(1) Both topical pimecrolimus and topical tacrolimus are more effective than placebo treatments for atopic dermatitis, but in the absence of studies that show long-term safety gains, any advantage over topical corticosteroids is unclear. (2) Topical tacrolimus is similar to potent topical corticosteroids and may have a place for long term use in patients with resistant atopic dermatitis on sites where side effects from topical corticosteroids might develop quickly.
Green C, Colquitt JL, Kirby J, et al. Topical corticosteroids for atopic eczema: clinical and cost effectiveness of once-daily vs. more frequent use. <i>Br J Dermatol</i> . 2005;152(1):130–41.	10	(1) No clear differences in outcomes between once-daily and more frequent application of topical corticosteroids.
Green C, Colquitt JL, Kirby J, et al. Clinical and cost-effectiveness of once-daily versus more frequent use of same potency topical corticosteroids for atopic eczema: a systematic review and economic evaluation. <i>Health Technology Assessment</i> . 2004;8(47):1–120.	10	(1) Clinical effectiveness of once-daily and more frequent application of potent topical corticosteroids is very similar, but it does not offer a basis for favoring either option. (2) The cost-effectiveness of once daily versus more frequent use will depend on the generalizability of the findings to the specific treatment decision and the relative product prices.
Hoare C, Li Wan Po A, Williams, H. Systematic review of treatments for atopic eczema. <i>Health Technology Assessment</i> . 2000;4(37):1–191.	272	(2) There was reasonable RCT evidence to support the use of oral cyclosporin, topical corticosteroids, psychologic approaches and ultraviolet light therapy. (2)There was insufficient evidence to make recommendations on maternal allergen avoidance for disease prevention, oral antihistamines, Chinese herbs, dietary restriction in established atopic eczema, homeopathy, house dust mite reduction, massage therapy, hypnotherapy, evening primrose oil, emollients, topical coal tar and topical doxepin. (3) There was no RCT evidence to support any clear clinical benefit on the use of avoidance of enzyme washing powders, cotton clothing as opposed to soft-weave synthetics, biofeedback, twice-daily as opposed to once-daily topical corticosteroids, topical antibiotic/steroid combinations versus topical steroids alone and antiseptic bath additives. (4) There was complete absence of RCT evidence on short bursts of potent versus longer-term weaker topical steroids, dilution of topical corticosteroids, oral prednisolone and azathioprine, salt baths, or impregnated bandages, wet-wrap bandages, water softening devices, allergy testing, and different approaches to organization of care.
Prevention

Partially hydrolyzed 100% whey protein infant formula and atopic dermatitis risk reduction: a systematic review of the literature. <i>Nutrition Reviews</i> . 2010;68(4):232–45.	18	All studies reported a reduced incidence of AD was observed in the PHF-W group compared with the intact protein cow's milk group.

Prevention		
Publication	Number of studies	Finding(s)
Kremmyda L, Vlachava M, Noakes PS, et al. Atopy Risk in Infants and Children in Relation to Early Exposure to Fish, Oily Fish, or Long-Chain Omega-3 Fatty Acids: A Systematic Review. <i>Clin Rev in Allergy & Immunol.</i> 2009.	29	(1) Majority of studies showed a protective effect of fish intake during infancy and childhood on atopic outcomes. (2) The provision of fish oil during pregnancy may reduce sensitization to common food allergens and reduce prevalence and severity of atopic dermatitis in the first year of life, with a possible persistence until adolescence. (3) Supplementation in infancy may decrease the risk of developing some manifestations of allergic disease, but this benefit may not persist as other factors come into play. (4) It is not clear whether fish oil can be used to treat children with asthma.
Anandan C, Nurmatov U, Sheikh, A. Omega 3 and 6 oils for primary prevention of allergic disease: systematic review and meta-analysis. <i>Allergy.</i> 2009;64(6):840–8.	10	Supplementation with omega 3 and omega 6 oils is unlikely to play an important role as a strategy for the primary prevention of sensitization or allergic disease.
Yang YW, Tsai CL, Lu, CY. Exclusive breastfeeding and incident atopic dermatitis in childhood: a systematic review and meta-analysis of prospective cohort studies. <i>Br J Dermatol.</i> 2009;161(2):373–83.	21	No strong evidence of a protective effect of exclusive breastfeeding for at least 3 months against AD, even among children with a positive family history.
Bath-Hextall F, Delamere FM, Williams H C. Dietary exclusions for improving established atopic eczema in adults and children: systematic review. <i>Allergy.</i> 2009;64(2):258–64.	9	(1) No benefit of an egg- and milk-free diet in unselected participants with atopic eczema. (2) No evidence of benefit in the use of an elemental or few-foods diet in unselected cases of atopic eczema. (3) There may be some benefit in using an egg-free diet in infants with suspected egg allergy who have positive specific IgE to eggs.
Chida Y, Hamer M, Steptoe A. A bidirectional relationship between psychosocial factors and atopic disorders: a systematic review and meta-analysis. <i>Psychosomatic Med.</i> 2008;70(1):102–16.	43	(1) A robust relationship between psychosocial factors and atopic disorders exists. (2) Findings support the use of psychological in addition to conventional physical and pharmacologic interventions, in the successful prevention and management of atopic disorders.
Gdalevich M, Mimouni D, David M, et al. Breast-feeding and the onset of atopic dermatitis in childhood: a systematic review and meta-analysis of prospective studies. <i>J Am Acad Dermatol.</i> 2001;45(4):520–7.	18	(1) Exclusive breast-feeding during the first 3 months of life is associated with lower incidence rates of atopic dermatitis during childhood in children with a family history of atopy. (2) This effect is lessened in the general population and negligible in children without first-order atopic relatives.
Pathogenesis

Diagnosis		
Publication	Number of studies	Finding(s)
Brenninkmeijer EEA, Schram ME, Leeflang MMG, et al. Diagnostic criteria for atopic dermatitis: a systematic review. <i>Br J Dermatol.</i> 2008;158(4):754–65.	27	(1) The U.K. diagnostic criteria are the most extensively validated. (2) Improvement of methodologic design for validation studies and uniformity in well-validated and applicable diagnostic criteria are needed to improve future intervention studies and to compare study results.
Outcome Measure		
Schmitt J, Langan S, Williams HC. What are the best outcome measurements for atopic eczema? A systematic review. <i>J Allergy Clin Immunol.</i> 2007;120(6):1389–98.	20	(1) There is adequate construct validity for 3 measurements (Severity Scoring of Atopic Dermatitis index [SCORAD], Eczema Area and Severity Index [EASI], and Three Item Severity Score), adequate internal consistency of 1 scale (Patient-oriented Eczema Measure [POEM]), adequate interobserver reliability of 5 measurements (Basic Clinical Scoring System; Nottingham Eczema Severity Score; Objective Severity Assessment of Atopic Dermatitis; Six Area, Six Sign Atopic Dermatitis severity score; and SCORAD), adequate test-retest reliability of 1 scale (POEM), and adequate sensitivity to change of 3 measurements (EASI, SCORAD, and Investigators' Global Atopic Dermatitis Assessment). (2) Most outcome measurements have adequate content validity, as assessed by patients and experts. (3) Only SCORAD, EASI, and POEM have been tested sufficiently on time to perform the assessment and performed adequately.
Terminology		
Langan SM, Thomas KS, Williams HC. What is meant by a “flare” in atopic dermatitis? A systematic review and proposal. <i>Arch Dermatol.</i> 2006;142(9):1190–6.	15	A flare of AD is defined as an episode requiring escalation of treatment or seeking additional medical advice. Consideration should also be given to totally controlled weeks and well-controlled weeks to assess overall disease activity in patients with AD.

diagnosis. Fortunately, with the use of currently available treatment options, most cases of AD can be successfully controlled. In time, an improved understanding of the genetic and immunologic basis of AD will provide further opportunities for the development of more effective therapies.

Treatment of Melasma

14

Yuri T. Jadotte, M.D., and Robert A. Schwartz, M.D., M.P.H.

SUMMARY

Melasma is one of the most common hyperpigmentation disorders, primarily affecting women of reproductive age. It tends to be more prominent in individuals with darker skin tones, typically in a symmetric pattern on the face and neck. The pathogenesis is still unclear. Possible etiologic agents include UV radiation, hormonal changes related to pregnancy or thyroid abnormalities, as well as antiseizure and photosensitive medications. Increased melanocyte number and/or excess melanin production may be involved in the pathophysiology of this disorder. There are many therapies for melasma, including hypopigmenting agents, chemical peels, dermabrasion, and various types of lasers. Preventative modalities should also be considered in the management of this condition, such as minimization of UV exposure and avoidance of certain drugs when possible. Elucidation of the pathogenesis of this condition may lead to better, more specific treatments.

SEARCH METHODOLOGY

We performed a PubMed search for all articles relating to “melasma” and “chloasma” and found 75 articles of particular interest. We have also evaluated many other articles and book chapters as well. Pertinent evidence-based information relevant to the epidemiology, etiology, diagnosis, and therapeutic management of the disorder were selected and included in this chapter.

INTRODUCTION

The word melasma is derived from the Greek word “melas”, which means “black spot or color”. It is also commonly known as “chloasma”, and “the mask of pregnancy”, because of its tendency to occur during pregnancy. These hyperpigmented patches typically appear on the face and neck, but may occur in other locations as well, such as the upper limbs. The development of melasma is often associated with known etiologic factors, although some cases may be idiopathic. Melasma is primarily a cosmetic disorder. However, given its potential psychologic repercussions and impact on quality of life, it should be appropriately treated at the patient’s request.

EPIDEMIOLOGY

Approximately 5-6 million women are affected by melasma in the United States.¹ Ninety percent of melasma cases are seen in women, particularly in individuals with darker skin types.² Melasma is thought to be more prevalent among Latinos.³ Incidences as high as 80% have been reported in Hispanic women.⁴ It appears that there is a high incidence of melasma in individuals with skin type IV to VI, particularly those of South American, Mediterranean, Asian, and African American descent.⁵⁻⁸ Melasma may be more apparent in those individuals, but people of all races can be affected.¹ It occurs in approximately 50-70% of pregnant women, and sporadically in approximately 10% of men.^{3,9,10}

ETIOLOGY AND PATHOGENESIS

Many etiologic agents have been identified in melasma. However, in most cases occurring in men and in one-third of cases occurring in women, no known causes have been identified.⁵ UV radiation, female hormonal activity, endocrine organ dysfunction including ovarian, testicular and thyroid abnormalities, family history, cosmetic products, photo-sensitive and antiseizure medications make up the majority of the known associated risk factors.^{5,11,12} Although the pathogenesis remains unclear, the hyperpigmentation seen in this condition is caused by an increased amount of melanin in the skin. This occurs either via melanotic hyperpigmentation, in which there is increased stimulation of melanogenesis, or melanocytic hyperpigmentation, in which there is an increase in the number of melanocytes.⁵ The pigment’s distribution pattern, whether in the epidermis, dermis or both, plays a significant role in the clinical appearance of melasma.⁵ The most strongly associated risk factor is *UV radiation*.¹¹ In a study done in Puerto Rico, clinical onset and exacerbation were most prominent during the summer with increasing sun exposure, with significant improvement occurring during the winter.¹³ The etiologic role of UV radiation is also well supported by histologic evidence of solar elastosis.¹⁴ UV radiation appears to cause hyperpigmentation via two mechanisms: increasing the number of melanocytes, and increasing melanin production. UV radiation leads

to increased levels of dermal stem cell factor, the latter of which has been shown to cause *in vitro* melanocyte proliferation and may be over expressed in melasma.^{15,16} UV radiation is also known to stimulate excess melanin production. In particular, UVB causes a greater increase in melanin production in more darkly pigmented melanocytes, which offers a possible explanation for the greater prevalence of melasma in darker skinned patients.^{17,18} A possible mechanism is via UVB-induced stimulation of the alpha-melanocyte stimulating hormone (α -MSH) and adrenocorticotropic hormone (ACTH). Both are derived from propiomelanocortin (POMC) and induce cyclic AMP production, which in turn stimulates tyrosinase activity, thereby increasing melanin production.^{19–21}

Female *hormonal activity* is another significant risk factor. This idea is supported by the fact that melasma is much more common in women, and that it tends to occur during their reproductive years. The presence of melasma in up to 75% of pregnancies, the period of greatest hormonal expression, further supports a hormonal etiology.²² There is additional evidence in support of hormonal activity as an etiology for melasma. Upregulation of estrogen receptors in affected skin in melasma has recently been demonstrated.²³ Women taking oral contraceptive pills have a greater incidence of melasma.²⁴ Combined estrogen and progesterone hormone replacement therapy in post-menopausal women with osteoporosis is associated with melasma.^{25,26} Melasma has not been reported in women who are on estrogen-only regimens.⁸ There is an association between androgen replacement therapy and melasma in men.²⁷ Although the pathogenic mechanism of sex steroids in melasma remains unclear, studies have shown that both alpha and beta-estradiols stimulate tyrosinase activity as well as melanin extrusion in melanocytes.^{28,29} *Endocrine organ dysfunction* may play a role in melasma. There is an association between increased LH levels and decreased estrogen levels identified in nine nulliparous women with idiopathic melasma.³⁰ Similarly, another study in men with idiopathic melasma documented increased LH levels as well.³¹ One study showed a four-fold difference in the prevalence of melasma between patients with thyroid abnormalities and the control group.³² *Family history* is also a significant risk factor. Between 30–70% of patients with melasma report a positive family history.^{9,10,33} A study on one set of identical twins showed that both developed melasma, while other siblings living under similar conditions did not, lending further support for genetics as a risk factor for melasma.³⁴

DIAGNOSIS

Melasma should be distinguished from other disorders of hyperpigmentation. This is especially important for potentially disfiguring or malignant disorders such as melanoma. Table 14-1 offers a differential diagnosis. Melasma is a clinical diagnosis that may be supported with histologic

TABLE 14-1—Differential Diagnosis of Melasma

Tinea versicolor

evidence if necessary. On physical examination, melasma typically appears as one of three clinical patterns: centrofacial, malar and mandibular.³⁵ Rarely, it may appear on the upper extremities.^{8,25,26,36} The macules and patches are generally symmetrical in appearance, but may have irregular borders and a blotchy color distribution.^{37,38} There are three histologic patterns: epidermal, dermal, and mixed.¹³ The histologic type correlates well with the clinical appearance.^{13,18} Epidermal melasma appears light brown, while dermal melasma appears bluish grey because of the Tyndall effect. Enhanced color contrast is seen with Wood's lamp examination in areas of epidermal melasma, which may serve as a screening method for the three histologic types and may help guide treatment selection.

THERAPEUTIC MANAGEMENT

What Types of Preventative Modalities Are Available for Melasma?

An essential and effective preventative modality for melasma is protection from UV radiation. Broad-spectrum sunscreens with both UVA and UVB protection are recommended. Sun blocks may also be used. Examples include micronized zinc oxide and titanium oxide applications. The new general guidelines from the American Academy of Dermatology recommending the use of SPF 30 instead of SPF 15 should be followed and may provide some additional protection from this disorder, as well as others related to actinic damage. Patients may also consider other UV protective measures, such as wearing wide-brimmed hats during the day to protect the face from excessive sunlight. This is especially important since the face is the most commonly involved location for melasma. Logically, other preventative methods should focus on a reduction of exposure to other potential etiologic agents, such as oral contraceptive pills, cosmetics and phototoxic agents, with complete cessation of the offending agent where possible. However, this may not always be feasible, such as in the case of pregnancy. Therefore, a thorough discussion of personal costs versus benefits may be undertaken on a case-by-case basis between the physician and patient.

What Are the Current Treatment Modalities for Melasma?

Current treatment modalities for melasma can be broadly categorized into two groups based on their mechanism of action: those that disrupt the biochemical and physiologic pathways that lead to normal melanin expression in the skin, and those that physically disrupt the different layers of the skin. The first group consists of the topical hypopigmenting agents, which can be sub-classified based on their particular mechanism of action. Some inhibit the biochemical formation of melanin, such as hydroquinone, azelaic acid, kojic acid, and ascorbic acid, while others interfere with its physiologic distribution or expression in the skin, and include tretinoin, glycolic acid, liquiritin, and N-acetyl-4-s-cysteaminylphenol (NACP). Both achieve the same clinical effect of hypopigmentation. Physically disruptive agents induce local destruction of cells and rely on the skin's regenerative properties to achieve their clinical effects. They include chemical peels, lasers, dermabrasion, and photodynamic therapy. Figure 14-1 illustrates the site of action of the topical hypopigmenting agents as well as the physically disruptive modalities.

Hydroquinone is one of the most effective treatments for melasma, and is a tyrosinase inhibitor.³⁸ Application of a 4% solution of hydroquinone is considered the gold

standard, although 2-4% solutions are also used.³⁹ As the concentration increases, the effectiveness of the drug also increases, while the side effect profile simultaneously worsens. Exogenous ochronosis, contact dermatitis, and adjacent hypopigmentation are known side effects.^{40,41} 4-6 weeks of therapy may be necessary before a clinical response is seen.⁴ The use of hydroquinone is currently a topic of controversy in the United States, particularly since it has been banned in some parts of the world, such as the European and Japanese markets.^{42,43} The outcome of this debate remains to be seen, but has spurred interest in developing other effective hypopigmenting agents.⁴² Azelaic acid is also a tyrosinase inhibitor, originally isolated from *Pityrosporum ovale*.⁴⁴ 20% azelaic acid may be more effective than 2% hydroquinone.⁴⁵ Kojic acid is another fungal metabolites isolated from *Aspergillus oryzae* that also inhibits tyrosinase.⁴⁶ Ascorbic acid is thought to block melanin synthesis by inhibition of tyrosinase. 5% ascorbic acid has been found to be more tolerable than 4% hydroquinone, and although less effective, may potentially serve as an alternative treatment.⁴⁷

Tretinoin increases keratinocyte proliferation, thereby accelerating epidermal cell turnover and regeneration, and decreasing melanin accumulation.⁴⁸ It is known to be effective in lightening actinic macules.⁴⁹ Studies using a 0.1% solution of tretinoin have shown that significant clinical

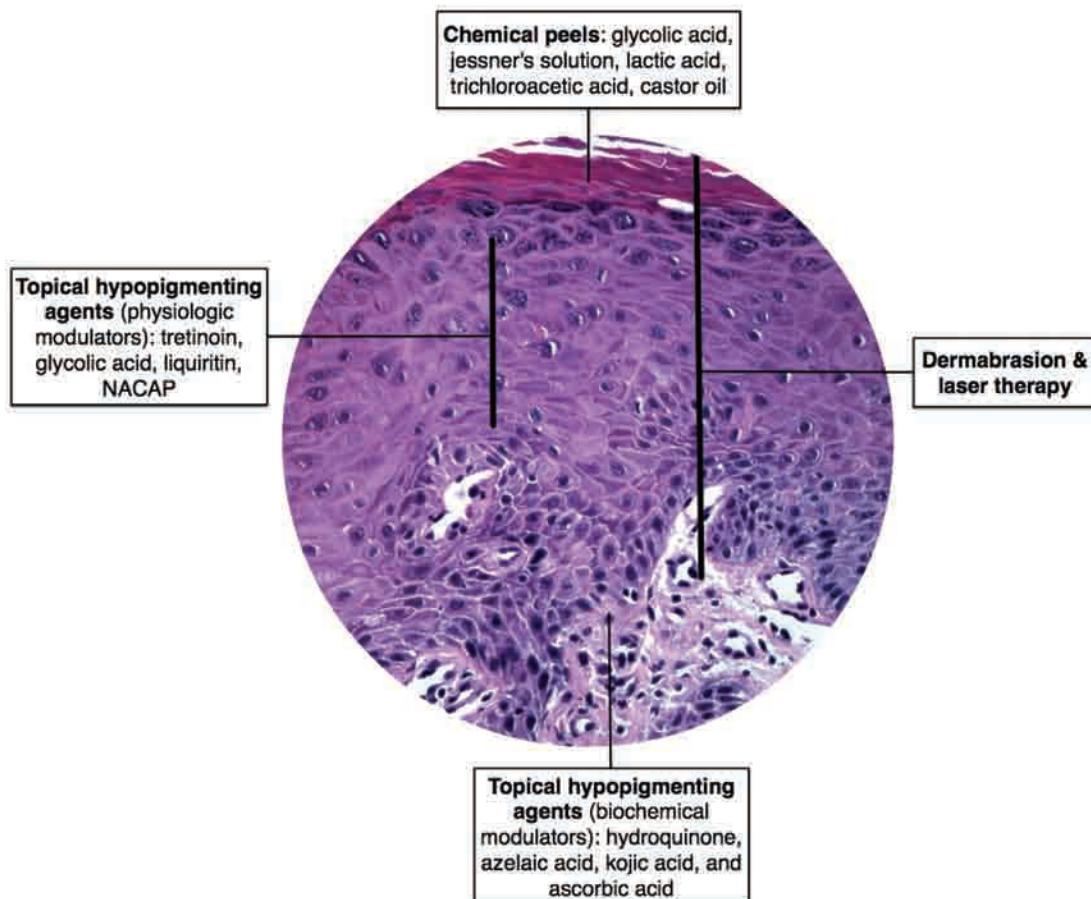

FIGURE 14-1 Site of action of therapeutic modalities for melasma.

improvements may take up to 24-40 weeks.^{50,51} Glycolic acid disperses melanin in the basal layer, increases dermal collagen synthesis, and stimulates epidermal cell lysis.⁵² Liquiritin, a liquorice extract, is also thought to dissipate melanin and can be used as a topical cream with minimal side effects.⁵³ N-acetyl-4-s-cysteamylphenol (NACP) decreases melanosomal transfer to keratinocytes, as well as the number of functioning melanocytes.

Physically disruptive agents tend to be useful in the treatment of recalcitrant melasma. *Chemical peels* induce skin exfoliation and subsequent revitalization. Glycolic acid peels are the most commonly used. A small study has shown that 1% tretinoin may be an effective and well-tolerated chemical peel.⁵⁴ Many other peeling agents are available, including Jessner's solution, salicylic acid, kojic acid, phenol-castor oil, lactic acid, and trichloroacetic acid.^{40,54,55} *Lasers* are primarily used for dermal melasma given its resistance to topical hypopigmenting agents. Q-switched lasers have been shown to effectively improve melasma.⁵⁶ Fractional laser therapy or photothermolysis causes microscopic zones of thermal damage in the epidermis and dermis, thereby reducing healing time when compared to other laser therapies. It is effective for resistant cases of melasma and can be safely used in dark-skinned patients.⁵⁷ A small pilot study reports 75-100% clinical resolution in 60% of patients.⁵⁸ *Superficial dermabrasion* physically disrupts the epidermis and dermis, and appears to have good long-term results. In one study, 97% of patients had no recurrence of melasma after 5 years post-treatment.⁵⁹ Side effects may include pruritus, milia, hypertrophic scars and permanent hypopigmentation.⁵⁹ Microdermabrasion may also offer some improvement.⁶⁰ Newer modalities for melasma include photodynamic therapy with aminolevulinic acid, and intralesional injection of tranexamic acid.^{61,62}

What's the Evidence for Combination Therapies?

Combination therapies do offer significant benefits when compared to monotherapy with a primary agent. In particular, many therapies have been tested as adjuncts to hydroquinone. For example, glycolic acid can hasten improvement and may be useful as an adjunct to topical hypopigmenting agents.^{63,64} Glycolic acid achieves this effect by thinning the stratum corneum and enhancing the penetration of other medications such as hydroquinone. One study showed significant improvement of melasma when 10% glycolic acid was added to 4% hydroquinone, vitamin C, E and sunscreens.⁶⁵ Kojic acid also appears useful when used in combination therapies. Clinical improvement increased from 45% to 60% when 2% kojic acid was added to a solution of 2% hydroquinone and 10% glycolic acid.⁴⁶ Sequential addition of corticosteroids after monotherapy with 20% azelaic acid showed earlier clinical improvement when compared to monotherapy with 20% azelaic acid.⁶⁶

Triple therapies, combining hydroquinone, tretinoin and a corticosteroid, are increasingly being employed, and are often considered first line therapy.^{35,40} Tri-Luma is a standard triple therapy containing 4% hydroquinone, 0.05% tretinoin, and 0.01% flutinolone. This triple combination has increased efficacy in facial melasma when compared to any combination of two components;⁶⁷ another study showed decreased severity of melasma in all skin types and races when this triple therapy was incorporated into a hydrophilic cream.⁶⁸ It is important to thoroughly discuss the risks and benefits of hydroquinone-based products with patients, given the current controversy surrounding these agents. A study on double therapy with tretinoin and mequinol showed equal effectiveness compared to 3% hydroquinone.⁶⁹ Two studies testing a combination Q-switched alexandrite laser (QSAL) and pulsed CO₂ laser produced better results than monotherapy with QSAL. The treatment options for melasma must be carefully selected for the appropriate clinical scenario. Figure 14-2 can serve as a summary of therapeutic options as well as a suggested management scheme.

What is the Prognosis for Melasma?

Given that melasma is primarily a cosmetic disorder with no significant systemic consequences, an evaluation of prognosis essentially revolves around the patient's self-perception of quality of life. We have identified two areas of importance to the clinical course or prognosis of melasma: the effect of the presence of risk factors such as oral contraceptives and pregnancy, and the impact of treatment choice.

The prognosis for melasma varies depending on the risk factors present in the patient. Similar to many other physiologic changes of pregnancy, melasma of pregnancy may undergo spontaneous remission within a few months after delivery.⁷⁰ However, melasma of pregnancy may persist postpartum in 9-30% of patients.^{22,71} One study suggests that melasma of pregnancy may recur in 7.6% of cases, even after postpartum remission from the first pregnancy. Melasma of pregnancy also presents a special challenge, given that many drugs have not been proven safe for use in pregnant women. Therefore, treatment is usually deferred in those patients. Melasma related to oral contraceptive use may resolve with cessation of the offending agent, although remission may be slow and incomplete.³⁷ Patient should thus be advised of this possibility prior to starting oral contraceptive therapy.

Prognosis also varies depending on the histologic type of melasma and whether or not the appropriate treatment is used. Epidermal melasma has a good prognosis when treated with topical hypopigmenting agents. This is good news, given that it appears to be the more common histologic subtype. One study found that this subtype was present in 69.2% of pregnant patients.⁷¹ Another study found epidermal melasma in 48.8% of cases.⁷² Dermal melasma, on the other hand, is very resistant

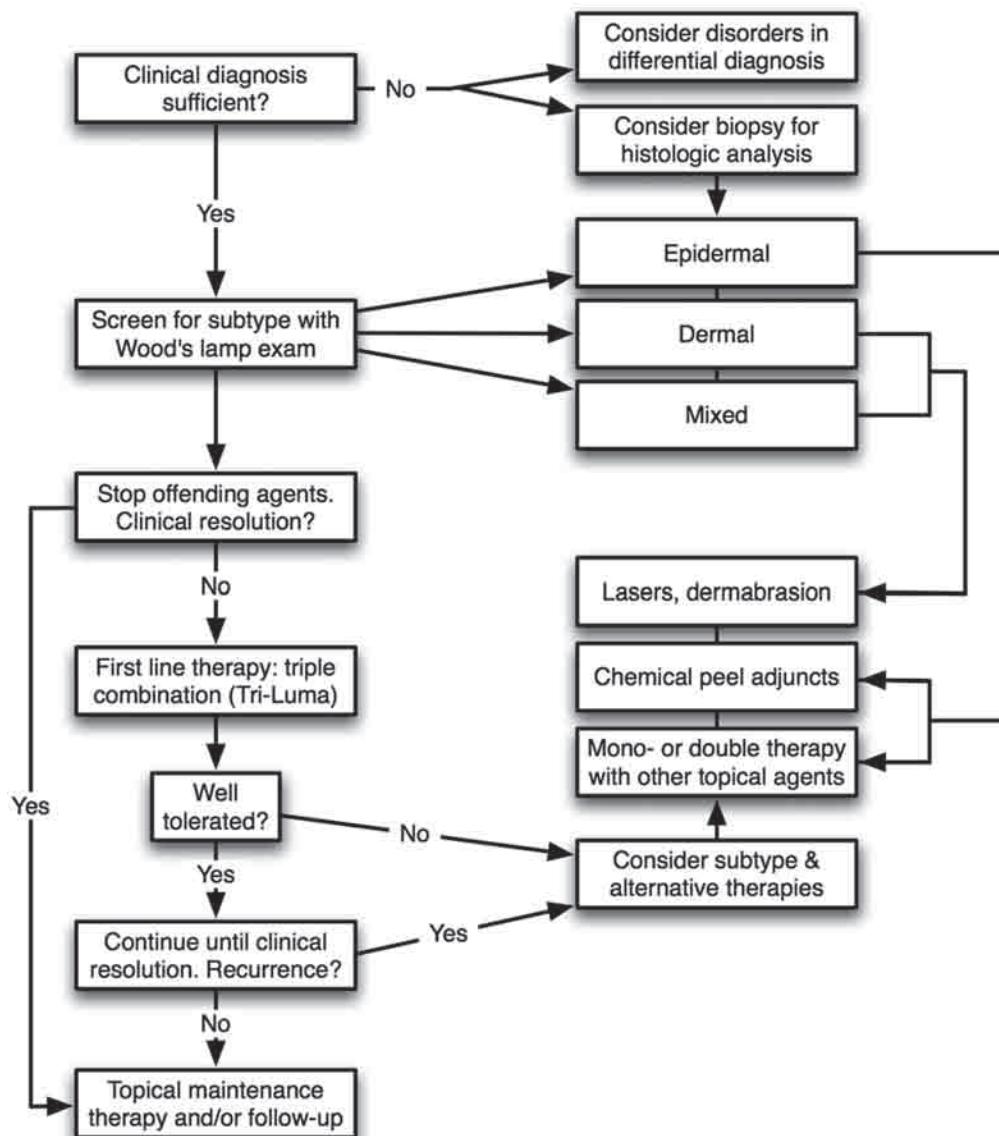

FIGURE 14-2 Suggested management scheme & therapeutic modalities.

to topical agents. Dermabrasion or lasers may be required for treatment of this type of melasma.³⁷ As expected, mixed type melasma requires a diversified approach to treatment, including both topical hypopigmenting agents and more invasive treatments such as lasers for clinical resolution.³⁸

What is the Impact of Melasma and its Effect on the Patient's Quality of Life?

Melasma can have a significant effect on the patient's quality of life, because of the psychologic impact of the disorder on self-perception. This has been demonstrated through the establishment of the Melasma Quality of Life Scale (MELASQOL) and its various adaptations.^{3,6,73} Studies have found minimal correlations between disease severity and quality of life. In other words, objective disease severity as assessed by a physician, using tools such as the melasma area and severity index (MASI), may not always coincide with the patient's perception of severity.^{6,74} This

may lead to under-diagnosis and possibly under-treatment of this disorder.⁴ The MELASQOL score focuses more on the psychologic impact of melasma. Disease severity strongly influences the aggressiveness of treatment choice, which in turn may affect the course and prognosis. Social life, recreation and leisure, and emotional well-being are reportedly the most affected areas of life in well educated White women, while physical health and money matters are also severely affected in Hispanic women.^{74,75} There is a consistent correlation between lower educational status and poor quality of life ratings for melasma.⁷⁵ In particular, facial blemishes appear to have a significant impact on quality of life of women.⁷³ 'What We Know' box on the following page provides a summary of the current evidence for melasma, a guide to what we know.

CONCLUSION

Melasma is a disorder of hyperpigmentation that primarily affects women in their reproductive years. It typically

What We Know

Epidemiology

- Melasma is primarily a facial disorder of women in their reproductive years.
- It may also be present in older women taking oral contraceptives or hormone replacement therapy, adolescents, and men, and may occur sporadically.

Etiology & Pathogenesis

- Risk factors include UV radiation, female hormonal activity, ovarian, testicular and thyroid abnormalities, family history, cosmetic products, photo-sensitive and antiseizure medications.
- The pathogenesis remains unclear.

Diagnosis

- Melasma is a clinical diagnosis, supported by histologic evidence if warranted.
- It appears as hyperpigmented macules in 3 clinical patterns: centrofacial, malar or mandibular.
- Melasma is classified into epidermal, dermal or mixed patterns of distribution of pigmentation.
- There are strong correlations between the histologic subtype and clinical appearance of the disease.

Therapeutic Management

- Broad-spectrum UV protection is an essential and effective preventative modality.
- Reduction of exposure to other risk factor may also be beneficial.
- Topical therapies are considered first line, whether they are use as mono, double or triple therapy.
- Topical therapies consist of various modulators of melanin synthesis and distribution.
- Biochemical modulators of melanin synthesis: hydroquinone, azelaic acid, kojic acid, ascorbic acid.
- Physiologic modulators of melanin distribution: glycolic acid, tretinoin, NACAP, liquiritin.
- Recalcitrant melasma cases show strong clinical improvement with physically disruptive agents.
- Physically disruptive agents: chemical peels, lasers, dermabrasion.
- Etiologic factors and treatment choice play an important role in the prognosis of the disorder.
- There is a potential disconnect between objective physician assessment of clinical severity and patient perception of severity, with a significant subsequent impact on quality of life.

N-acetyl-4-s-cysteamylphenol (NACAP).

appears as macules and patches on the face in either a central, malar or mandibular pattern. Several etiologic factors have been identified. Histologically, melasma can be classified as epidermal, dermal and mixed, depending on the primary location of melanin accumulation. The histologic classification may influence treatment selection. Epidermal melasma tends to respond well to topical hypopigmenting agents. Dermal melasma tends to be more resistant to topical hypopigmenting agents. Mixed melasma requires a more varied approach. More invasive treatments such as chemical peeling, various lasers, and dermabrasion may be necessary in cases of recalcitrant melasma. Triple combination therapies with topical agents are considered first line treatments. If poorly tolerated, the patient may be switched to single or double therapy. Recalcitrant melasma can be treated with chemical peels in combination with topical agents, or with lasers and dermabrasion. Topical agents may be used as maintenance therapy. There may be a significant disconnect between the physician's objective assessment and the patient's subjective experience of disease severity. Although the disorder is primarily cosmetic in nature, adequate treatment is warranted at the patient's request.

Treatment of Psoriasis

Rupa Pugashetti, M.D., Jacqueline De Luca, M.D., and Steven R. Feldman, M.D.

INTRODUCTION

Psoriasis vulgaris is a chronic inflammatory disease which affects multiple organ systems, presenting predominantly with skin and joint manifestations. It is characterized by erythematous, scaly plaques and papules. Such lesions can be painful and pruritic and can significantly impact a patient's quality of life (QOL). Psoriasis affects approximately 2% of the population, and is associated with psoriatic arthritis (a seronegative spondyloarthropathy), inflammatory bowel disease, cardiovascular disease and diabetes.

Plaque psoriasis is the most common form of psoriasis, with characteristically well-demarcated, erythematous scaly plaques present on the skin. While favored sites include the buttocks, lower back, scalp, and extensor surfaces including the elbows and knees, any area of the skin may be affected. When plaques are present on the soles or palms, painful cracking and fissuring may occur. Approximately 80% of patients have mild to moderate psoriasis and the remaining 20% have moderate to severe psoriasis, in which greater than 5% of the BSA is affected or specific areas including face, genitals, hands or feet are affected.¹

Inverse psoriasis classically presents in areas of skin folds including the axilla, groin, inframammary, perineal and intergluteal locations. Erythrodermic psoriasis is characterized by generalized full-body erythema with varying degrees of scaling, and symptoms including hypothermia, chills, and fluid loss secondary to the highly inflammatory skin lesions. Pustular psoriasis can be either localized or generalized and represents clinically visible collections of neutrophils. The acute, generalized form of pustular psoriasis may present with fever. Guttate psoriasis is characterized by small, drop-like pink papules on the trunk and extremities. Guttate psoriasis may be precipitated by a preceding upper respiratory infection caused by group A beta-hemolytic streptococcus and is often seen in younger patients.

PSYCHOSOCIAL ISSUES AND PATIENT RESOURCES

As the skin manifestations of psoriasis can vary widely in distribution, severity and the percentage of body surface area (BSA) affected, treatment must be individualized.

There is an array of possible therapies to choose from depending on the character of the skin lesions, QOL considerations and patients' concomitant medical issues. However, the first step in the treatment of psoriasis includes addressing psychosocial issues and patient education. The National Psoriasis Foundation is a tremendous resource in the United States which provides information to patients about psoriasis, treatment options, advocacy programs and support groups. On the National Psoriasis Foundation website (www.psoriasis.org), patients can find informative brochures about psoriasis, psoriatic arthritis, medications used to treat the disease, illustrated storybooks for children, and information about advocacy programs such as the Walk to Cure Psoriasis. Another available resource is Psoriasis Cure Now (www.psoriasis-cure-now.org) which specifically targets lawmakers in advocating for research and where patients can access information about current available therapies.

The psychosocial impact of psoriasis can be profound, and it is integral for clinicians to recognize that this psychologic impact may not necessarily relate to the clinical extent or severity of a patient's disease. Psoriasis has been associated with a lack of self-esteem and a higher incidence of depression, the prevalence of which may be as high as 60%.^{2,3} In some patients, the depression is so severe that patients may contemplate suicide. In one particular study, 5% of patients with psoriasis reported active suicidal ideation and 10% of patients reported a wish to be dead.⁴

Psoriasis can affect a patient's occupational functioning and personal relationships. In one study examining 300 patients with psoriasis, the disability experienced by patients with psoriasis was found to be comparable to patients with cancer, heart disease, diabetes, and depression.⁵ The Dermatology Life Quality Index is widely used to measure QOL in psoriasis studies.⁶ Another QOL tool, the Psoriasis QOL 12-item instrument, can help discriminate among various degrees of psoriasis severity and can be responsive to clinical change due to treatment.^{7,8} Another instrument which incorporates QOL measurement with a measurement of psoriasis severity by BSA is the Koo-Menter Psoriasis Instrument, which can help clinicians evaluate a patient's physical psoriasis severity as well as impact on QOL.⁹ The impact of the disease on

patients must be considered when evaluating and balancing the potential risks and benefits of treatment. The psychosocial impact can be large even when patients have a small BSA affected by psoriasis, for instance, patients with palm and sole involvement are often impacted more than patients with more severe involvement on other parts of the body.^{10,11}

PATIENT ADHERENCE TO TREATMENT

Adherence is defined as the degree to which a patient uses treatment as prescribed by their healthcare provider.¹² Multiple factors play a role in adherence to treatment, including the treatment provided, the clinical severity of psoriasis, and the patient themselves. Some 40% of patients report not using their treatments as directed because of inconvenience, time constraints, cost, complicated instructions and perception of low efficacy^{13,14}; actual nonadherence rates may be much higher. A Danish study found that 50% of psoriasis treatment prescriptions weren't even filled.¹⁵ Treatment outcome may affect a patient's satisfaction with treatment, which in turn may affect adherence to treatment. Poor adherence to treatment should be considered when a patient's disease is not improving as expected.¹⁶ Encouraging adherence is a critical consideration when treating chronic diseases such as psoriasis.

Measures to improve patient adherence include establishing a strong physician-patient relationship, addressing the psychosocial impact of psoriasis, motivating patients to use their medication by having them return for an appointment shortly after beginning treatment, using a treatment vehicle which the patient prefers, and making the treatment plan simple for the patient to both understand and follow.¹⁷ Considering patients' preference for different vehicles may help improve adherence. Although ointment formulations were traditionally considered to be more potent than cream formulations (particularly for dry, scaly conditions), clinicians must assess and consider whether the patient will adhere to such treatment or if other vehicles such as creams, solutions, foams or sprays would be more suitable for a particular patient. Patients should be involved in the decision-making process regarding what particular therapy and vehicle they will be prescribed. Inevitably, the best treatment for a patient is the one, which they will actually use consistently. Finally, reducing the time between initiation of treatment and the first return visit (or other form of contact) may motivate a patient to improve initial adherence and treatment outcome.¹⁷

EVALUATION OF TREATMENT

Evaluation of psoriasis treatment in clinical trials incorporates specific assessment tools. The Psoriasis Area and Severity Index (PASI) is a commonly used measure of psoriasis severity for patients with moderate-to-severe disease, assessing erythema, induration, scaling, and the

percentage of affected BSA.¹⁸ The PASI is not frequently used in routine clinical practice. In clinical trials, a 75% improvement in the PASI (PASI75) is used as a measure of psoriasis treatment success. This is a stringent measure of success, as many patients with less than 75% improvement in PASI may be very pleased with their degree of improvement.

Other psoriasis severity measures include the Physicians Global Assessment (PGA) whereby clinical investigators estimate the overall severity of a patient's psoriasis on a scale from clear to severe.¹⁸ Clear or almost clear status is typically used as the primary outcome measure for assessing success in trials for mild-to-moderate psoriasis. Another quantitative assessment of psoriasis severity includes BSA measurement, approximating 1% of BSA to the area of a patient's open handprint, extending from the wrist to fingertips.¹⁸ In clinical practice, dermatologists use subjective assessments of psoriasis severity, taking into consideration location, induration of plaques, symptoms, BSA involvement, and the physical and emotional disease burden carried by the patient.

TOPICAL TREATMENTS FOR PSORIASIS

The majority of psoriasis patients have limited disease comprising less than 5% BSA, and topical treatment may be suitable for them. Many topical agents provide reasonably high efficacy and safety. Furthermore, topical treatments may be used as adjunctive therapy to systemic treatment, biologic agents, and phototherapy. Recommending the use of topical treatments as monotherapy when the psoriasis is too extensive for the patient to apply topical treatment to all the spots is probably not a rational treatment strategy.¹⁹

Topical vehicles include ointments, creams, gels, foams, solutions, sprays, oils, lotions, tape, and shampoo. Depending on the body site and patient preference, a particular vehicle can be chosen. For instance, some patients will prefer to use a medicated shampoo for the treatment of scalp psoriasis, while others may prefer a solution or foam. Topical agents can be used in combination, but there may be compatibility issues. For example, acid products should not be used with calcipotriene, as calcipotriene is not stable in an acid environment.¹⁹ Topical agents may be used continuously or intermittently, depending on the nature of the patient's disease and the topical agent being used. Generally, more potent agents are used intermittently to decrease the potential risk of side effects.

Topical Corticosteroids

Topical corticosteroids are available in a variety of strengths and formulations, and remain a widely utilized topical treatment of psoriasis. Mechanisms of action of corticosteroids include decreasing inflammation, decreasing proliferation, and vasoconstrictive and immunosuppressive effects. Topical steroids range in strength from

class I (superpotent) and class II (potent) to class VII (least potent).

The short term use of class I (superpotent) topical steroids for psoriasis has been established in vehicle-controlled studies. In a 2-week double-blind controlled trial (n=204), patients with moderate to severe psoriasis treated with halobetasol propionate ointment had a 92% improvement in PGA as compared to the vehicle group, which experienced a 39% improvement.²⁰ In another double-blind study of patients treated with clobetasol solution for moderate to severe psoriasis, 81% of patients achieved 50% or more clearance after 2 weeks of use, compared to 22% in the vehicle group.²¹ One of the newer formulations for topical steroids is a foam vehicle. In one 2-week double-blind trial (n=81) of patients with mild to moderate psoriasis treated with clobetasol foam, 58% of patients achieved moderate or better improvement, and in a similar trial (n=279) 68% of patients achieved clearance or near clearance of psoriasis while using clobetasol foam.^{22,23}

In a double-blind study of patients with psoriasis (n=35) treated with desoximetasone cream (class II) for 3 weeks, 68% of treated patients compared to 23% in the vehicle-treated group achieved overall improvement.²⁴ In a double-blind study of patients with scalp psoriasis (n=27) 74% of patients treated with halcinonide solution (class II) achieved good or excellent response compared to 45% of patients in the vehicle group.²⁵ In two randomized studies of patients with moderate to severe psoriasis (n=383), 68 to 69% of patients treated with a class III agent, fluticasone propionate, had excellent, good or clear skin after 4 weeks of usage, compared to 29% in the vehicle group.²⁶ In a double-blind placebo-controlled trial for patients with moderate to severe scalp psoriasis (n=172), 72% of patients treated with betamethasone valerate foam (class IV) achieved an improvement in the PGA score compared to 47% in the placebo group.²⁷ In another study among 40 patients with psoriasis, 70% of patients treated with betamethasone valerate foam for 3 months achieved greater than 50% improvement compared to 24% in the placebo group.²⁸ In a double-blind vehicle-controlled study of patients with mild to moderate psoriasis (n=190), 41% of patients treated with hydrocortisone 17-butyrate 21-propionate cream, a class V agent, responded with good or excellent improvement, compared to 18% in the vehicle group.²⁹ In a randomized, double-blind trial of patients with scalp psoriasis (n=89), 83% of patients treated with a class VI agent, fluocinolone acetonide 0.01% oil, had good or better improvement from baseline, compared to 36% of patients treated with a vehicle oil.³⁰ In one large systematic review of topical corticosteroid treatment for psoriasis, potent and superpotent strength formulations were more efficacious compared to mild and moderate topical steroids.³¹

The primary limitation of the aforementioned studies involving topical corticosteroids is the short time duration during which safety and efficacy were evaluated. Notably,

psoriasis may recur following discontinuation of the topical corticosteroid. Psoriasis may also become resistant to topical corticosteroids over time, a phenomenon termed tachyphylaxis. While traditionally tachyphylaxis was presumed to result in some type of desensitization to the drug, it may be largely because of poor adherence.

The recommended dosing of topical corticosteroids for the indication of plaque psoriasis is 1-2 times daily as monotherapy, and can be adjunctive to phototherapy and systemic agents (though there is some concern that use of topical corticosteroids with phototherapy may reduce the duration of remissions associated with phototherapy). For class I steroids, the available data support a duration of 2-4 weeks of treatment, and for less potent corticosteroids there is no specific endpoint recommended. For superpotent topical steroids such as clobetasol and halobetasol, the weekly use should not exceed a maximum of 50g.¹⁹ However, following a therapeutic clinical response, a gradual reduction in patient usage is recommended. Lower potency corticosteroids can be used in the intertriginous areas, face, and on infants.¹⁹ Clinicians should consider that highly potent topical steroids have a greater efficacy than less potent treatment agents. When prescribing a topical corticosteroid, the vehicle, the area of usage, patient preference, and age of the patient should all be considered.

Adverse effects of topical corticosteroids can be either local or systemic. Local toxicities include local skin atrophy, development of striae, contact dermatitis, rosacea and telangiectasias. Potential systemic effects include hypothalamic-pituitary-adrenal (HPA) axis suppression, which can occur with continued use of medium or high-potency topical steroids. Increased intraocular pressure, cataracts, glaucoma, and avascular necrosis of the femoral head are rare adverse effects. Limiting the use of topical corticosteroids to intermittent use can help decrease the risk of such toxicities. There is no specific baseline monitoring recommended, but intermittent monitoring for cutaneous atrophy is advised if patients are using the medicine continuously. Children using topical corticosteroids extensively over the long-term should have their growth assessed on a regular basis. For infants and children, there is a higher risk of systemic side effects because of an increased skin surface/body mass ratio. Topical corticosteroids are pregnancy category C.

Vitamin D Analogues

Calcitriol is a natural vitamin D molecule, and calcipotriol (calcipotriene) is a synthetic vitamin D analogue used for the treatment of psoriasis. The mechanism of action is believed to be mediated by binding to vitamin D receptors, leading to keratinocyte differentiation and inhibition of proliferation. Calcitriol is available as an ointment and calcipotriene is available in a solution and cream form in the United States. In a randomized study of patients with scalp psoriasis, 60% of patients had clearance or marked

improvement after treatment with calcipotriene solution compared to 17% in the vehicle group.³² In one randomized placebo-controlled trial of patients with plaque psoriasis, 70% of patients had a PASI 75 improvement when treated with calcipotriene ointment as compared to 19% in the placebo group.³³ In a right-left comparison study, 74% of patients treated with calcipotriol had improvement or clearance compared to 18% in the vehicle group.³⁴ In a 52-week trial evaluating calcitriol, 324 patients with mild to moderate plaque psoriasis were treated with calcitriol ointment 3 microg/g twice daily. Improvements in a global severity score were seen over the course of treatment and the ointment was considered to be safe and well-tolerated throughout 52 weeks of treatment with no effect on calcium homeostasis.³⁵ Calcitriol is thought to be better tolerated for use on sensitive areas such as the face, flexural surfaces, and the hairline, causing less irritation.³⁴

Vitamin D analogues are recommended for twice-daily dosing to affected areas. Adverse reactions can include irritation in lesional or perilesional skin, a reversible elevation of serum calcium if large quantities are used (>100 g/week of calcipotriol or >200 g/week of calcitriol), and photosensitivity. There is no contraindication to combining these agents with ultraviolet B (UVB) phototherapy, but calcipotriene can be inactivated by ultraviolet A (UVA) light and should only be applied after and not before exposure to UVA light.³⁶ These agents are pregnancy category C, but there is no information on excretion into breast milk. Use among pediatric patients appears to be safe.³⁷

A calcipotriene/betamethasone propionate ointment preparation was studied in 1603 patients for 4 weeks. 48% of patients in the treatment group achieved absent to mild disease compared to 16.5% of patients in the calcipotriene group.³⁸ In a 52-week long study (n=828), at least 69% of patients treated with calcipotriene 0.005% and betamethasone 0.064% achieved almost clear or clear status, and there were no drug-related serious adverse events including HPA axis suppression after 52 weeks of usage.³⁹

Tazarotene

Tazarotene is a topical retinoid approved for the treatment of psoriasis. It is thought to normalize keratinocyte differentiation and diminish hyperproliferation. In one vehicle-controlled trial, there was 50% or more improvement seen in 63% of patients treated with tazarotene 0.1%, compared to 31% of patients treated with vehicle gel for 3 months.⁴⁰ In two large controlled trials (n=1303), 40%-51% of patients treated with tazarotene 0.1% and tazarotene 0.05% cream, achieved an overall lesion assessment of none, mild, or minimal after 12 weeks of treatment.⁴¹

Topical tazarotene is indicated for once daily use. Most common side effects include local skin irritation and photosensitivity, and the irritation can be minimized by combination use with topical corticosteroids.¹⁹ One controlled study of tazarotene with UVB light showed that combined

use decreased the amount of ultraviolet light needed to for a good clinical response.⁴² Tazarotene is pregnancy category X as it is a teratogenic retinoid, and cannot be used during pregnancy. Excretion in human milk is unclear. For pediatric usage, tazarotene is approved for acne ages 12 years and older, but there is no data for pediatric psoriasis patients.

Tacrolimus and Pimecrolimus

Tacrolimus and pimecrolimus are topical calcineurin inhibitors, which help block the synthesis of inflammatory cytokines, which play a role in psoriasis. These agents are efficacious when used under occlusion for the treatment of plaque psoriasis. Tacrolimus and pimecrolimus are also effective for facial and intertriginous psoriasis without occlusion, avoiding concerns about atrophy and other side effects associated with topical corticosteroids in these sensitive areas. In a randomized, controlled study of patients with facial and intertriginous psoriasis (n=167), 65% of patients had a clear or almost clear response after 8 weeks of treatment with tacrolimus 0.1% ointment, compared to 31% in the placebo group.⁴³ In another randomized, double-blind study of patients with intertriginous psoriasis (n=57), 71% of patients had clear or almost clear response after 8 weeks of treatment with pimecrolimus 0.1% cream, compared to 21% in the placebo group.⁴⁴

Tacrolimus and pimecrolimus are not FDA-approved for psoriasis but may be especially helpful off-label for psoriasis affecting the face and intertriginous areas. These topical agents can be applied twice daily with no set endpoint. Common adverse effects include a burning sensation, irritation, and itching. There is a controversial 'black box' warning which has been issued in the United States by the FDA for both tacrolimus ointment and pimecrolimus cream, because of a lack of long-term safety data and a potential risk for development of lymphoma.^{45,46} Notably, there is currently no clinical evidence suggesting an association between these topical agents and an increased risk of malignancy, including lymphoma.⁴⁷ These topical calcineurin inhibitors are pregnancy category C and are not recommended for use in nursing mothers. These agents are approved for adults and children at least 2 years of age with atopic dermatitis.

Coal Tar

Coal tar is composed of thousands of compounds, distilled from coal, and has been used in the treatment of psoriasis for nearly a century. Coal tar is thought to suppress DNA synthesis in keratinocytes, but its mechanism has not been fully elucidated. Combination of crude coal tar with ultraviolet light has been used in the intensive Goeckerman treatment regimen since the 1920s, and is effective for moderate to severe psoriasis. In a double-blind randomized study of patients with mild to moderate psoriasis (n=324), patients treated with 1% coal tar lotion had better

improvement in PASI compared to those treated with a 5% coal tar extract.⁴⁸ In another study (n=18), patients treated with 5% liquor carbonis detergens (LCD) had a greater improvement compared to treatment with emollient.⁴⁹

Coal tar is available in numerous formulations. Coal tar is often poorly tolerated by patients because of cosmetic issues such as staining of clothes and odor of tar. This may limit patients' adherence to treatment. Adverse events can include photosensitivity, irritant contact dermatitis, and folliculitis. In humans, there is no convincing data to suggest an association between coal tar and increased risk of carcinogenicity, and epidemiologic studies do not show an increased risk of skin cancer in patients using coal tar.⁵⁰ However, one study did demonstrate increased carcinogen excretion, specifically urinary 1-hydroxypyrene, from urine of patients treated with topical coal tar.⁵¹ In a recent literature review, authors concluded that topical coal tar can be used for short time periods during pregnancy.⁵² Coal tar compounds should be used with caution in pediatric patients.

Anthralin

Anthralin has been used topically for the treatment of psoriasis but is used less frequently as more cosmetically acceptable agents are currently available. Anthralin may help normalize keratinocyte differentiation and prevent T-cell activation.⁵³ In one small controlled study, patients using upto 2% concentration of anthralin twice daily for 4 weeks had better results compared to placebo.⁵⁴ In another controlled study, patients receiving 1 minute of treatment with 2% dithranol daily for 3 weeks had better results compared to placebo.⁵⁵

Anthralin is most commonly used for short contact therapy in an outpatient setting. There are several doses available, but treatment can begin with a 1% concentration and increasing concentration over time as tolerated. Common side effects include irritation of the skin, as well as staining of skin and clothing. There is no reported long-term systemic toxicity associated with anthralin. Anthralin should be applied cautiously, and patients who are exposed to anthralin for more than 2 hours may experience increased frequency of irritation. This agent should be applied cautiously to intertriginous zones and the face because of the potential for skin irritation. Anthralin is pregnancy category C and should be used with caution in pediatric patients.

Salicylic Acid

Salicylic acid is a topical keratolytic agent.⁵⁶ There have been no placebo-controlled studies evaluating salicylic acid monotherapy for psoriasis, but salicylic acid has been combined with other topical treatment agents, whereby it may help increase skin penetration of other agents secondary to its keratolytic effect. In a comparator study

of tacrolimus and salicylic acid versus tacrolimus alone (n=24), there was greater efficacy in the combination group.⁵⁷ In another study of patients with moderate to severe psoriasis (n=408), salicylic acid and mometasone was more effective than mometasone alone.⁵⁸ Salicylic acid should not be combined with other salicylate drugs. Sufficient systemic absorption to cause salicylism can occur if applied to a large percentage of BSA or in patients with liver or renal dysfunction. Salicylic acid blocks UVB, and application immediately prior to UVB phototherapy is not recommended. Salicylic acid usage appears to be safe in pregnancy but should be avoided in children because of the risk for systemic absorption.

PHOTOTHERAPY AND PHOTOCHEMOTHERAPY

Ultraviolet (UV) phototherapy includes narrowband UVB phototherapy (NB-UVB), broadband UVB phototherapy (BB-UVB), psoralen with UVA (PUVA) and excimer laser treatment. The effects of UV therapies can include rapid depletion of dermal and epidermal lymphocytes, dendritic cells, and macrophages.⁵⁹

Phototherapy is frequently utilized for patients whose psoriasis may be moderate to severe, and cannot be controlled with topical medications. UVB phototherapy is a first-line treatment option in moderate-to-severe psoriasis patients because of its efficacy, cost effectiveness, and safety profile. Furthermore, phototherapy may be considered as a suitable treatment option for patients with concomitant medical problems for whom systemic and biologic agents are not options. Patients must be able to receive phototherapy treatments regularly, often 3 times per week initially. This requirement can be burdensome for some patients, and efficacy will be limited if patients are not able to adhere to their treatment schedule.

Broadband-UVB and Narrowband-UVB Phototherapy

Ultraviolet B light has been utilized for the treatment of psoriasis since the 1920s, beginning with the Goeckerman treatment regimen in 1925. However, UVB in the form of sunlight has been used much longer than this. UVB light may lead to decreased proliferation of keratinocytes and decreased numbers of Langerhans cells, affecting antigen presentation.⁶⁰ Broadband UVB light ranges from 280-320 nm, and early studies established its efficacy in the treatment of psoriasis. In one study, 20 of 28 patients treated with erythemogenic doses of BB-UVB phototherapy experienced resolution of plaque psoriasis.⁶¹ In another trial, 90% of psoriatic patients experienced complete disease clearance with BB-UVB combined with petrolatum 3 times weekly for 3-13 weeks.⁶² Remission times have also been prolonged when using BB-UVB for maintenance therapy.⁶³

Narrowband-UVB light uses only a limited range of the UVB spectrum, emitting a distinct band of high-intensity light from 311 to 313 nm. Based on earlier studies, the 313-nm wavelength is thought to have the greatest risk/benefit ratio for psoriasis.^{64,65} Although NB-UVB was initially used more frequently in Europe, it is now utilized worldwide for the treatment of psoriasis.

One pilot study (n=10) comparing the efficacy of NB-UVB to BB-UVB in patients with psoriasis, found that NB-UVB is more efficacious.⁶⁶ In one right-left study comparing NB- and BB-UVB, 60% of patients had similar efficacy regardless of which UVB treatment was used, while the remaining 40% of patients had better results when treated with NB-UVB.⁶⁷ In another right-left study, there was faster clearing among patients treated with NB-UVB, compared to BB-UVB phototherapy.⁶⁸ Additionally, in another study, there was histopathologic resolution of 59% of psoriatic lesions treated with BB-UVB phototherapy, compared to 88% of psoriatic lesions treated with NB-UVB phototherapy.⁶⁹ Maintenance therapy with NB-UVB may also be beneficial. In one randomized controlled trial, 55% of patients who received maintenance therapy with NB-UVB twice weekly for 4 weeks, then weekly for 4 weeks, after 3 months of initial treatment were in remission at 1 year.⁶¹

The long-term safety data of UVB therapy remains controversial. It has not been established whether UVB phototherapy is carcinogenic in humans but overall results suggest that UVB therapy is a safe treatment modality. In a comprehensive review of BB-UVB and skin cancer risk, 11 clinical studies of 3400 participants were examined.⁷⁰ No published study showed an increased skin cancer risk, with the exception of one PUVA cohort study demonstrating an increased rate of genital tumors in men who had received PUVA phototherapy and BB-UVB. The contemporary standard of care thus includes genital shielding. There was no increased skin cancer risk in a retrospective 25-year study of 280 patients treated with BB-UVB and coal tar.⁵⁰ Furthermore, a retrospective study of patients with psoriasis receiving UVB phototherapy from 1994 through 2000 did not show an increased risk of skin cancer associated with either NB- or BB-UVB phototherapy.⁷¹

Treatment recommendations for UVB light, as indicated for generalized psoriasis, vary and specific treatment protocols vary widely. Initial dosing for BB-UVB therapy can be according to skin type, ranging anywhere from 20-60 mJ/cm² with subsequent incremental increases of 5-20 mJ/cm². For NB-UVB, the initial dosage according to skin type may range from 300-800 mJ/cm² and incremental dosage increase ranging from 100-150 mJ/cm².⁷² Dosage can also be calculated according to minimal erythema dose (MED), beginning with an initial NB-UVB dosage of 50% MED with subsequent increases at 10% the initial MED.⁷² Treatments may range from 2-4 times per week initially, with a course ranging from 15-25 treatments depending on the patient's clinical response. For NB-UVB, a single

course may range from 15-20 treatments but is generally longer for BB-UVB, with 20-30 treatments usually needed to induce clearance.

Adverse events can include erythema, burning, irritation and pruritus along with a theoretical risk of carcinogenesis. Patients must notify the phototherapy staff of new medications, as caution should be exercised when using photosensitizing medications. Furthermore, when UVB light is used in conjunction with retinoid agents such as acitretin, the dosage of UVB light may need to be reduced. UVB phototherapy is generally considered to be safe during pregnancy and in pediatric patients, although there have been no formal studies conducted in children.

PUVA Phototherapy

PUVA treatment refers to combining UVA light, at a wavelength of 320-400nm, with the use of 5- or 8-methoxysoralen which helps to sensitize cells to light. Psoralens intercalate between DNA bases, and form cross-links which can prevent replication of DNA following exposure to UVA light. Additionally, PUVA may lead to death of antigen presenting cells.⁷³ Psoralens can be administered topically, through soaking in a dilute solution or by painting a higher concentration topical psoralen agent directly on the lesions. Psoralen can also be administered orally, but some patients do not tolerate oral psoralen because of gastrointestinal complaints such as nausea. In the United States, the only available oral psoralen is 8-methoxysoralen but in Europe 5-methoxysoralen is used as well.

In one large multicenter study (n=1308), evaluating PUVA in the treatment of psoriasis in the United States, Fitzpatrick skin type was used to determine the initial dose, and incremental increases in the dosage of light were fixed.⁷⁴ Patients were treated 2-3 times weekly followed by high intensity, long-wave UVA light. In this study, 89% of patients achieved clearance of their psoriasis, and once remission was induced, there was no difference in a maintenance regimen of once weekly, once every other week, or once every third week. In another large, multicenter trial (n=3175) conducted in Europe, the minimal photo-toxic dose was used to initiate therapy and incremental increases in dosage were based upon skin response.⁷⁵ Patients received an average of twenty exposures to UVA light required for clearance over 5.3 weeks, and 89% of patients overall achieved clearance. Comparing these two studies, the European study utilized approximately half the total cumulative UVA dose for clearance of psoriasis as compared to the United States study. In two systematic reviews examining PUVA studies, between 70-100% of patients treated with PUVA achieved clearance of psoriasis, generally within 24 treatment sessions.^{76,77} Although many patients experience remission for up to 6 months following PUVA treatment, some patients require maintenance PUVA 1-2 per month to maintain good control of the disease.

Bath PUVA therapy can be as efficacious as oral PUVA, but this form of therapy is not used frequently in the United States.⁷⁸ Soak PUVA may be an effective therapy for psoriasis affecting the palms and soles, whereby 8-methoxypsoralen is dissolved in water. UVA light should generally be administered 30 minutes after a topical psoralen is applied, whether through soak or paint.

PUVA is known to lead to skin aging, multiple lentigines, and an increased risk of nonmelanoma skin cancers.⁷⁹ This risk may correlate with a total cumulative dosage of UVA light, and increases in individuals who have undergone more than 200 PUVA treatments.⁸⁰ One large-scale prospective study in the United States identified an additional risk of melanoma with increasing UVA exposure after 15 years of follow-up, primarily in patients who had received at least 250 PUVA treatments.⁷⁹ Another large-scale, long-term Scandinavian study with the same length of follow-up did not show an increased risk of melanoma.⁸¹ The basis for this difference is not clear, but limiting lifetime exposure to 200 PUVA sessions may help minimize the risk of skin cancer in at-risk patients and in patients with lower Fitzpatrick skin types.⁸² Furthermore, patients with a history of PUVA treatment may not be appropriate for treatment with immunosuppressive agents such as cyclosporine because of the potential for skin cancers to occur.

General recommendations for PUVA include oral administration of 8-methoxypsoralen at 0.4-0.6 mg/kg prior to exposure to UVA. Treatment can be administered 2-3 times weekly initially. An initial course of PUVA may be under 25 treatments, depending on clinical response. Patients should wear ultraviolet-protective eyewear for at least 12 hours following ingestion of psoralen. Patients must continue to undergo full body skin checks by dermatologists. PUVA is considered pregnancy category C and there have been no studies commenting on the use of PUVA in pediatric patients.

Targeted-UVB Phototherapy

Targeted UVB phototherapy has become available through the 308-nm excimer laser and a variety of nonlaser devices. These localized treatment devices can target psoriatic plaques without affecting perilesional or unaffected areas of skin. In a pilot study evaluating the 308-nm excimer laser for the treatment of psoriasis, 8-16 times the MED was used and 11 of 16 patients achieved a PASI 75 after 4 weeks.⁸³ In another study, there was greater than 95% clearance of psoriatic plaques following an average of just 10.6 treatments, when using dosages at 1-3 MED, which was considered medium-dose therapy.⁸⁴ A multicenter study was conducted (n=124) in which patients with plaque psoriasis were treated initially with a dosage of 3 MED; after an average of 6 treatments, 72% of patients achieved clearance and 84% of patients achieved a PASI 75 response following two excimer laser treatments.⁸⁵

In another study of patients with psoriasis (n=40), a 77% improvement in plaque psoriasis was seen after approximately 14 treatments.⁸⁶

Remission rates following excimer laser therapy continue to be examined. In five patients achieving at least a PASI 75 response using excimer laser therapy, a tapering schedule of laser treatment was conducted using one treatment weekly for 1 month, followed by one treatment every 2 weeks for 1 month, and one treatment 4 weeks later. These patients maintained at least a PASI 50 response following the taper period.⁸⁷ Palmoplantar psoriasis has also been treated with the excimer laser in one study (n=54), with complete clearance in 57% of patients following 10-13 laser treatments.⁸⁸

The evidence examining dosage and treatment protocols for excimer laser therapy is extremely limited, and dosage may be guided by induration and scaling of the plaque as well as Fitzpatrick skin type. Treatment protocols have utilized both MED as well as plaque induration. Generally, excimer laser therapy is conducted 2-3 times weekly with at least 48 hours separation between treatments. Side effects consist of erythema, burning, irritation, blistering, and hyperpigmentation of the treated area. Long-term safety with regards to carcinogenesis is not available. Localized phototherapy is considered to be safe in pregnancy although formal studies have not been conducted. One pilot study utilizing excimer laser treatment in children (n=7) had an adverse effect profile similar to that of adults treated with psoriasis, and the excimer laser and other localized treatment devices are generally considered to be safe for use in the pediatric population.⁸⁹

TRADITIONAL SYSTEMIC AGENTS

Methotrexate

Traditional systemic therapies for psoriasis are commonly prescribed for patients with more extensive psoriasis (i.e. more than 10% BSA affected, or for patients with debilitating symptoms secondary to psoriasis). Methotrexate is one of the oldest systemic therapies, and worldwide is the most commonly prescribed systemic medication for the treatment of psoriasis. Methotrexate was initially approved by the FDA for the treatment of psoriasis in 1972. This agent functions by inhibiting dihydrofolate reductase, an enzyme involved in the synthesis of cofactors necessary for the production of nucleic acids. Methotrexate affects rapidly dividing cells, and it is thought to inhibit the proliferation of lymphoid tissue at low weekly doses.⁹⁰ Recently, consensus guidelines on the use of methotrexate were published by the National Psoriasis Foundation.⁹¹

There have been three recent studies examining the efficacy of methotrexate for psoriasis. In one blinded comparison trial (n=90), methotrexate and cyclosporine were compared at 12 weeks. The PASI 75 response was 60% for the methotrexate group and 71% for the cyclosporine

group; the average dose of methotrexate was not stated.⁹² Another recent randomized study compared methotrexate and cyclosporine in 68 patients, with no placebo arm.⁹³ In the cyclosporine group, the average PASI improvement was 72% as compared to 58% in the methotrexate group; the mean dose of methotrexate was not stated. In the CHAMPION study, Saurat et al. conducted a double-blind, controlled study comparing methotrexate to adalimumab, including a separate placebo arm (n=250).⁹⁴ The PASI 75 response after 16 weeks was 80% in the adalimumab treatment group, as compared to 36% in the methotrexate arm and 19% in the placebo arm. Notably, the dosage of methotrexate initially was 7.5 mg for 2 weeks, then 10 mg for 2 weeks, 15 mg for 4 weeks and could subsequently be titrated upwards depending on clinical response. Furthermore, after 8 weeks of treatment, subjects who had achieved a PASI 50 response in the methotrexate group did not have any further increase in dosage, and the overall mean dose of methotrexate was 19 mg. The efficacy of methotrexate may have been greater with a longer duration of treatment.

One possible toxicity from methotrexate usage is elevated liver function tests and commonly, minor elevations of liver enzymes are seen. According to current recommendations, if the elevation exceeds 2x normal, clinicians should check liver function tests more frequently.⁹¹ If the elevation exceeds 3x normal, consider reducing methotrexate dosage, and if the elevation exceeds 5x normal, discontinue methotrexate.⁹¹ Other toxicities can include: anemia, aplastic anemia, thrombocytopenia, leukopenia, nausea, vomiting, diarrhea, fatigue, interstitial pneumonitis, fever, chills, gastrointestinal ulceration, photosensitivity, decreased resistance to infection and alopecia.⁹¹

Regarding liver biopsies, clinicians can first determine whether a patient is considered high or low risk for hepatotoxicity secondary to methotrexate. Risk factors for hepatotoxicity may include a history of greater than moderate alcohol consumption, persistent abnormal liver chemistry laboratory findings, history of hepatitis B or C, diabetes mellitus, obesity, previous exposure to hepatotoxic drugs, family history of an inheritable liver disease and hyperlipidemia.⁹¹ For patients considered low-risk, a baseline liver biopsy is not necessary and a first biopsy is recommended following 3.5-4 g cumulative methotrexate dosage.⁹¹ For high-risk patients, consider a baseline biopsy with subsequent biopsies following 1-1.5 g methotrexate ingestion.⁹¹ It should be noted that some dermatologists choose not to recommend liver biopsies for their patients, as well as many rheumatologists who treat patients with methotrexate.

Methotrexate is recommended for severe psoriasis which has not responded adequately to other therapies such as topical treatment. It is administered as a single oral dose weekly, which is titrated upwards to achieve an optimal response but should not exceed 30 mg/week.⁹⁵ An initial test dose of 2.5-5 mg is recommended and baseline monitoring should include blood count and liver function

tests. Folic acid supplementation of 1-5mg daily except for the day on which methotrexate is taken can be used.⁹⁵ Methotrexate is absolutely contraindicated for patients with the following: alcoholic liver disease, alcoholism, chronic liver disease, immunodeficiency syndromes, leukopenia, thrombocytopenia, and bone-marrow hypoplasia.⁹⁵ Methotrexate is both teratogenic and an abortifacient and is pregnancy category X. Its use is contraindicated in pregnant women, nursing mothers, and in women attempting to conceive.⁹⁵

Cyclosporine

Cyclosporine was originally used as an immunosuppressant in organ transplant recipients since the early 1970s, with efficacy for psoriasis first described in 1979.⁹⁶ Cyclosporine binds to cyclophilin, leading to calcineurin inhibition and decreased levels of inflammatory cytokines such as interleukin-2.⁹⁷ Cyclosporine is rapidly and consistently effective, making it particularly helpful for psoriasis crisis management.

Cyclosporine leads to a PASI 75 response in 50-70% of patients at a dosage of 3 mg/kg/day.⁹⁸ Cyclosporine dosed between 2.5 to 5 mg/kg/day for 12 to 16 weeks can lead to dramatic improvement in psoriasis in 80-90% of patients.⁹⁹⁻¹⁰¹ In one randomized trial of intermittent cyclosporine treatment lasting up to 12 weeks (n=400), patients were either abruptly discontinued from cyclosporine or had cyclosporine dosage gradually tapered.¹⁰¹ The average time to relapse was 113 days for patients who had tapered off treatment at 1 mg/kg/week and 109 days for those who had abruptly stopped treatment. The short cyclosporine courses were generally tolerated well. In another study of patients (n=217) treated with cyclosporine at 1.25-5 mg/kg/day for 6-30 months, 12.5% of patients were maintained on a dosage of 1.25 mg/kg/day without experiencing loss of efficacy.¹⁰²

The most serious toxicities associated with cyclosporine include hypertension and nephrotoxicity.¹⁰³ While observed renal impairment is often reversed following cyclosporine discontinuation, long-term therapy with cyclosporine can lead to permanent kidney damage and decrease in renal function.^{104,105} Renal impairment can be either acute or chronic, where increased glomerular fibrosis may result from a longer duration of treatment and increasing dosage.⁹⁵ Additionally, cyclosporine usage may put patients at increased risk for the development of nonmelanoma skin cancers, specifically squamous cell carcinomas; this risk may be particularly increased in patients who have received previous PUVA treatments.¹⁰⁶ Regarding internal malignancies, patients with psoriasis treated with cyclosporine do not have a significantly increased risk as compared to the general population, but the study conducted was not sufficiently statistically powered to rule out a potential increased risk of malignancy.¹⁰⁷ Patients with uncontrolled kidney disease, hypertension, and history of malignancy

are not considered appropriate candidates for cyclosporine. Other toxicities may include the following: headaches, paresthesias, gingival hyperplasia, acne, nausea, vomiting, myalgias, hypertrichosis, fatigue, hypomagnesemia, hyperkalemia, hyperbilirubinemia, increased risk of infection and increased risk of lymphoproliferative disorders.⁹⁵

Cyclosporine is indicated for adults with severe, recalcitrant psoriasis who are not immunocompromised, although some guidelines suggest the use of cyclosporine for moderate to severe psoriasis. Furthermore, cyclosporine is effective for erythrodermic, generalized pustular and palmoplantar psoriasis.⁹⁵ Recommended dosing is between 2.5-5.0 mg/kg/day in two divided doses, decreasing the dose by 0.5-1.0 mg/kg when psoriasis has cleared or if toxicities have been observed.⁹⁵ In the United States, cyclosporine is approved for 1 year of continuous treatment and outside of the United States for 2 years of continuous usage. Cyclosporine may be initiated again after an intermittent rest period.

Recommended monitoring at baseline includes: blood pressure x2, BUN and creatinine x2, urinalysis, liver function enzymes, CBC, magnesium, potassium, lipid profile, uric acid and possible pregnancy test.⁹⁵ Patients should be monitored carefully for renal toxicity with monthly serum creatinine levels, and the package insert recommends that an elevation of serum creatinine greater than 25% should lead to a 25-50% decrease in cyclosporine dose.^{108,109} Cyclosporine is pregnancy category C and has been associated with decreased duration of pregnancy and lower birth weight in patients who were receiving cyclosporine for transplantation, but does not appear to be teratogenic. The efficacy and safety of cyclosporine in children with psoriasis has not been formally established.

Acitretin

Oral retinoids are derivatives of vitamin A and affect epidermal differentiation and proliferation. Acitretin is the active metabolite of etretinate and has been used for the treatment of psoriasis since 1988. In clinical trials, various dosages have been used and the efficacy and side effects of acitretin are dose dependent. In one study, the average PASI improved by 70-75% after 3 months of acitretin treatment; patients had been treated with 40 mg daily for 4 weeks followed by an individually adjusted dose for the subsequent 8 weeks.¹¹⁰ In another study, 23% of patients treated with 50 mg/day of acitretin for 8 weeks achieved a PASI 75 response.¹¹¹ In a study of 59 patients, acitretin was initiated at a dose of 20 mg daily and increased by 10 mg every 2 weeks until a dosage of 70 mg was reached.¹¹² While 41% of patients experienced marked improvement or clearance of psoriasis, more than a third of patients withdrew from the study because of adverse events. In a study of patients with plaque psoriasis, after 6 months of continuous treatment, 75% of patients had reached PASI 50 and after 1 year of continuous treatment, 88% of patients still in the study

had reached PASI 50 response.¹¹³ Etretinate, the pro-drug of acitretin, has reported usage in erythrodermic psoriasis.¹¹⁴ Acitretin is considered a safe and effective treatment in psoriasis patients who are HIV-positive because it is not considered to be significantly immunosuppressive.¹¹⁵ Furthermore, acitretin is considered to be a rapidly effective treatment for pustular psoriasis, with efficacy in 84% of patients with generalized pustular psoriasis.¹¹⁶

Potential toxicities associated with acitretin can include the following: alopecia, xerosis, xerophthalmia, dry mouth, cheilitis, paresthesias, paronychia, headaches, pseudotumor cerebri, depression, nausea, myalgias, increased liver function tests, and hypertriglyceridemia.⁹⁵ The more commonly observed side effects include mucocutaneous dryness and increased triglycerides. Overall, low-dose acitretin at 25 mg/day is better tolerated by patients compared to 50 mg/day.

Acitretin is approved by the FDA for adults with severe plaque psoriasis and recommended dosing is 10-50 mg/day (lower doses should be used to minimize risk of side effects). Importantly, when acitretin is added while a patient is receiving UV phototherapy, the UV light dose should be reduced by 30-50%.⁹⁵ Baseline monitoring recommended includes lipid profile, liver function enzymes, renal function tests, CBC, and possible pregnancy test.⁹⁵ Acitretin is a systemic retinoid and is pregnancy category X. It is a potent teratogen and is absolutely contraindicated in women of childbearing potential.⁹⁵ Its use in the pediatric population has not been studied and safety has yet to be established.

NONTRADITIONAL SYSTEMIC AGENTS

Nontraditional systemic agents include azathioprine, hydroxyurea, leflunomide, mycophenolate mofetil, sulfasalazine, tacrolimus, and 6-thioguanine. None of these agents are currently approved by the United States FDA for the treatment of psoriasis. The available evidence for efficacy in psoriasis is limited, and these drugs have a variety of toxicities (Table 15-1).

Azathioprine is a purine analogue which blocks purine synthesis, and is commonly used as an immunosuppressant agent for renal transplantation. Azathioprine has been used off label for blistering disease, atopic dermatitis, and psoriasis. Hydroxyurea is an antimetabolite, which is thought to function by inhibiting DNA replication. The major dose-limiting side effect is hematologic toxicity; hydroxyurea is often useful when methotrexate is contraindicated because of liver disease. Leflunomide is a disease-modifying antirheumatic medication which has been used in the treatment of psoriasis and is indicated for rheumatoid arthritis. It inhibits pyrimidine biosynthesis but is more complicated to use than is methotrexate. Mycophenolate mofetil is approved as an immunosuppressive agent for prophylactic treatment in organ transplant recipients. It is the pro-drug of mycophenolic acid which interferes with T-cell proliferation by blocking de novo synthesis

TABLE 15-1—Nontraditional Systemic Agents

Agent	Evidence for Treatment of Psoriasis	Potential Toxicities ⁹⁵
Azathioprine	In one study, 19/29 patients experienced a PASI 75 response ¹¹⁷ In another study, 5/10 patients had >25% reduction in psoriasis ¹¹⁸	Bone marrow suppression, malignancy, squamous cell carcinomas, increased risk of infection, hepatitis, pancreatitis
Hydroxyurea	In one study 55% of patients had a 70% reduction in PASI score after 36 weeks ¹¹⁹ In one study comparing methotrexate to hydroxyurea, patients had a 48% reduction in PASI score at 3 months ¹²⁰	Bone marrow suppression, gastrointestinal symptoms, dermatologic reactions, temporary impairment of renal tubular function, pulmonary fibrosis, neurologic disturbances
Leflunomide	In a randomized controlled trial of 190 patients, 17% of patients had a PASI75 response compared to 8% in the placebo group ¹²¹	Nausea, diarrhea, weight loss, severe liver injury, pancytopenia, thrombocytopenia, agranulocytosis,
Mycophenolate Mofetil	In a study of 23 patients, mean reduction of 47% in PASI score at 12 weeks with patients treated 1-1.5g BID ¹²² In a study of 11 patients treated with 1g BID for 3 weeks followed by 0.5g BID for 3 weeks, there was 47% reduction in PASI score was at 6 weeks ¹²³	Diarrhea, nausea, vomiting, leukopenia, anemia, thrombocytopenia, dysuria, increased incidence of infections, progressive multifocal leukoencephalopathy, hypercholesterolemia, electrolyte disturbances, peripheral edema
Sulfasalazine	In a randomized controlled trial, 7/17 patients experienced moderate improvement in psoriasis after 8 weeks of 3-4g/day treatment compared to 1/27 patients in placebo group ¹²⁴	Anorexia, headache, oligospermia, nausea, vomiting, pruritus, rash, fever, urticaria, hemolytic anemia
Tacrolimus	Patients dosed at 0.05mg/kg had no difference from placebo after 3 weeks, but when dosed at 0.1-0.15mg/kg, there is a significant improvement in PASI score compared to placebo at 9 weeks ¹²⁵	Tremor, headache, diarrhea, nausea, hypertension, abnormal kidney function results
6-Thioguanine	Retrospective, open-label study of 40 patients showed 78% achieved complete or almost complete clearing of psoriasis – dosage schedules and amounts varied widely ¹²⁶	Liver toxicity, increased liver function tests, myelosuppression, hyperuricemia, photodermatitis, gastric ulcers, aphthous ulcers, nonmelanoma skin cancer, taste changes, herpes zoster

BID, twice a day; PASI, psoriasis area sensitivity index.

of guanine nucleotides. Sulfasalazine is thought to have anti-inflammatory properties and is frequently used in the treatment of inflammatory bowel disease; although it has limited efficacy, it is not associated with the organ toxicities associated with methotrexate and cyclosporine. Tacrolimus is a macrolide antibiotic indicated for prophylaxis in organ transplant recipients; it functions as a calcineurin inhibitor. Topical use is described above. Oral tacrolimus can be used similar to cyclosporine. Finally, 6-thioguanine is a metabolite of azathioprine which has been used in the treatment of inflammatory bowel disease; a major concern with this drug is the potential for inducing hepatic vein thrombosis.

BIOLOGIC AGENTS

The biologic agents are proteins produced either through recombinant technology or extracted from animal tissue, and can be used for the treatment of psoriasis. There are five biologic agents which are FDA approved for psoriasis, with one recently withdrawn by the manufacturer. Notably, the data evaluating the safety and efficacy of biologics for psoriasis is based on studies of adults age 18 and older with the single exception of etanercept, which has been evaluated in the pediatric age group.¹²⁷

Alefacept

Alefacept is a recombinant dimeric fusion protein in which the extracellular portion of lymphocyte function-associated antigen (LFA)-3 is linked to the Fc region of human IgG1. Alefacept inhibits activation and decreases the number of memory-effector CD45 RO+ cells.¹²⁸

In the phase III trials, alefacept was administered at 15 mg/week intramuscularly, and 21% of patients achieved a PASI 75 response by week 14 after a 12-week dosing period.¹²⁹⁻¹³² The endpoint for these studies was at 14 weeks, but the maximum response to alefacept was generally observed approximately 6-8 weeks following the last intramuscular injections. Patients who respond to alefacept initially may achieve further benefit through successive treatment courses, each lasting 12 weeks. Patients who achieved a PASI 75 response to alefacept maintained at least a 50% reduction in PASI for a median of 7 months.¹²⁸ Furthermore, patients who experienced at least a 50% improvement in PASI score also had a significant improvement in the Dermatology Life Quality Index as compared to placebo.¹²⁸ There is currently no way to predict which patients may improve significantly with alefacept therapy.

Alefacept is recommended for patients with moderate to severe psoriasis, administered by a 15 mg intramuscular

injection weekly for 12 weeks with a 12 week follow-up nontreatment period.¹²⁷ Patients beginning treatment with alefacept should have a baseline CD4 lymphocyte count with repeated monitoring every other week, and alefacept should not be administered whenever the CD4 count decreases below 250 cells/mL.¹³³ It is recommended that alefacept treatment be discontinued if the CD4 count remains below this threshold for 4 weeks continuously.¹³³ Alefacept is contraindicated in patients infected with HIV; however it should be noted that HIV-positive patients were not included in the phase III pivotal trials.¹²⁷ Alefacept is pregnancy category B.

Efalizumab

Efalizumab is a recombinant humanized monoclonal IgG1 antibody which is directed against the CD11a subunit of LFA-1. This agent interferes with activation and trafficking of T-lymphocytes.¹³⁴ Efalizumab dosage is administered subcutaneously at an initial dose of 0.7 mg/kg followed by 1mg/kg thereafter.¹³⁵ Based on the phase III clinical trials, between 27-39% of patients achieved a PASI 75 response following 12 weeks of treatment with efalizumab.^{134,136,137} Furthermore, after 24 weeks of efalizumab treatment, 44% of patients achieved a PASI 75 response.¹³⁸ In a randomized, placebo-controlled trial, efalizumab was effective for hand and foot psoriasis.¹³⁹

However, by April 2009, there were three confirmed and one unconfirmed but suspected case of progressive multifocal leukoencephalopathy among patients who had been receiving efalizumab treatment continuously for at least 3 years.¹⁴⁰ Three of the cases had resulted in death. Progressive multifocal leukoencephalopathy (PML) is a rare and progressive demyelinating disease which is caused by activation of the JC virus; it is usually fatal, and there is no effective treatment currently available. Efalizumab was thus pulled from the market by European and Canadian regulatory agencies, and subsequently was voluntary pulled from the United States market by its manufacturer Genentech, Inc. in April 2009.¹⁴⁰ As of June 2009, efalizumab is no longer available in the United States.

Adalimumab

Adalimumab is a human antitumor necrosis factor α (TNF- α) monoclonal antibody. Adalimumab binds to both soluble and membrane-bound TNF- α and prevents its interaction with TNF receptors on the cell surface.¹⁴¹ Currently, adalimumab is approved by the FDA for psoriasis, juvenile rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, Crohn's disease, and adult rheumatoid arthritis. Dosing for psoriasis is initiated with an 80 mg subcutaneous loading dose followed 1 week later by a 40 mg subcutaneous dose and then a 40 mg dose subsequently every 2 weeks.¹⁴²

In the pivotal phase III clinical trial evaluating the safety and efficacy of adalimumab (n=1212), patients received adalimumab or placebo for the first 16 weeks of the study.¹⁴³ By week 16, 71% of patients in the adalimumab treatment arm versus 7% in the placebo group had achieved a PASI 75 response. Patients who maintained a PASI 75 response through week 33 were re-randomized 1:1 to receive either adalimumab or placebo. This period of the trial from weeks 33 through 52 was designed to examine the duration of treatment effect and compare the proportion of patients in each group who lost adequate response. Loss of adequate response is defined specifically as an increase in PASI score by 6 points in addition to a loss of PASI 50 response. The percentage of patients rerandomized to placebo who lost adequate response was 28%, compared to 5% in the patients who continued adalimumab treatment. Although rebound of psoriasis typically does not occur following discontinuation of adalimumab, clearance of psoriasis is better maintained with its continuous use.

Potential toxicities of adalimumab include the following: painful injection site reactions in up to 15% of patients, rare reports of serious infections such as tuberculosis and opportunistic infections, rare reports of malignancy, multiple sclerosis, drug-induced lupus (without neurologic or renal complications), and exacerbation of congestive heart failure.¹²⁷ Recommended monitoring at baseline includes a purified protein derivative (PPD) test, liver function enzymes, CBC, and hepatitis screening. Yearly PPD, periodic CBC, and periodic liver function tests can be considered. An evidenced-based review of laboratory monitoring found that only PPD testing was well supported by evidence.¹⁴⁴ Adalimumab is pregnancy category B.¹²⁷

Etanercept

Etanercept is a recombinant human TNF- α receptor fused with the Fc portion of IgG1. It binds to both soluble and membrane-bound TNF- α molecules and thus functions as a TNF- α antagonist.¹⁴⁵ Currently, etanercept is approved by the FDA for moderate to severe plaque psoriasis, rheumatoid arthritis, juvenile rheumatoid arthritis, psoriatic arthritis and ankylosing spondylitis. Etanercept is dosed at 50 mg subcutaneously twice weekly for 12 weeks followed by 50 mg weekly continuously thereafter.

In a phase III trial evaluating the efficacy of etanercept, 34% of patients achieved a PASI 75 response at week 12 after receiving 25 mg twice weekly, and 49% of patients achieved a PASI 75 response after receiving 50 mg twice weekly, compared to 4% in the placebo group.^{146,147} After 24 weeks of treatment, a PASI75 response was observed in 59% of patients receiving 50 mg twice weekly.¹⁴⁶ Notably, some patients will have a loss of clinical response during the step-down period at 12 weeks when the dose is reduced from 50 mg twice weekly to 50 mg weekly. In clinical

practice, some dermatologists pursue continued treatment at 50 mg twice weekly if a patient no longer clinically responds to weekly dosing and if the patient's insurance agrees to cover this dosing regimen. However, etanercept is not indicated for this dosage schedule, such dosing is considered off-label, and is not cost effective compared to other options. Etanercept discontinuation typically does not result in rebound of psoriasis.¹⁴⁷

There has been one clinical study examining the safety and efficacy of etanercept in the pediatric population; no other reports of the use of biologic agents for psoriasis in children were reported.¹⁴⁸ Etanercept was administered once weekly at 0.8 mg/kg, up to a maximum of 50 mg, in children and adolescent patients ages 4-17 years with plaque psoriasis. In this group, 57% of patients achieved a PASI 75 result compared to 11% in the placebo group.

Toxicities associated with etanercept are similar to those associated with adalimumab and include the following: mild pruritus at the injection site, rare cases of serious infections such as tuberculosis, rare cases of malignancy, drug-induced lupus, multiple sclerosis, exacerbation of congestive heart failure, and cytopenia.¹²⁷ Baseline monitoring recommended is a PPD test, liver function enzymes and CBC; a yearly PPD and periodic CBC and liver function tests can be considered.¹²⁷ Etanercept is pregnancy category B and is contraindicated in septic patients.¹²⁷

Infliximab

Infliximab is a murine-human chimeric antibody, which is composed of a human IgG1 region and a mouse variable region.¹⁴⁹ Infliximab binds to both transmembrane and soluble TNF- α molecules. Currently, infliximab is approved by the United States FDA for use in treating psoriasis, psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis, Crohn's disease, and ulcerative colitis. Unlike the other TNF- α inhibitors, infliximab is administered as an intravenous infusion. Typically, it is dosed at 5 mg/kg for 2 to 3 hours at weeks 0, 2, 6 and then every 8 weeks subsequently for the treatment of psoriasis.¹⁵⁰ In the phase II trials, approximately 80% of patients achieved a PASI 75 response by week 10 following 3 intravenous doses of infliximab.¹⁵¹ Furthermore, after 10 weeks of therapy, there was a 91% improvement in the Dermatology Life Quality Index.¹⁵² Patients who receive continuous treatment with infliximab not only achieve a better clinical response as compared to patients who receive intermittent therapy, but these patients are also less likely to develop antichimeric antibodies against infliximab.¹⁵²⁻¹⁵⁵ Some clinicians administer low-dose methotrexate to patients in order to decrease the formation of antibodies against infliximab.¹⁵⁶ Infliximab has continued efficacy and during the pivotal phase III trial, 61% of patients had maintained a PASI 75 response by week 50, after nearly a year of therapy at 5 mg/kg with 8-week intervals.¹⁵⁶

Toxicities associated with infliximab include serum sickness and infusion reactions (which occur more frequently in patients who have developed anti-drug antibodies), rare malignancies including hepatosplenic T-cell lymphoma in adolescents, rare cases of serious infections such as tuberculosis, drug-induced lupus, multiple sclerosis, exacerbation of congestive heart failure and new onset of congestive heart failure.¹²⁷ The majority of infusion reactions, which occur in approximately 16% of patients, consist of mild urticaria and pruritus, but some patients experience chest pain, shortness of breath, hypertension, and rarely anaphylaxis.¹²⁷ As infusion reaction risk correlates with the presence of antichimeric antibodies; patients treated with methotrexate, or other immunosuppressive therapies tend to have a lower incidence of infusion reactions.¹²⁷ Recommended monitoring at baseline includes PPD, liver function tests, CBC and hepatitis screening; consider a yearly PPD examination and periodic CBC and liver function tests.¹²⁷ Infliximab is contraindicated in patients with New York Heart Association class III or IV congestive heart failure, at the dosage of 5 mg/kg or greater.¹²⁷ Infliximab, like the other biologic agents previously discussed, is pregnancy category B.

Tumor Necrosis Factor- α Inhibitors

The TNF- α antagonists have been used in the treatment of inflammatory diseases for over a decade and are being used with increasing frequency for the treatment of plaque psoriasis. General recommendations pertaining to the class of TNF- α antagonists have been established by an American Academy of Dermatology work group of psoriasis experts, with regards to adverse events and monitoring for patient safety.¹²⁷

Due to reports of tuberculosis reactivation, tuberculosis testing through a PPD test should be performed at baseline on all patients who will be treated with an anti-TNF agent.¹⁵⁷ TNF antagonists are contraindicated in patients with active, serious infections and should not be used with live vaccines. Hepatitis B reactivation following treatment with TNF inhibitors has been reported and all patients should be screened for hepatitis B infection at baseline. TNF antagonists should not be used in patients with multiple sclerosis or other demyelinating diseases. These agents should not be used in first-degree relatives of patients with multiple sclerosis based on evidence that they have a potentially increased risk of developing multiple sclerosis (sibling relative risk between 18-36).¹⁵⁸ TNF blockers should be used with caution in patients with congestive heart failure, and it is recommended that patients with New York Heart Association class III or IV avoid use of any TNF inhibitor.¹⁵⁷ Patients with New York Heart Association class I or II congestive heart failure who have an ejection fraction of <50% should also avoid use of any TNF inhibitor.¹⁵⁷

SYSTEMATIC REVIEWS AND RECOMMENDATIONS

With the wide variety of psoriasis treatment options available—all with different side effect profiles, practicability, and cost—systemic reviews and treatment guidelines are needed to help educate patients on the relative risks and benefits of treatment, to support physicians' treatment decision-making, and to inform other parties (payers and regulators) about appropriate treatment paradigms Tables 15-2 and 15-3.

For topical psoriasis therapies there has been one large systematic Cochrane review in 2002 by Mason et al. which found that topical Vitamin D, corticosteroids, dithranol and tazarotene were more effective than placebo. It also found no significant difference in head-to-head comparisons of Vitamin D agents against topical corticosteroids. Moreover, combined treatment with Vitamin D with corticosteroids performed significantly better than Vitamin D alone, or corticosteroid alone.¹⁵⁹

Current guidelines reflect these findings accordingly. The current U.S. guidelines set out by Menter et al. graded the evidence on an I-III scale, and made clinical recommendations based on the best available evidence from grade A-C. Grade A recommendations were based on consistent and good-quality patient-oriented evidence, grade B recommendations were based on inconsistent or limited-quality patient-oriented evidence, and grade C recommendations were based on consensus, opinion, or case studies. A grade A recommendation was given to the combination use of a topical vitamin D analogue with a topical corticosteroid. Other recommended topical treatments with grade A recommendations included corticosteroids, tazarotene, and vitamin D analogues. Tacrolimus, pimecrolimus and coal tar were supported by grade B recommendations.¹⁹ Canadian guidelines also recommend calcipotriol, and calcipotriol/betamethasone dipropionate combination.¹⁶⁰

In Europe, Nast et al. published S3-Guidelines for Germany that also recommended topical corticosteroids, vitamin D analogs, and their combination. Tazarotene and dithranol were also recommended, however dithranol was only recommended during hospitalization and neither was recommended nor discouraged for outpatient treatment. Calcineurin inhibitors were also neither recommended nor discouraged. Coal tar use, however, was highly inadvisable for use as monotherapy or in combination therapy. As opposed to the U.S.'s grade B recommendation. The use of coal tar, according to the German recommendations, is obsolete with only one, albeit poor, study evaluating the efficacy for monotherapy, which did not show any statistically significant difference from placebo. They further cited that coal tar is carcinogenic (especially when combined with UV light), and is not desirable for patients because of its color and odor.¹⁶¹

For phototherapy, the guidelines for the US, Canada, and Europe are all relatively similar. The U.S. guideline

found oral PUVA, and combination of PUVA with topical or systemic agents supported by a grade A recommendation. Narrowband UVB therapy and excimer laser therapy are recommended with a grade of B. And, the combination of UVB with topical agents, systemic agents, or biologic agents are also recommended with grade of B. Broadband UVB therapy is recommended with grade of C.¹⁶² The Canadian guidelines recommend PUVA phototherapy with grade B and UVB phototherapy recommended with grade D.¹⁶⁰ The European S3-Guidelines recommend narrowband UVB as first choice for induction therapy for moderate to severe psoriasis vulgaris. PUVA is next choice if UVB is not effective, but not for long-term treatment. Excimer lasers are advised to be limited to the targeted treatment of individual psoriatic plaques.¹⁶³ German S3-Guidelines highly recommended phototherapy as an induction therapy, and recommended excimer lasers for targeted treatment of individual psoriatic plaques. Phototherapy was neither recommended nor discouraged for combination use with dithranol and corticosteroids. However, phototherapy was not recommended for long-term treatment, or for combination with topical vitamin D3 analogs.¹⁶¹

Systemic treatments, both with traditional and biologics, have been the focus of many systematic reviews. A recent meta-analysis comparing the systemic agents, published by Warren et al. in 2010, found that several traditional nonbiologic systemic therapies have equal or superior efficacy to some biologic therapies. For example, fumaric acid esters and cyclosporin were found to be more effective than efalizumab. Meta-analyses comparing some of the biologic therapies for psoriasis showed that for short-term treatment efficacy (10–16 weeks): infliximab, etanercept 50 mg twice weekly, etanercept 25 mg twice weekly, efalizumab, alefacept. Rates of adverse events, however, were significantly higher with infliximab, efalizumab, and alefacept than with placebo.¹⁶⁴

Despite the findings of this meta-analysis, the U.S. guidelines gave grade A recommendations for the biologics (adalimumab, etanercept, infliximab, alefacept, and efalizumab), while methotrexate, cyclosporine, sulfasalazine, tacrolimus and acitretin were given grade B recommendations.^{165,166} Azathioprine, mycophenolate mofetil and 6-thioguanine were given grade C recommendations.¹⁶⁶ In Canada, the biologics (adalimumab, infliximab, etanercept, alefacept) are also recommended with grade A. Cyclosporine was also recommended, but with grade B.¹⁶⁰

European guidelines differ from North American countries in their use and recommendation for fumaric acid esters, and for their disapproval of acitretin. In the European S3-Guidelines both fumaric acid esters and cyclosporine were recommended for induction in moderate to severe psoriasis vulgaris. Fumaric acids were also recommended for use in combination with topical treatments. Methotrexate recommendations were mixed because of the limited evidence available. Retinoids were not recommended as a first choice for monotherapy. Adalimumab, etanercept, and infliximab were only recommended for

TABLE 15-2—Recent Systematic Reviews and Guidelines for Psoriasis Therapy

Article	Focus	Methodology	Limitations
Mason et al. Topical Treatments for Chronic Plaque Psoriasis: Cochrane Review	Focus on topical therapies for psoriasis	The Cochrane database, EMBASE, MEDLINE, Science Citation Index, National Research Register were all searched through 2005. Review included 131 RCTs with 21,448 participants.	Studies evaluated were typically approximately 6 weeks long, while in clinical practice patients use topical agents for months to years. Few long-term studies evaluating topical agents are available.
Menter et al. Guidelines of Care for the Management of Psoriasis and Psoriatic Arthritis	Section 3: Treatment of Psoriasis with Topical Therapies	An evidence-based model was used to search the MEDLINE database from 1960-2008. Evidence was graded on a 3-point scale and clinical recommendations made with grade of A, B, or C.	Few randomized, controlled studies are available for evaluating coal tar therapy and in comparing different topical agents in the treatment of psoriasis.
Menter et al. Guidelines of Care for the Management of Psoriasis and Psoriatic Arthritis	Section 5: Phototherapy and Photochemotherapy	An evidence-based model was used to search the MEDLINE database from 1960-2009. Evidence was graded on a 3-point scale and clinical recommendations made with grade of A, B, or C.	Limited and conflicting data available regarding combination of Vitamin D agents with phototherapy. Limited data on use in the pediatric population, but UVB therapy generally considered a second-line therapy for pediatric psoriasis patients who fail topical therapies. No data on systemic PUVA in pediatric populations, may be used with caution in patients under 18 years old.
Menter et al. Guidelines of Care for the Management of Psoriasis and Psoriatic Arthritis	Section 4: Treatment of Psoriasis with Systemic Agents	An evidence-based model was used to search the MEDLINE database from 1960-2008. Evidence was graded on a 3-point scale and clinical recommendations made with grade of A, B, or C.	Limited literature available regarding the use of methotrexate and cyclosporine in pediatric population. Cyclosporine use during pregnancy based on data from patients undergoing organ transplantation (not psoriatic patients); cyclosporine pregnancy category C.
Smith et al. British Association of Dermatologists Guidelines for Use of Biological Interventions in Psoriasis 2005	Review current anti-TNF and anti-T cell biologic therapies approved for psoriasis in the UK	Literature review performed on EMBASE and MEDLINE from 1990 through 2005 for clinical trials involving etanercept, infliximab and efalizumab; scoring performed for strength of evidence.	Conclusion regarding efalizumab was made prior to published reports of association with long-term efalizumab use and progressive multifocal leukoencephalopathy. Only efalizumab, infliximab and etanercept were evaluated (adalimumab, alefacept were not licensed in the UK at time of review).
Papp et al. Canadian Guidelines for the Management of Plaque Psoriasis	Evaluation of topical agents, systemic agents, biologics and phototherapy for psoriasis	Scottish Intercollegiate Guidelines Network used to evaluate over 5000 peer-reviewed articles and assign strength of recommendations.	Guideline committee with potential conflict of interest. Ten industry supporters funded the guidelines.
Menter et al. Guidelines of Care for the Management of Psoriasis and Psoriatic Arthritis	Section 1: Biologic Therapies for Psoriasis	An evidence-based model was used to search the MEDLINE database from 1990-2007. Evidence was graded on a 3-point scale and clinical recommendations made with grade of A, B, or C.	Guttate, pustular, inverse, erythrodermic psoriasis subtypes not considered in this analysis. Conclusion regarding efalizumab was made prior to published reports of association with long-term efalizumab use and progressive multifocal leukoencephalopathy.

Article	Focus	Methodology	Limitations
<p>Pathirana et al. European S3-Guidelines on the systemic treatment of psoriasis vulgaris and</p> <p>Pathirana et al. On the development of the European S3 guidelines on the systemic treatment of psoriasis vulgaris: structure and challenges.</p>	<p>Guidelines for systemic treatments of psoriasis vulgaris</p>	<p>Medline, EMBASE, and the Cochrane Library were searched from May 2005 to October 2007 for efficacy of the systemic treatments of plaque psoriasis. Studies were appraised by one methodologist using a standardized literature evaluation form (LEF), and later by a member of the dEBM. If the two appraisals differed, the study was reassessed. 678 studies were evaluated, 114 fulfilled inclusion criteria. Levels of evidence were graded on a 4-point scale and clinical recommendations made with PASI 75 results</p> <p>A list of key questions concerning the different systemic therapies was compiled and graded (using a DELPHI procedure) by the guidelines group and distributed to the authors of the individual chapters who answered questions. Some of the more important questions were also subject to consensus consisting of a nominal group process and a DELPHI procedure. A passage was regarded as consented when $\geq 75\%$ of the voting experts agreed. There was external review by experts according to the AGREE recommendations, and by European dermatological societies according to the EDF Standard Operation Procedure.</p>	<p>Possible conflict of interest that may have influenced the outcomes of the guidelines. Further, there was limited editorial independence from the funding body. Total time for developing the guidelines took 44 months due to extensive internal and external review.</p>
<p>Warren et al. What's new in psoriasis? Analysis of the clinical significance of systematic reviews on psoriasis published in 2007 and 2008.</p>	<p>Summarizes 6 systematic reviews on psoriasis published from January 2007 to October 2008</p>	<p>PubMed, MEDLINE, EMBASE were searched using a systematic review filter. Also searched were The Cochrane Library, the Database of Abstracts of Reviews of Effects (DARE) and the Health Technology Assessment Database and of the NLH Skin Disorders Specialist.</p>	<p>Only six systematic reviews met inclusion criteria.</p> <p>Limited studies on appropriate use of screening and monitoring tests with biologics (currently, they are neither supported nor refuted)</p> <p>Limited studies evaluating the effectiveness of existing psychological interventions in psoriasis.</p>
<p>Nast et al. Evidence-based (S3) guidelines for the treatment of psoriasis vulgaris and</p> <p>Nast et al. Evidence-based (S3) guideline for the treatment of psoriasis vulgaris - Update: "Therapeutic options" and "Efalizumab"</p>	<p>To develop evidence-based guidelines for the management of psoriasis, specifically induction therapy in cases of mild, moderate, and severe plaque-type psoriasis in adults. Update adjusts guidelines for efalizumab (Raptiva) for which the European Medicines Agency (EMEA) recommended suspension as of February 19, 2009.</p>	<p>Systematic search of the literature was conducted in May 2005. 6,224 publications searched and 142 studies fulfilled the inclusion criteria. Studies assessed using a literature evaluation form (LEF). Levels of evidence were graded on a 4-point scale. Guidelines were developed following the recommendations of the AWMF. Guidelines Group defined important sections as passages requiring consensus. These were discussed and approved following formal consensus processes (Nominal Group Technique) in the framework of the consensus conferences. An expert group who evaluated treatment efficacy, level of evidence, safety, practicability, and cost/benefit ratio developed the therapeutic recommendations. Recommendations were then finalized during interdisciplinary consensus conferences.</p> <p>Efalizumab (Raptiva) guidelines changed with the guideline group consenting by way of Delphi method</p>	<p>Some treatments with strong strength of recommendations had LOE level 3 and 4.</p> <p>No S3 guidelines for adalimumab or ustekinumab included in the update (in 2010 a complete revision is expected which will include these 2 drugs).</p>

TABLE 15-3—Guidelines for Childhood Psoriasis Treatment and Complementary Medicine

Article	Focus	Methodology	Major Conclusions	Limitations
de Jager et al. Efficacy and safety of treatments for childhood psoriasis: A systematic literature review.	Systematically review treatment efficacy and safety in childhood psoriasis. Propose a recommendation for topical and systemic treatment.	PubMed, EMBASE, and the Cochrane Controlled Clinical Trial Register were searched for efficacy and safety of all treatment options in childhood psoriasis and a level of evidence was determined. 64 studies could be included, describing 646 children in total. Of these 64 studies, only 6 were RCTs.	Calcipotriene (grade A) +/- topical corticosteroids (grade C) is treatment of choice for mild to moderate childhood psoriasis. For treatment-resistant flexural and/or facial psoriasis, tacrolimus 0.1%, grade C, can be added. If this treatment regimen is not effective, or if psoriasis is moderate to severe, treatment with dithranol, grade C, is recommended. NB-UVB, grade C, can be considered in adolescents for short duration after above treatments fail. Antibiotics, grade C, can be considered in case of guttate psoriasis and suspicion of a streptococcal infection. MTX, grade C, is the systemic therapy of choice. Retinoids, grade C, can be used for pustular and erythrodermic psoriasis for short-term treatment. Treatment with cyclosporine, grade C, should only be used in exceptional cases. Etanercept, grade A, should be considered as a third-line drug as long-term side effects and risks are unknown	Limited number of RCTs, so all LOEs were included. Most of the evidence is of a low level, grade C and D. Only treatment with vitamin D and etanercept have higher LOE (level A). Most literature concerns induction of remission, rather than maintenance therapy, follow-up period and duration of remission. None of the studies have long-term safety profiles.
Smith et al. Complementary and alternative medicine for psoriasis: a qualitative review of the clinical trial literature.	Review clinical trial literature on complementary and alternative medicine for psoriasis treatment	PubMed, MEDLINE, EMBASE, and AMED (Allied and Complimentary Medicine) were all searched up to January 2008 for randomized, controlled trials in the English language for which clinical response of psoriasis was the primary end point.	No evidence was found for vitamin D, zinc, acupuncture, topical vitamin B12 and avocado oil, or selenium. There was conflicting evidence for aloe vera, fish oil, climatotherapy, and mind/body interventions. Evidence of effect was found with neem, <i>M. aquifolium</i> , inositol among psoriasis taking lithium, and Chinese medicine (all with only one study for support).	Low quality of studies (as assessed by Jadad scores) due to lack of blinding as an inclusion criteria and that most trials used an as-treated analysis rather than an ITT. Only one author determined inclusion of studies and assignment of Jadad scores.

induction therapy, only if the conventional systemic agents were inadequate in response, contraindicated, or not tolerated. Neither alefacept nor efalizumab were recommended as a first choice among the biologics for induction therapy.¹⁶³ Britain's guidelines recommend etanercept, infliximab, and efalizumab for chronic phase psoriasis with strength of recommendation A.¹⁶⁷ Last, the German S3 guidelines also highly recommended fumaric acid esters for long-term therapy, and also made a recommendation for use in induction therapy as well. Other highly recommended medications were etanercept and infliximab for induction therapy. Cyclosporine alone or in combination with topical preparations (vitamin D3 analogs or corticosteroids) was also recommended, although not highly, for induction therapy. Methotrexate was recommended for long-term therapy while acitretin, again, was not recommended because of its lack of efficacy.¹⁶¹

CONCLUSION

Treatment options available for psoriasis vary widely, and it is integral for patients and physicians to work together in building an appropriate treatment plan. Patients are encouraged to use the National Psoriasis Foundation website to learn about classification of psoriasis severity and for a comprehensive list of currently available psoriasis treatments with descriptions. Patients can access educational brochures about both topical and systemic treatments at <http://www.psoriasis.org/netcommunity/learn03>. Patients can also access *It Works For Me*, a unique online resource from the National Psoriasis Foundation which includes hundreds of helpful tips and treatment reports from patients who have successfully managed their psoriasis and/or psoriatic arthritis.

Deciding on a treatment regimen for psoriasis involves several factors. Psoriasis severity will be considered and treatment will depend on the localized versus generalized nature of disease. Mild psoriasis affects <3% BSA, moderate psoriasis affects between 3 to 5–10% BSA and severe psoriasis affects more than 5–10% BSA. Patients with more mild to moderate disease (localized) may be managed with topical treatment, whereas patients with moderate to severe (generalized) psoriasis will consider topicals as adjunct treatment to phototherapy, acitretin, methotrexate, cyclosporine, and biologic agents. Physicians must additionally consider the location of a patient's psoriasis (i.e., hands, feet, genitals, face) and its effect on quality of life.

Patient adherence to treatment will influence the efficacy of a particular therapy. Involving the patient in decision-making in choosing a particular vehicle for topical medication, or using a combination topical treatment, may improve adherence to a treatment regimen. The best vehicle for topical treatment is ultimately the one which the patient will use. Finally, cost-effective management for extensive disease must also be taken into account. For moderate to severe psoriasis, UVB phototherapy is considered the best first-line option, with or without the addition of acitretin, followed by PUVA, methotrexate, and the biologic agents.

What We Know

- Topical agents including corticosteroids, vitamin D analogues, tazarotene, tacrolimus, pimecrolimus, coal tar, anthralin, and salicylic acid have all demonstrated efficacy in the treatment of psoriasis. Special consideration should be given to the strength and duration of use of topical corticosteroids because of the risk of local and systemic side effects.
- Ultraviolet phototherapy (UVB and PUVA) is efficacious for generalized psoriasis and may be considered the most cost-effective treatment for extensive disease, with or without the addition of acitretin.
- Systemic agents including methotrexate, cyclosporine, and acitretin are efficacious in the treatment of psoriasis, and methotrexate is the most cost-effective treatment for generalized psoriasis following phototherapy.
- The biologic agents including infliximab, adalimumab, etanercept, and alefacept have demonstrated efficacy in the treatment of psoriasis. Physicians should follow the recommended monitoring guidelines outlined in this chapter based on AAD consensus guidelines.

Treatment of Lichen Planus

Parastoo Davari, M.D., Farzam Gorouhi, M.D.,
and Nasim Fazel, M.D., D.D.S.

Lichen planus (LP) was first defined by Dr. Wilson in 1869 as an inflammatory disorder of the stratified squamous epithelia of unknown etiology.¹ Lichen planus is a relatively common disorder that affects the skin, mucous membranes, nails, hair, and rarely esophagus. Lichen planus is characterized by itchy red-purple papules most commonly on the extremities of middle-aged adults.² Oral LP (OLP) can be the sole clinical presentation of the disease.

CLINICAL SUBTYPES

Cutaneous lichen planus (CLP) has different clinical subtypes: annular, linear, hypertrophic, atrophic, vesiculobullous, palmoplantar, follicular, actinic, and lichen planus pigmentosus. The classic skin lesions of lichen planus are characterized by shiny, red to purple-colored, flat-topped, papules, sometimes showing a small central depression. A thin, transparent, and adherent scale may be located on top of the lesion. Fine, whitish points or lacy lines referred to as Wickham's striae may be present over the surface of well-developed papules.³ OLP mainly has six clinical presentations: erosive, atrophic, papular, reticular, plaque-like, and bullous. OLP typically presents in buccal mucosa (80-90%) with a bilateral white network (reticular) pattern. Reticular OLP is the most common subtype and is usually asymptomatic. Atrophic or erythematous OLP has thinned reddened mucosa with faint white striae. Erosive/ulcerative OLP is the most advanced subtype with a multifocal pattern of distribution. It is clinically important because the lesions are painful. A pseudomembrane sometimes covers the ulcer. Table 16-1 addresses the most common sites of involvement for some subtypes. The pattern of vulvovaginal mucosal LP is similar to OLP. The most significant unfortunate outcome of chronic erosive vulvar LP is scarring. It can cause resorption of the labia minora (agglutination) and clitoral hood, resulting in clitoral burying (68%) and narrowing of the introitus (59%). Scarring and adhesions of the vagina make sexual intercourse impossible.⁴⁻⁶ Figure 16-1 demonstrates different types of LP.

DIFFERENTIAL DIAGNOSIS

Annular lichen planus may resemble granuloma annulare but the latter lacks any scale or Wickham's striae. Mucous membrane pemphigoid has a similar clinical presentation to erosive/ulcerative OLP. The whitish hyperkeratotic striae and presence of skin involvement can be the main differentiating signs.⁷ Vulvar mucosal LP can be mistaken with lichen sclerosis or vulvovaginal blistering diseases and the only ways to distinguish them would be the presence of Wickham's striae or biopsy.

ETIOLOGY AND EPIDEMIOLOGY

Emotional stress, tobacco use, oral or gastrointestinal candidiasis, diabetes mellitus, autoimmune diseases, internal malignancies, dyslipidemia, human papillomavirus (HPV), and hepatitis C virus (HCV) are some of the predisposing and risk factors for LP.² These associations have been strongly proven.

T-cell activation is central to the pathogenesis of lichen planus. Antigen-specific CD8 positive cytotoxic T-cell infiltration in epithelium results in apoptotic basal keratinocytes. Some nonspecific mechanisms may have a partial role in the pathogenesis, including matrix metalloperoxidase activation, mast cell degranulation, basement membrane alteration, and chemokine/cytokine secretion. The main pathologic process in LP is a cell-mediated response in the dermoepidermal junction.⁸ LP induces the activation of helper T lymphocytes in the deeper layers of the skin in the early stages. T helper activation leads to cytokines secretion including interleukin-2, interleukin-6, interleukin-12, interferon gamma, and TNF-alpha and TNF-beta and most importantly chemokine (C-C motif) ligand 5. Unfortunately, the exact etiology remains to be discovered.

The estimated prevalence of LP varies from 0.22% to 5%.⁹⁻¹³ In a paper from Britain, the incidence of LP has been reported as 32-37 per every 100,000 person. It typically affects middle-aged adults of both genders. No sexual

TABLE 16-1—The Most Common Sites of Involvement in LP Based on Subtypes	
	Sites of involvement
Cutaneous Lichen Planus	
Actinic	Sun exposed areas
Atrophic	All parts of body
Erosive	Soles of feet
Follicular	Scalp
Guttate	Trunk
Hypertrophic	Ankles and interphalangeal joints
Linear	Leg – scratched area
Nail disease	Fingernails
Papular	Flexor surfaces
Bullous	Feet
Oral lichen Planus	
Reticular	1- Buccal mucosa and mucobuccal folds 2- Lateral and dorsum parts of tongue 3- Gingiva and vermillion portion of lip
Atrophic	Attached gingiva
Erosive	1- Lateral and Ventral portions of tongue 2- Buccal mucosa
Bullous	Posterior and inferior parts of buccal mucosa

predilection is evident but some reports noted a slight predominance in women (2:1).¹⁴ This is partially unusual for an autoimmune disease and suggests other unknown parallel mechanisms.

Prognosis

Cutaneous lichen planus remits within 6 months to a year but hypertrophic CLP may persist for years if left untreated. Reticular OLP is usually asymptomatic but can have a chronic or progressive nature. The location and severity of the lesions in erosive OLP may change over time with cycles of concurrent healing and lesion formation. Erosive lesions do not heal spontaneously. Patients with erosive OLP or generalized LP have a poor quality of life. Proper and immediate treatment strategies are needed to contain the symptoms and signs for these patients. The association between virus infections (such as HPV and HCV) and LP is a topic of debate. Syrjänen et al.¹⁵ performed a meta-analysis to investigate the role of HPV in OLP patients. The odds ratios for HPV in general and HPV-16 were remarkable and significant [5.12 (95%CI: 2.40-10.93) and 5.61(95%CI: 2.42-12.99, respectively]. This finding provides further evidence that HPV is present in OLP patients more frequently than the normal population and

it may transform OLP into squamous cell carcinoma.¹⁶ Erosive OLP and hypertrophic CLP are the main subtypes with malignant potential. HPV vaccination and/or HPV screening in chronic erosive OLP and hypertrophic CLP cases can be considered.

Moreover, we performed a meta-analysis of all included studies in three previously published meta-analyses¹⁷⁻¹⁹ in addition to five new studies.²⁰⁻²⁴ (Figure 16-2) The included studies evaluated the prevalence of HCV in LP patients and compared it with a control group. Based on data pooling of 64 comparisons, there is a statistically and clinically significant common odds ratio of 5.58 (95% CI, 3.72-8.38) for the study group compared with the control population in favor of the association between LP and HCV. Subgroup analysis based on geographical distribution showed a similar trend reported by Shengyuan et al.¹⁷ Regardless of the nature of the relationship between HCV and LP (association or co-existence), we recommend developing a regional screening protocol for HCV in LP patients. LP patients with evident risk factors for HCV should be screened because serious complications can arise, if left untreated. Additionally, a well-designed prospective cohort study with a proper sample size is needed to establish these relationships.

Methods

Types of Studies

All systematic reviews and all randomized-controlled trials (RCTs) of any design that evaluate the effectiveness of any intervention for cutaneous and/or mucosal (oral and/or genital) lichen planus were considered.

Types of Participants

Studies in which a physician diagnosed cutaneous and/or mucosal lichen planus clinically and/or histopathologically were included. Skin or mucosal involvement in these patients could be the sole presentation or with each other.

Types of Interventions

We included studies that compare at least one active treatment with a control, which may be a placebo, no treatment, or an alternative intervention. We considered all treatments, including but not limited to the following categorized therapies: topical corticosteroids, systemic corticosteroids, retinoids (e.g., acitretin, etretinate, oral isotretinoin, and tretinoin), vitamin D3 analogues (e.g., KH 1060, calcipotriol), topical immunomodulators (e.g. pimecrolimus, tacrolimus), immunosuppressives, phototherapy (e.g., UVA, UVB, PUVA), surgery (cryosurgery, laser therapy), anti-microbials (e.g., metronidazole, griseofulvin,

FIGURE 16-1 A. Reticulated white striae of the lower labial mucosa; B. Reticulated white striae of the buccal mucosa; C. Reticulated white striae of the lower lip proper; D. Confluent reticulated white striae of the lateral tongue; E. Focal erosions of the maxillary attached gingiva.

FIGURE 16-1 (Continued) F. Violaceous papules on the dorsal hand and volar wrist (courtesy of Dr. Omid Zargari); G. Reticulated white striae involving the glans penis (courtesy of Dr. Omid Zargari); H. Hypertrophic lichen planus: centrally eroded hyperkeratotic plaques involving the lower leg; I. Dorsal pterygium of the thumbnail; J. Zosteriform lichen planus: linearly oriented confluent violaceous papules on the arm.

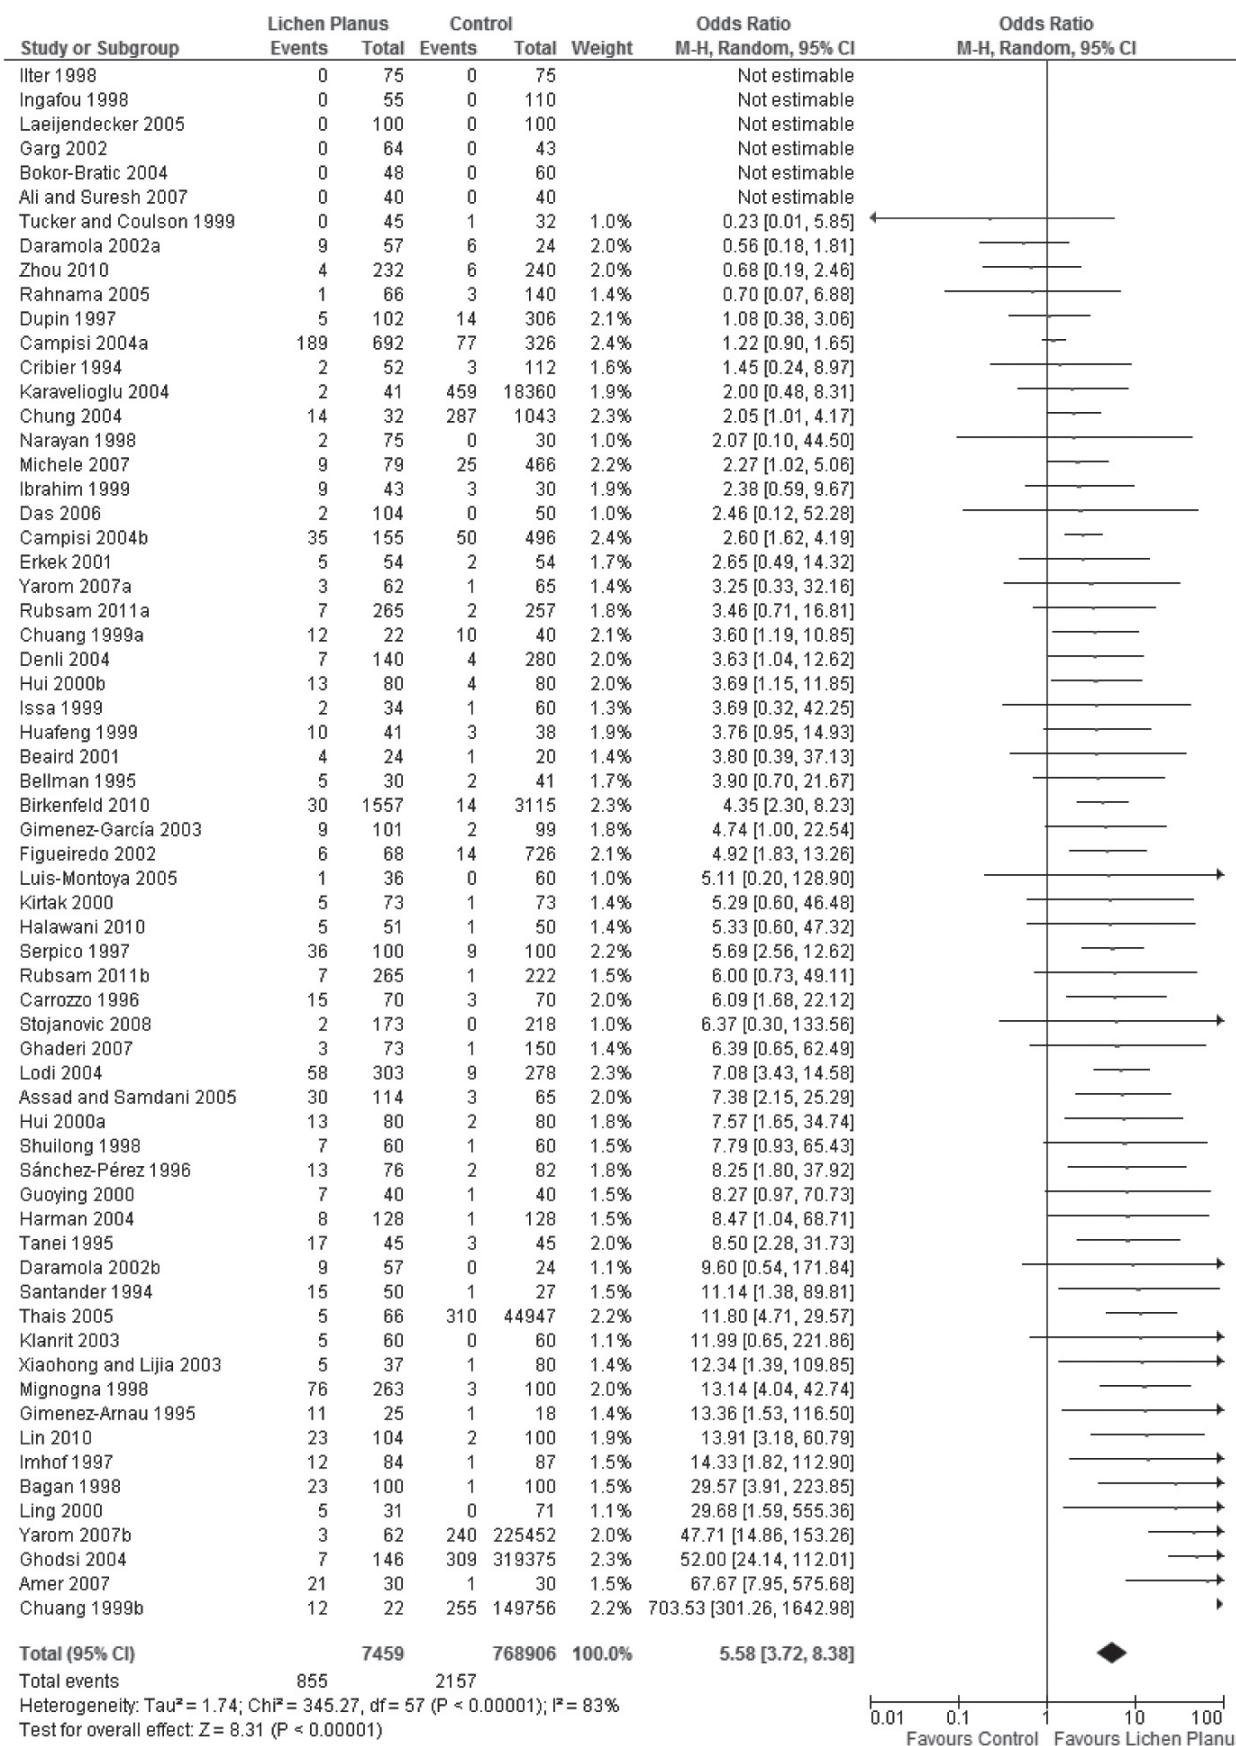

FIGURE 16-2 Meta-analysis of all studies that evaluate the prevalence of hepatitis C among LP patients vs. control populations. Odds ratios were calculated for all relevant studies using Mantel-Haenszel method and random effect model. Complete references are provided as online appendix 1.

miconazole, hydroxychloroquine), biologic therapies (e.g., alefacept, adalimumab), complementary and alternative medicine (e.g., homeopathic medicine, traditional Chinese medicine)

Search Strategy

Pubmed, Medline, and EMBASE were searched using terms: Lichen and Planus

Notice: There is no definitive and immediate cure for LP lesions in many circumstances and this fact makes it challenging for both patients and physicians (dermatologists, dentists, and gynecologists). Life-long clinical follow-up is fundamental.

Seven relevant systematic reviews were found and summarized in Table 16-2. There is no comprehensive recent systematic review that covers all relevant RCTs.

What are the effects of topical and systemic treatments on CLP? (Table 16-3)

Corticosteroids

Corticosteroid medicines are derivatives of the natural corticosteroid hormones that are produced by the adrenal glands. They are the mainstay of LP treatment.

EFFICACY: One randomized trial compared oral prednisolone 30 mg plus topical hydrocortisone-17-butyrate cream to topical hydrocortisone-17-butyrate cream only regimen for 10 days and reported significantly more patients with clinical response with the combined regimen.²⁵

SAFETY: Mild heartburn and euphoria occurred in oral prednisone group but not in topical corticosteroids only

TABLE 16-2—Systematic Reviews of LP

Study	Number of Included RCTs	Period of Literature Search	Diseases Covered	Treatments Covered	Notes
Cribier 1998 ⁷⁶	3	1966-March 1998	Cutaneous and mucosal lichen planus	Retinoids, Phototherapy, Corticosteroids, Griseofulvin, Cyclosporine	No indication of seeking the possibility of meta-analysis, underestimation of relevant RCTs
Al Johani 2009 ⁷⁷	10 (269 patients)	1966-December 2008	Oral lichen planus	Calcineurin inhibitors	All oral diseases were included. Non-English abstracts were considered. Non-randomized studies were considered. Although covered all relevant trials but considered some as non-randomized. No meta-analysis.
Chan 2000 ⁷⁸ & Zakrzewska 2005 ⁷⁹	11 (223 patients)	1966-2007	Oral lichen planus	Cyclosporine, Topical or systemic retinoids, Topical steroids, Phototherapy	Underestimation of relevant RCTs. Gaeta et al. was included although it is not a RCT
Yu-liang 2009 ⁸⁰	14 (358 patients in included English papers)	1966-2007	Oral lichen planus	Cyclosporine, Tacrolimus, Pimecrolimus, Total glucosides of Peony, Corticosteroids, Retinoids, Chitin	Quasi-randomized controlled trials were also included. Underestimation of relevant RCTs.
Zhong-cheng 2008 ⁸¹	3 (72 patients)	1990-2007	Oral lichen planus	Pimecrolimus	Limited to pimecrolimus
Elad 2010 ^{82,83}	16 (588 patients)	1948-2010	Oral lichen planus and other oral mucosal conditions	Pimecrolimus Tacrolimus Cyclosporine Retinoids BCG-PSN	A comprehensive systematic review of all immunomodulators and immunosuppressives. Non-randomized trials were considered too.

BCG-PSN, Polysaccharide nucleic acid fraction of bacillus Calmette-Guerin; RCT, randomized controlled trial.

TABLE 16-3—Treatments of CLP

Study	Design	No. of Patients*	Comparators	Therapy Duration	Efficacy Results	Safety Results	Follow-up Duration	Notes
Kellett, 1990 ²⁵	Randomized double-blind placebo-controlled, single center trial	19 vs. 19 (14 vs. 14)	Oral prednisolone 30 mg plus topical hydrocortisone-17-butryrate cream twice daily vs. placebo daily plus topical hydrocortisone-17-butryrate cream twice daily	10 days	Physician VAS severity, patient VAS severity, median time to clearance 18 weeks vs. 29 weeks, Clinical improvement, p<0.05 for all	Mild heartburn: 1/14 vs. 0/14; Euphoria: 1/14 vs. 0/14 euphoria, p>0.05 for both	2 years	All types of LP, Long term follow-up
Laurberg, 1991 ³⁴	Randomized double-blind placebo-controlled, multi center trial	32 vs. 33 (28 vs. 31)	Three capsules (10 mg) of acitretin vs. placebo daily	8 weeks	Clinical improvement: 18/28 (64.3%) vs. 4/31 (12.9%), p<0.05	Dry lips, cheilitis, dry mouth, dry nose, dry skin, scaling, and hair loss were seen more frequently in acitretin group.	No	CLP (with or without OLP) cases were included. Well explained randomization concealment. No wash-off period between phases of the study. No detectable plasma levels of acitretin.
Omidian 2010 ²⁹	Randomized, double-blind, placebo controlled, single center trial	26 vs. 26 (23 vs. 21)	Oral sulfasalazine vs. placebo at initial doses of 1 g/day increasing 0.5 g per 3 days up to 2.5 g/day	3–6 weeks	Clinical improvement: 21/23 (91.3%) vs. 2/21 (9.5%); pruritus 2/23 (8.7%), vs. 18/21 (85.7%), p<0.05 for both	8/26 (nausea, epigastric pain and diarrhea, mild leukopenia, low grade fever, headache, and skin rash (30.7%)) vs. 0/26 (0%), p<0.05; In sulfasalazine group, 3 left the study due to side effects.	No	Generalized LP
Sehgal 1972 ³¹	Randomized, double-blind, placebo controlled, single center trial	19 vs. 19 (17 vs. 17)	Oral griseofulvin vs. placebo 500 mg/day	4–6 weeks	Clinical improvement: 12/17 (70.6%) vs. 6/17 (35.3%), p<0.05	No side effects	No	CLP

(Continued)

TABLE 16-3—Treatments of CLP (Continued)

Study	Design	No. of Patients*	Comparators	Therapy Duration	Efficacy Results	Safety Results	Follow-up Duration	Notes
Glade 1998 ²⁶	Randomized, double-blind, placebo controlled, single center trial	5 vs. 5	KH1060 1µg/g ointment vs. placebo twice daily	8 weeks	Unclear clinical results (no significant difference)	Burning sensation: 1/5 (20%) vs. 3/5 (60%), p>0.05	No	Chronic idiopathic CLP
Boulou 2000 ²⁷	Randomized, double-blind, placebo controlled, single center trial	49 vs. 43 (38 vs. 36)	KH1060 1µg/g of ointment vs. placebo twice daily	8 weeks	Clinical improvement: 14/38 (36.9%) vs. 15/36 (41.7%), p>0.05	No side effects	4 weeks	Non localized CLP
Theng 2004 ²⁸	Randomized, open label, active controlled, single center trial	15 vs. 16	Calcipotriol 50 mg/g versus betamethasone 0.1% ointments twice daily	12 weeks	Thickness improvement: 7/15 (46.7%) vs. 8/16 (50%), p>0.05	Erythema and pruritus: 7/15 (20%) vs. 0/16 (0%), p>0.05	No	Nonfacial CLP

* The numbers in the parenthesis denote the number of patients per group who finished the study. CLP, cutaneous lichen planus; OLP, oral lichen planus; VAS, visual analogue system.

group.²⁵ Other possible adverse events for topical steroids would be local skin atrophy, or telangiectasis. Long-term application of oral corticosteroids may be avoided or reserved for more severe flare-ups.

LIMITATIONS AND COMMENTS: This is a small RCT that proved beneficial additive effects of oral prednisone to topical corticosteroids therapy. Additionally, the therapy duration was short enough to avoid the development of more serious side effects such as bleeding, seizure, or bone fracture.

Retinoids (Acitretin)

Retinoids have been used in medicine for over 50 years. Acitretin is a second-generation retinoid and is taken orally.

EFFICACY: In the only randomized trial, acitretin was shown to be more efficacious than placebo. Twenty-one out of 32 patients (65.6%) in acitretin group and 8 out of 33 (24.2%) in placebo group had clinical improvement.

SAFETY: In the only published RCT, the adverse events were more frequent in acitretin group (87.5% vs. 51.5%)

LIMITATIONS AND COMMENTS: Women must avoid becoming pregnant for at least 2-3 years after discontinuing acitretin because of birth defect concerns. Acitretin interferes with the action of microdose progestin contraceptive pills. Pregnancy tests should be regularly taken while taking acitretin. Safety and efficacy ratio of acitretin should be considered in LP patients.

Vitamin D analogues

Calcipotriol is a vitamin-D analogue, and has around 1% potency of the natural hormone calcitriol or 1,25 dihydroxycholecalciferol. It is mainly used for psoriasis. Additionally, KH1060 is a potent analogue of 1 alpha, 25-dihydroxyvitamin D3.

EFFICACY: Two randomized placebo-controlled trials evaluated the efficacy of KH1060 in CLP and found no significant benefit.^{26,27} One randomized open label trial compared calcipotriol 50 mg/kg with betamethasone 0.1% ointment and addressed no meaningful difference in efficacy.²⁸

SAFETY: At least based on published randomized trials, there is no major adverse event for KH1060. Calcipotriol patients may have more pruritus or erythema.²⁸

LIMITATIONS AND COMMENTS: There is no evidence to support KH1060 for CLP and evidence for calcipotriol needs reconfirmation.

Sulfasalazine

Sulfasalazine is an anti-inflammatory agent that is extensively used in inflammatory bowel disease especially ulcerative colitis. It is also an alternative therapy for rheumatoid arthritis. The ingested form is not active and would be activated into 5-aminosalicylic acid by colonic bacteria.

EFFICACY: One RCT showed successful treatment of generalized LP with sulfasalazine with an efficacy of 91.3% compared to 9% with placebo.²⁹

SAFETY: In the only RCT, eight patients in the sulfasalazine group experienced adverse effects such as nausea, epigastric pain, truncal skin rash, headache, and fever.²⁹ In an uncontrolled study, 4/20 (20%) of patients discontinued sulfasalazine treatment because of more serious adverse events such as gastric pain, poor glycemic control, fever and cutaneous rash.³⁰

LIMITATIONS AND COMMENTS: Based on current literature, sulfasalazine is remarkably effective but not so safe. It should be reserved for widespread disease or severe flare-ups because of intolerable side effects such as nausea, epigastric pain, and fever.

Griseofulvin

EFFICACY: Sehgal et al. found 70.6% efficacy for griseofulvin versus 35.3% for placebo in the only randomized study.³¹ It is in contradiction with the finding of Massa and Rogers that Griseofulvin was a better option for OLP but not for cutaneous lesions.³²

SAFETY: Sehgal et al. reported no side effects for griseofulvin.³¹ This is in contradiction with other studies that reported some side effects in up to 50% of patients.³³

LIMITATIONS AND COMMENTS: Based on the only randomized trial, griseofulvin is an effective drug for LP³¹ but based on other non-randomized studies, the efficacy of this drug is under question.^{32,33}

What are the effects of topical corticosteroids on mucosal LP? (Table 16-4)

Topical corticosteroids are known as first line therapy for LP. They are preferred over systemic corticosteroids, except during acute exacerbations based on expert opinions.

EFFICACY: Nine RCTs were identified for topical steroids. In one trial, triamcinolone acetonide mouthwash was compared to its commercially available 0.1% paste. The

TABLE 16-4—Oral and Topical Corticosteroids for Mucosal LP

Study	Design	No. of Patients*	Comparators	Therapy Duration	Efficacy Results	Safety Results	Post Treatment Follow-up Duration	Notes
Oral Corticosteroids								
Malhorta, 2008 ⁴³	Randomized, open label, active-controlled single center trial	25 vs. 24	5 mg of betamethasone orally for 2 consecutive days per week vs. topical triamcinolone acetonide (0.1%) paste thrice	3+3 months	Good to excellent response: 17/25 (68.0%) vs. 16/24 (66.0%); Symptom-free state 13/25 (52%) vs. 12/24 (50%), relapse 9/23 (39.1%) vs. 5/23 (21.7%), p>0.05 for all	14/25 (56.0%) vs. 6/24 (25.0%), p=0.05	No	Symptomatic OLP, The change in the quality of life with treatment was not measured
Topical Corticosteroids								
Cawson, 1968 ³⁶	Randomized double-blind active-controlled, single center trial	30 vs. 18	Betamethasone valerate (0.1 mg) pellets vs. hydrocortisone (2.5 mg) pellets, QID	4 weeks	Significant improvement: 20/30 (66.6%) vs. 3/18 (16.6%), p<0.05	Candidiasis: 4/30 (13.3%) vs. 0/18 (0%), P>0.05	Up to 3 years (No Follow-up in betamethasone group)	No randomization concealment. In hydrocortisone group, Randomized and non-randomized patients have been mixed.
Tyldesley, 1977 ³⁵	Randomized double-blind placebo-controlled, single center trial	12 vs. 11 (11 vs. 9)	Betamethasone valerate vs. placebo, 2 puffs, QID (0.8 mg)	8 weeks	Moderate to good treatment response: 8/11 (72.7%) vs. 2/9 (22.2%), p<0.05	Candidiasis: 8/11 (72.7%) vs. 7/9 (77.7%), p>0.05. One case of acute pseudomembranous Candidiasis in active group	No	Diagnosis was mainly based on clinical manifestations.
Hegarty, 2002 ³⁷	Randomized, open label, active controlled, single center, crossover trial	22 vs. 22	Fifty µg two-dose unit fluticasone propionate sprays vs. betamethasone sodium phosphate mouthrinse (500 µg), each 4 times daily	6 weeks	Symptomatic improvement (VAS): 15.3 (95% CI:7.8 to 22.8) vs. 11.0 (95% CI:3.8 to 18.2); OHIP: 3.9 (95% CI:1.2 to 6.7) vs. 3.7 (95% CI:0.4 to 7.1; OHQoL: 4.5 (95% CI:1.4 to 7.5) vs. 4.1 (95% CI:1.4 to 6.7), p>0.05 for all	Nausea: 4/22 (18.1%) vs. 0/22 (0%); Bad taste and smell: 6/22 (27.2%) vs. 0/22 (0%); Dry mouth: 2/22 (9.0%) vs. 0/22 (0%) P>0.05 for all	No	Erosive ulcerative OLP
Campisi, 2006 ⁵⁴	Randomized, observer-blinded, parallel group active-controlled clinical single center trial	20 vs. 30 (18 vs. 27)	Clobetasol-17-propionate ((lipid-loaded microspheres 0.025%) compared with clobetasol-17-propionate (lipophilic ointment in a hydrophilic phase 0.025%)	1 month (twice daily) + 1 month (once daily)	VAS pain score (0-100): 22.9 ±21.3 vs. 33.5± 19.5, p=0.05; Clinical improvement: 14/17 (82.4%) vs. 24/28 (85.7%), p>0.05; Appropriate patient compliance: 14/17 (82.3%) vs. 24/28 (85.7%), p>0.05	acute oral candidiasis 1/17 (5.9%) vs. 2/28 (7.1%), p>0.05	5 months	Atrophic-erosive lichen planus ; Appropriate follow-up visits

Carbone, 2009 ³⁹	Randomized, double-blind, placebo-controlled single center trial	18 vs. 17 (15 vs. 15)	Clobetasol propionate 0.025% vs. clobetasol propionate 0.05% twice daily	2 months	No side effects	Atrophic erosive OLP; The patients of both groups received anti- myotic prophylaxis (miconazole 2% gel once daily plus chlorhexidine 0.12% mouth rinse without alcohol 3 times daily).		
	Muzio, 2001 ⁴⁰	Randomized, double-blind, active-controlled single center trial	8 vs. 8 vs. 8	Clobetasol propionate 0.05% ointment 3 times daily vs. clobetasol propionate 0.05% in an adhesive denture paste twice daily vs. clobetasol propionate 0.05% in an oral analgesic base (Orabase-B) twice daily	Up to 15 days	Candidiasis: 1/18 (5.5%) vs. 7/18 (38.9%) vs. 2/18 (11.1%), p<0.05	No	OLP (mainly erosive/ ulcerative)
Ungphaihoon 2005 ³⁴	Randomized, open label, active controlled single center trial	11 vs. 9	Triamcinolone acetonide 0.1% mouth-wash vs. triamcino-lone acetonide 0.1% paste four times daily	4 weeks (1- 16 weeks)	Symptom improvement in, 4 weeks: 10/11 (90.9%) vs. 9/9 (100%); Sign improvement: 10/11 (90.9%) vs. 9/9 (100%), p>0.05 for both	Candidiasis: 0/11 (0%) vs. 2/9 (22.2%), p>0.05	Unclear	Symptomatic OLP
Buajeeb, 2000 ⁴²	Randomized, open-label, active- controlled, single center trial	15 vs. 15 vs. 18	Fluocinolone acetonide 0.1% gel (with carbopol resin 1% vs. 0.5%) vs. fluocinolone acetonide in orabase 0.1% four times daily	4 weeks	Clinical improvement: 13/15 (86.6%) vs. 13/15 (86.6%) vs. 15/18 (83.3%), p>0.05	Candidiasis: 0/15 (0%) vs. 0/15 (0%) vs. 1/18 (5.5%), p>0.05	No	Erosive/atrophic OLP included
Voute 1993 ⁴¹	Randomized, double-blind, placebo- controlled, single center trial	20 vs. 20	Fluocinonide 0.025% ointment vs. placebo 6 times daily	9 weeks	Sign improvement: 16/20 (80%) vs. 6/20 (30%), p<0.05; sign improvement for erosive OLP: 10/14 (71.4%) vs. 6/13 (46.1%), p>0.05; Symptom improvement: 18/20 (90%) vs. 12/20 (60%), p=0.06	No side effects	No	OLP

* The numbers in the parenthesis denote the number of patients per group who finished the study.
QID, four times a day; OLP, oral lichen planus; VAS, visual analogue system OHQoL, oral health impact profile; OHQoL, oral health quality of life.

results were comparable in improving signs and symptoms.³⁴ Betamethasone valerate aerosol had remarkable clinical improvement in 72.7% of patients, whereas placebo achieved 22.2%.³⁵ On the other hand, betamethasone valerate pellets were found to be superior to hydrocortisone pellets (66.6% vs. 16.6%, respectively).³⁶ Furthermore, betamethasone sodium phosphate mouth rinse was comparable to fluticasone propionate spray in a 6-week clinical trial in terms of symptomatology improvement, McGill pain score, oral health impact profile and quality of life.³⁷ Clobetasol-17-propionate is a superpotent corticosteroid. Two different formulations of Clobetasol-17-propionate including lipid-loaded microspheres 0.025% and lipophilic ointment in a hydrophilic phase 0.025% were compared with each other. Both had similar efficacy, except for the ability to alleviate pain with the former formulation worked better.³⁸ In another RCT, 0.025% and 0.05% concentrations of clobetasol propionate were evaluated. Both concentrations had remarkable effects on erosive-atrophic OLP. Relapse occurred more frequently with the lower concentration.³⁹ Muzio et al. investigated three different preparations of clobetasol propionate (0.05% ointment three times daily versus 0.05% in an adhesive denture paste twice daily versus 0.05% in Orabase-B twice daily) for erosive-ulcerative OLP. They found that clobetasol propionate in an adhesive denture paste would have the best efficacy results.⁴⁰ Voute et al. addressed the remarkable clinical efficacy of fluocinonide 0.025% in adhesive paste in a randomized placebo-controlled study.⁴¹ It was shown that fluocinolone acetonide gel 0.1% in two different base forms and fluocinolone acetonide 0.1% in orabase has similar efficacy and safety.⁴²

SAFETY: Candidiasis is the most common adverse effect. Some studies did use antimycotic agents to prevent fungal oral infections and that is the reason for inconsistent results. In a study, Muzio et al. addressed the fact that candidiasis occurs more frequently with clobetasol propionate in an adhesive denture paste as oppose to the other forms.⁴⁰ Nausea and dry mouth can develop with more potent topical steroids. Longer durations of therapy can cause more serious local effects such as skin atrophy.

LIMITATIONS AND COMMENTS: Betamethasone valerate and fluocinonide 0.025% ointment are the only topical corticosteroid that has been compared with placebo for OLP.

What are the effects of systemic corticosteroids on mucosal LP? (Table 16-4)

EFFICACY: Malhotra et al.⁴³ randomized the patients to receive either oral mini-pulse therapy of betamethasone 5 mg for

2 consecutive days weekly or triamcinolone acetonide (0.1%) paste thrice daily for 3 months followed by stepwise tapering during the next 3 months. Symptomatology cure was achieved in 52% versus 50% of patients, respectively. Good to excellent clinical response was noted in 68% versus 66% of patients, respectively.

SAFETY: Patients on mini pulse therapy of oral beta-methasone had more side effects (56%) in comparison with triamcinolone acetonide paste (25%), P<0.05.⁴³

LIMITATIONS AND COMMENTS: There is not enough evidence-based literature to support the idea of using systemic corticosteroids for mucosal LP. This study shows evidence that oral mini-pulse corticosteroid therapy can be as effective as topical triamcinolone paste. Betamethasone oral mini-pulse treatment can achieve clinical response faster than topical medication but with more safety concerns and quicker relapse. Hence, it may help to alleviate severe flare-ups.

What are the effects of calcineurin inhibitors on mucosal LP? (Table 16-5)

Calcineurin inhibitors (immunomodulators) belong to the azomycin class of macrolactam immunosuppressives, acting by the inhibition of T-cell activation via the calcineurin pathway and inhibition of the release of numerous inflammatory chemokines, and therefore acting as anti-inflammatory and immunomodulator agent. The mechanism of action of pimecrolimus and tacrolimus is similar but it is more selective for pimecrolimus as it has no effect on dendritic (Langerhans) cells.⁴⁴ It has lower permeation through the skin than topical steroids or topical tacrolimus, although they have not been compared with each other for their permeation ability through mucosa.⁴⁵ On the other hand, tacrolimus is more potent.

Pimecrolimus

EFFICACY: Four placebo-controlled RCTs⁴⁶⁻⁴⁹ were appraised for pimecrolimus 1% cream with a total of 72 evaluable erosive OLP patients. Pimecrolimus is at least more effective than placebo in curing the erosive lesions (odds ratio of 10.41 [95% CI, 1.84-58.97], P=0.008), but not necessarily in improving symptoms such as VAS pain scores (mean difference of 0.42 [95% CI, -2.11-2.95], P>0.05). On the other hand, pimecrolimus was as effective as triamcinolone acetonide paste according to one study.⁴⁵

SAFETY: Meta-analysis of all four studies revealed that burning sensation occurs more frequently with pimecrolimus than placebo (odds ratio of 7.67 [95% CI, 1.24-47.36], P=0.03) or triamcinolone acetonide.⁴⁵

TABLE 16-5—Calcineurin Inhibitors for Mucosal LP

Study	Design	No. of patients*	Comparators	Therapy Duration	Efficacy Outcomes [†]	Safety Results	Post Treatment Follow-up Duration	Notes
Swift 2005 ⁴⁸	Randomized, double-blind, vehicle-controlled, single-center trial	10 vs. 10	Pimecrolimus 1% cream vs. placebo	4 weeks	Ulceration (area, mm ²), Erythema (area, mm ²), VAS discomfort score	1/10 (10%, burning sensation) vs. 0/10 (0%), P>0.05	No	Erosive OLP, Short treatment duration
Passeron 2007 ⁴⁷	Randomized, double-blind, vehicle-controlled, single-center trial	6 vs. 6	Pimecrolimus 1% cream vs. placebo	4 weeks	Mean physician assessment	2/6 (33.3%, burning sensation) vs. 0/6 (0%), P>0.05	Not clear	Erosive OLP, Small sample size, Short treatment duration, Detectable pimecrolimus plasma levels
Volz 2008 ⁴⁹	Randomized, double-blind, vehicle-controlled, single-center trial	10 vs. 10	Pimecrolimus 1% cream vs. placebo	4 weeks	Investigator's global assessment, Ulceration, Erythema	5/10 (50%, 4 burning sensation cases), vs. 1/10 (10%, no burning sensation cases), P>0.05	4 weeks (only responding patients)	Erosive OLP, Short treatment duration
McCaughay 2010 ⁴⁶	Randomized, double-blind, vehicle-controlled, single-center trial	10 vs. 11 (8 vs. 11)	Pimecrolimus 1% cream vs. placebo	6 weeks	Investigator's global assessment: Pain, erythema, erosion	Drug-related adverse event 0/10 (0%) vs. 1/11 (9%), p>0.05	No	Erosive OLP, Detectable pimecrolimus plasma levels in 9 out of 10 cases
Gorouhi 2007 ⁴⁵	Randomized, investigator-blind, active-controlled, single-center trial	20 vs. 20 (18 vs. 17)	Pimecrolimus 1% cream vs. triamcinolone acetonide 0.1% paste QID	8 weeks	VAS pain score, Oral Health Impact Profile score, Thongprasom Clinical score	2/20 (10%, burning sensation) vs. 0/20 (0%), P>0.05	8 weeks	OLP; Pimecrolimus plasma levels were not measured. Assessor blind only. Chlorhexidine mouthrinse were added to prevent candidiasis
Laeijendecker 2006 ⁵²	Randomized active-controlled, single center trial	20 vs. 20	Tacrolimus 0.1% ointment vs. triamcinolone acetonide 0.1%	6 weeks	Clinical improvement	8/20 (40%) vs. 3/20 (15%), p>0.05; Recurrent headaches were reported.	Mean: 14-15 months	Symptomatic OLP, No Evidence of study blindness, No measurement of tacrolimus plasma level

(Continued)

TABLE 16-5—Calcineurin Inhibitors for Mucosal LP (Continued)

Study	Design	No. of patients*	Comparators	Therapy Duration	Efficacy Outcomes[†]	Safety Results	Post Treatment Follow-up Duration	Notes
Corrocher 2008 ⁵¹	Randomized double-blind active-controlled, single center trial	16 vs. 16	Tacrolimus 0.1% ointment vs. clobetasol propionate 0.05% ointment four times daily	4 weeks	Median pain score, Median score of burning, sensation, Median mucosal extension	9/16 (56.2%, transient burning sensation) vs. 0/16 (0%), p<0.05	2 weeks	Moderate to severe OLP, Short duration of treatment Undetectable plasma levels of tacrolimus.
Radfar 2008 ⁵⁰	Randomized double-blind active-controlled, single center trial	15 vs. 15	Tacrolimus 0.1% ointment vs. clobetasol 0.05%, ointment [#]	6 weeks	0–10 pain VAS score, Lesion size, Clinical response	No side effects	9 months	Erosive/ulcerative OLP; Nystatin oral rinse was applied to prevent candidiasis.
Eisen 1990 ⁵³	Randomized double-blind placebo-controlled, single center trial	8 vs. 8	Cyclosporine 0.1% moth rinse (1500 mg/day) vs. placebo	8 weeks	Erythema, Erosions, Reticulation, Symptoms (pain)	16/16 (100%, Burning sensation) vs. 8/8 (100%, Burning sensation), Precipitation of the solution: 12/16 (75%) vs. 3/8 (37.5%), P>0.05 for both	Up to 6 months	Symptomatic OLP; Plasma levels of cyclosporine reached to 150 ng/ml; Small sample size
Conrotto 2006 ⁵⁴	Randomized double-blind active-controlled, single center trial	20 vs. 20	Cyclosporine 1.5% ointment (26 mg/day) vs. clobetasol 0.025% ointment, twice daily	8 weeks	Clinical improvement, Symptomatology	Adverse events: 6/20 (30%) vs. 1/20 (5%), p<0.05	8 weeks	Atrophic/eruptive OLP; Plasma levels of cyclosporine were undetectable; Miconazole gel and chlorhexidine mouthrinse were added to prevent candidiasis.
Yoke 2006 ⁸⁵	Randomized active-controlled, single center trial	68 vs. 71	Cyclosporine 0.1% solution vs. triamcinolone acetonide 0.1% in orabase 3 times daily	8 weeks	Clinical improvement	14/68 (20.5%, Burning sensation) vs. 3/71 (4.2%, p<0.05); GI problems: 4/68 (5.8%) vs. 0/68 (0%, p>0.05); One case of swelling and itching of lips was reported in cyclosporine group.	No	Plasma levels of cyclosporine reached to 340 ng/ml. Randomization concealment was clearly stated. Blindness is not clear.

Sieg 1995 ⁸⁶	Randomized investigator-blind active-controlled, single center trial	6 vs. 7	Cyclosporine 0.1% solution vs. triamcinolone acetonide 0.1% in orabase 3 times daily	6 weeks	Clinical Improvement, Complete response	0/6 (0%) vs. 3/7 (42.8%, Burning sensation), p>0.05	One year	One patient with abnormal plasma levels of cyclosporine due to swallowing the drug; Small sample size; The results were not reported explicitly.
Thongprasam 2007 ⁸⁷	Randomized blind active-controlled, single center trial	6 vs. 7	Cyclosporine 0.1% solution vs. triamcinolone acetonide 0.1% in orabase 3 times daily	8 weeks	Clinical improvement	4/6 (66.6%, Burning sensation) vs. 0/7 (0%); Gastrointestinal discomfort, Breast tenderness, Dizziness, Itching, swelling lips, and Petechial Hemorrhages	One year	One patient with transient abnormal plasma levels of cyclosporine; Small sample size Comparability of the baseline data is uncertain.

* The numbers in the parenthesis denote the number of patients per group who finished the study.

† Efficacy results have been presented in Figures 14-3, 14-4, and 14-5.

‡ 4 times/day for 2 weeks followed by 3 times/day for 2 weeks, 2 times/day for 1 week, and 1 timer/day for 1 week CLP, cutaneous lichen planus; QID, four times a day; OLP, oral lichen planus; VAS, visual analogue system.

LIMITATIONS AND COMMENTS: Pimecrolimus is effective in erosive OLP with limited transient side effects (burning sensation). Its effect size can reach as high as triamcinolone paste. Future studies should focus on maintenance therapy of chronic refractory OLP with this agent and document its safety profile. Moreover, it is important to compare pimecrolimus and tacrolimus in the treatment of mucosal LP.

Tacrolimus

EFFICACY: Two RCTs compared tacrolimus 0.1% with clobetasol propionate 0.05% ointment.^{50,51} Based on data pooling, tacrolimus improve the signs of OLP better than clobetasol propionate (15.84 [0.12, 85.20], p=0.0009). Another RCT, evaluated the efficacy of tacrolimus 0.1% ointment to triamcinolone acetonide 0.1%. Tacrolimus was more potent than triamcinolone (clinical improvement: 90% vs. 45%, respectively).⁵²

SAFETY: Corrocher et al. reported 56.2% and 0% side effects in tacrolimus and clobetasol groups, respectively.⁵¹ A similar trend was observed when tacrolimus was compared to triamcinolone (40% vs. 15%, respectively).⁵² Radfar et al. found no side effects in either group.⁵⁰ Meta-analysis of data showed inconsistent results in this regard.

LIMITATIONS AND COMMENTS: Burning sensation is the main side effect. It resolves quickly and is noted more frequently with tacrolimus than topical corticosteroids. Tacrolimus is more potent than clobetasol in terms of clinical improvement. Tacrolimus is recommended as second line therapy for mucosal LP lesions with limited response to corticosteroids.

Cyclosporine

Cyclosporine was initially isolated from the fungus *tolypocladium inflatum* isolated from a soil sample obtained by Sandoz scientists at Hardangervidda, Norway in 1969.

EFFICACY: There are five RCTs for cyclosporine in treatment of mucosal LP. The routine dose of cyclosporine was 100 mg/mL. Cyclosporine showed improvement in pain, erosion, reticulation, and erythema when compared to placebo.⁵³ When compared to clobetasol, cyclosporine was less effective (65% vs. 95%). However, cyclosporine and clobetasol had similar effects on symptom relief.⁵⁴ Three studies investigated the efficacy and safety of cyclosporine and triamcinolone acetonide 0.1% in orabase. The relatively higher efficacy of triamcinolone is established (odds ratio of 0.46 [95% CI, 0.25-0.87], p=0.02) in addition to fewer side effects (odds ratio of 10.88 [95% CI, 3.34-35.41], P<0.0001).

SAFETY: Burning sensation, swelling, and itching of the lips are the most common symptoms.

LIMITATIONS AND COMMENTS: Although it has been shown in one trial that cyclosporine is better than placebo, triamcinolone and clobetasol were proven to be more effective than cyclosporine.

What are the effects of retinoids on mucosal LP? (Table 16-6)

Isotretinoin

EFFICACY: Two relevant RCTs were recognized. Isotretinoin 1% gel and placebo gel improved the clinical signs in 90% and 10% of OLP patients, respectively.⁵⁵ Scardina et al. compared two concentrations of isotretinoin gel (0.18% and 0.05%). They did not differ significantly with regards to symptom relief, however, the higher concentration cured the erosions in 74.3%, whereas the 0.05% gel had the same effect in 25.7% of patients.⁵⁶

SAFETY: Burning, stinging, superficial desquamation, erythema^{55,56} and photosensitivity can occur.

LIMITATIONS AND COMMENTS: Efficacy of isotretinoin gel on erosions is inconsistent and needs further confirmation.

Tretinoin

EFFICACY: One placebo-controlled RCT noted a significantly higher cure rate in tretinoin 0.1% group.⁵⁷ In a pseudo-randomized trial, tretinoin 0.05% was compared to fluocinolone acetonide 0.1%. Fluocinolone was superior to tretinoin for clinical improvement and pain, however, they were comparable for the treatment of erosive lesions.⁵⁸

SAFETY: Oral dryness and irritation were reported.⁵⁸

LIMITATIONS AND COMMENTS: Tretinoin 0.1% may be considered as an alternative.

Etretinate

Etretinate was approved by the FDA in 1986 for severe psoriasis.

EFFICACY: One placebo-controlled RCT showed remarkable clinical response in etretinate group.⁵⁹

SAFETY: Severe side effects were observed in six patients (out of 23). Side effects of chopped lips and dry skin occurred in all etretinate treated patients. Furthermore, etretinate increased ALT levels in three patients.⁵⁹

LIMITATIONS AND COMMENTS: Etretinate was subsequently removed from the United States market in 1998 because of the high risk of birth defects and it is not recommended.

TABLE 16-6—Retinoids for Mucosal LP

Study	Design	No. of Patients*	Comparators	Therapy Duration	Efficacy Results	Safety Results	Post Treatment Follow-up Duration	Notes
Oral Retinoids								
Hersl 1982 ⁵⁹	Randomized double-blind placebo-controlled, single center, cross-over trial	14 vs. 14 (10 vs. 14)	Etretinate 75 mg vs. placebo daily	8 weeks	Clinical improvement: 12/14 (85.7%) vs. 2/25 (8%), p<0.05	Severe side effects: 6/23 (26%) vs. 0/14 (0%), p<0.05; Dry cheilitis plus dry scaly skin: 23/23 (100%) vs. 0/14 (0%) p<0.05; Increased ALAT levels: 3/23 (13%) vs. 0/14, (0%), p>0.05	3 months	Non-responsive OLP
Topical Retinoids								
Scardina 2006 ⁵⁶	Randomized open label, active-controlled, single center trial	35 vs. 35	Isotretinoin 0.18% gel vs. isotretinoin 0.05% gel twice daily	3 months	Disappearance of erosive/atrophic lesions: 26/35 (74.3%) vs. 9/35 (25.7%), p<0.05; 0-10 pain VAS score: 0 vs. 4, p>0.01	No side effects except transient increased burning sensation and pain within 30 minutes after drug application	10 years (ongoing)	OLP
Giustina 1986 ⁵⁵	Randomized double-blind placebo-controlled, single center trial	11 vs. 11 (10 vs. 10)	Isotretinoin 0.1% gel vs. vehicle gel twice daily	8 weeks	Clinical improvement (0-5 scale): 9/10 (90%) vs. 1/10 (10%), p<0.05; Symptom free: 5/6 (83%) vs. 3/6 (50%), p>0.05	Transient burning in all patients in both groups, Superficial desquamation and erythema with isotretinoin group	No	OLP; Well explained randomization, concealment, No detectable plasma levels of isotretinoin, Less impressive results for erosive OLP.
Boisnic 1994 ⁵⁷	Randomized double blind, placebo-controlled, single center trial	10 vs. 10	Tretinoin 0.1% ointment vs. placebo ointment twice daily	4 months	Clinical improvement after 2 months: 8/10 (80%) vs. 5/10 (50%), p>0.05; clinical improvement after 4 months: 9/10 (90%) vs. 4/10 (40%), p=0.05; Complete cure after 2 months: 3/10 (30%) vs. 1/10 (10%), p>0.05; Complete cure after 4 months: 7/10 (70%) vs. 1/10 (10%), p<0.05	Generally transient burning sensation in both groups with 2 patients with dry mouth, p>0.05%	4 months	OLP; Erosive cases were excluded. No detectable plasma levels of isotretinoin.

* The numbers in the parenthesis denote the number of patients per group who finished the study. OLP, oral lichen planus; VAS, visual analogue system.

What are the effects of aloe vera on mucosal LP? (Table 16-7)

Aloe vera Linne is a succulent from the Aloe family. The use of aloe vera is being promoted for a large variety of conditions.

EFFICACY: Three randomized placebo-controlled trials were found in this regard. Choonhakarn et al.⁶⁰ and Salazar-Sanchez et al.⁶¹ assessed aloe vera in OLP and Rajar et al.⁶² in vulvar LP. We pooled the data for clinical response (odds ratio of 20.85 [95% CI, 7.79-55.81], p<0.00001). There is a significant trend toward effectiveness of aloe vera in comparison with placebo for mucosal LP.

SAFETY: In all three trials, only two patients in the aloe vera group encountered an adverse event and the meta-analysis showed no difference between aloe vera and placebo (odds ratio of 5.39 [95%CI, 0.25-117.77], p>0.05)

LIMITATIONS AND COMMENTS: There is no standard dose of aloe vera for mucosal LP. Rajar et al. published the only randomized trial for vulvovaginal LP.⁶²

What are the effects of other treatments on LP? (Table 16-8)

PUVA

PUVA is a combination therapy that consists of psoralen treatment plus UVA exposure. It is mainly used for psoriasis and vitiligo

EFFICACY: One randomized open label within patient trial compared the effects of PUVA therapy with control. After 12 sessions of PUVA therapy, the lesions remarkably healed (81.7%) compared to the control lesions (37.5%).⁶³

SAFETY: PUVA causes limited systemic adverse events like nausea, dizziness, photosensitivity, headache, and paresthesia.

LIMITATIONS AND COMMENTS: PUVA therapy is not the most convenient therapeutic option for LP patients because they need to travel to the phototherapy center for each treatment session. More importantly, PUVA increases the

TABLE 16-7—Aloe Vera for Mucosal LP

Study	Design	No. of Patients	Comparators	Therapy Duration	Efficacy Outcomes*	Safety Results	Post Treatment Follow-up Duration	Notes
Choonhakarn 2008 ⁶⁰	Randomized, double-blind, placebo-controlled, parallel, single center trial	27 vs. 27	Aloe vera gel vs. placebo gel twice daily	8 weeks	Clinical response (Thong-prasom score), 0-10 VAS pain score	2/27 (7.4%, mild itching) vs. 0/27 (0%), p>0.05	No follow-ups	OLP (2 had CLP too)
Rajar 2008 ⁶²	Randomized, double-blind, placebo-controlled, parallel single center trial	17 vs. 17	Aloe vera gel vs. placebo gel twice daily	8 weeks	Clinical response (Thongprason score)	No side effects	No follow-ups	Vulvar LP (5 had CLP too) Control gel did not contain the baseline ingredients of the active gel.

TABLE 116-8—Calcineurin Inhibitors for Mucosal LP (Continued)

Study	Design	No. of patients*	Comparators	Therapy Duration	Efficacy results	Safety results	Post Treatment Follow-up Duration	Notes
Xiong 2009 ⁶⁵	Randomized active controlled, assessor-blind, single center trial	31 vs. 25 (27 vs. 22)	Intralesional injection of 0.5 ml BCG-PSN every other day vs. intralesional injection of 10 mg triamcinolone acetonide every week	2 weeks	Clinical cure: 27/31 (87.0%) vs. 22/25 (88%); Erosive area: 27.86±27.97 vs. 25.68±34.65; VAS score: 2.45±1.64 vs. 2.40±1.38, p>0.05 for all	3/31 (9.7%) vs. 2/25 (8.0%), p>0.05	3 months	Erosive LP, Sufficient follow-up duration
Wu 2010 ⁶⁶	Randomized, active-controlled, double-blind, single center trial	37 vs. 32 (18 vs. 17)	Thalidomide 1% paste vs. dexamethasone 0.043% paste, three times daily	1+3 weeks	0-10 VAS pain score: 2.77±2.00 vs. 2.88±1.45, p>0.05; Erosion free: 18/33 (54.5%) vs. 17/30 (56.6%), p>0.05	Burning sensation: 2/37 (5.4%) vs. 2/32 (6.3%), p>0.05	3 months for recurrence, 12 months for adverse events	Erosive OLP
Agha-Hosseini 2009 ⁶⁶	Randomized double-blind, placebo controlled, multicenter trial	20 vs. 17	Single dose of Purslane (235 mg) vs. placebo	1 day	Clinical improvement: 17/20 (85.0%) vs. 3/17 (17.6%), p<0.05; Symptom relief 20/20 (100%) vs. 12/17 (70.5%), p<0.05	No side effects	6 months	Mucosal LP (mainly OLP), long term follow-up
Nolan 2009 ⁷⁵	Randomized, double-blind, placebo controlled, single center trial	62 vs. 62 (113)	Hyaluronic acid 0.2% gel vs. placebo 4-5 times daily	4 weeks	Pain VAS, p>0.05; erosive / ulcerated area: -3.1±0.7 vs. -2±0.7, p<0.05	No side effects	No	Atrophic/erosive OLP
Mousavi 2009 ⁷⁴	Randomized investigator-blind, placebo controlled, single center trial	15 vs. 15	Single dose of Ignatia vs. placebo every month	4 months	Lesion size: 2.2 vs. 4.3, p<0.05; VAS pain score: 1.3 vs. 4, p<0.05	No side effects	No	Atrophic/erosive OLP; No standard deviation was reported for all mean values.
Lin 2005 ⁷³	Randomized open label, active controlled, single center trial	47 vs. 47	Tripterygium hypoglaicum tablet (2.7 gr/day) vs. Tripterygium glycosides tablet (1-1.5mg/kg/day)	3 months	Erosion improvement: 41/47 (87.2%) vs. 29/47 (61.7%), p<0.05; For ulcerative subtype: 18/21 (85.7%) vs. 11/21 (52.3%), p<0.05	Menstrual disturbance: 6/24 (25%) vs. 0/22 (0%), p<0.05; Leukocytopenia: 1/47 (2.1%) vs. 0/47 (0.0%), p>0.05	No	Erosive OLP; The study lacks a proper control group (placebo or an established therapy for OLP)

* The numbers in the parenthesis denote the number of patients per group who finished the study.
BCG-PSN, Polysaccharide nucleic acid fraction of bacillus Calmette-Guerin; CLP, cutaneous lichen planus; OLP, oral lichen planus; PUVA, psoralen plus ultraviolet A; VAS, visual analogue system.

risk of squamous cell carcinoma and this can magnify OLP's malignant potential. Because of PUVA's side effects and aforementioned concerns, it should be reserved for generalized LP or refractory erosive OLP cases. Furthermore, narrowband UVB phototherapy can be considered as an alternative.

Thalidomide

Thalidomide, or alpha-Phthalimido Glutarimide, is a racemic glutamic acid derivative synthesized in Germany in 1956 by Kunz, Keller, and Muckter. Topical thalidomide has been used for aphthous stomatitis, graft versus host disease, and chronic discoid lupus erythematosus.

EFFICACY: Wu et al. have demonstrated comparable efficacy results of thalidomide 1% paste and dexamethasone 0.043% paste for erosive OLP.⁶⁴

SAFETY: It was a 1-4 weeks thalidomide treatment period and the investigators observed no major side effects. The frequency of burning sensation was the same as dexamethasone group.⁶⁴

LIMITATIONS AND COMMENTS: Oral thalidomide has several serious adverse effects (e.g., teratogenicity, neurotoxicity, and venous thromboembolic events). Moreover, there is no long-term follow-up study and/or phase 4 clinical trials for topical thalidomide to prove its efficacy and safety. Thus, topical thalidomide 1% should be reserved as a second or third line short-term medication.

Polysaccharide nucleic acid fraction of bacillus Calmette-Guerin (BCG-PSN)

Bacillus Calmette-Guerin polysaccharide nucleic acid (BCG-PSN), the third-generation BCG extract with various immunologic active materials including polysaccharide and nucleic acid, has the ability to regulate the subsets of T cells (CD4 and CD8 cells) and subtypes of helper T cells (Th1 and Th2).⁶⁵

EFFICACY: In one trial, BCG-PSN was compared with triamcinolone intralesionally and 87% versus 88% of patients had clinical cure, respectively.⁶⁵

SAFETY: Burning sensation and swelling occurred in 9.7% of patients in the BCG-PSN group versus 8% of patients in triamcinolone group.⁶⁵

LIMITATIONS AND COMMENTS: Generally, intralesional injections can be used for non-healing hypertrophic or erosive lesions. BCG-PSN can be considered in this regard.

Purslane

Portulaca oleracea (Purslane) is an annual succulent in the family Portulacaceae. It contains several biologically

active compounds including omega-3 fatty acids, minerals, β-carotene, melatonin and vitamins A, C and E.⁶⁶

EFFICACY: One randomized placebo-controlled study, proved a dramatic effect of single dose Purslane (235 mg) even after 6 months.⁶⁶

SAFETY: No side effects were reported. Purslane should be used with caution in patients with kidney stones.⁶⁶

LIMITATIONS AND COMMENTS: More trials on this remedy for OLP would be of interest and may support its use as a second line therapy.

Curcuminoid

Curcuminoid is a curcumin and/or a derivative of curcumin with different chemical groups that are formed to increase solubility of curcumins and make them suitable for drug formulation.⁶⁷

EFFICACY: Chainani-Wu et al. showed no difference between curcuminoid plus oral prednisone versus oral prednisone only.⁶⁸

SAFETY: No curcuminoid-related side effect was observed.⁶⁸

LIMITATIONS & COMMENTS: Such a design to investigate the additive effects of curcuminoid to 60 mg oral prednisone may underestimate the efficacy of curcuminoid. Curcuminoids cannot be recommended for mucosal LP.

Miconazole

Miconazole, an antifungal agent, is mainly used for skin infections such as athlete's foot, tinea cruris and vaginal yeast infections.

EFFICACY: Miconazole 2% gel once daily plus clobetasol propionate 0.05% twice daily treatment had a similar clinical response comparable with clobetasol propionate 0.05% only treatment.⁸⁸

SAFETY: Oral candidiasis occurred in 0% versus 50% of patients with or without miconazole treatment, respectively.⁸⁸

LIMITATIONS AND COMMENTS: Miconazole is recommended to avoid candidiasis in mucosal LP but is not recommended as a therapeutic agent for LP lesions.

Mesalazine

Mesalazine or 5-aminosalicylic acid (5-ASA), is an anti-inflammatory drug used to treat inflammatory bowel diseases such as ulcerative colitis and mild-to-moderate

Crohn's disease. Mesalazine is a bowel-specific aminosalicylate drug that acts locally in the gut and has its predominant actions there, thereby having few systemic side effects.⁶⁷ It is also the active component of sulfasalazine.

EFFICACY: One RCT compared mesalazine 5% gel with clobetasol propionate 0.05% and found similar efficacy.⁶⁹

SAFETY: Sardella et. al. noted no side effect with mesalazine.⁶⁹

LIMITATIONS AND COMMENTS: As other studies reported that gastric side effects occurred after using higher concentrations of mesalazine gel or foam,^{70,71} long-term follow-up studies are needed to ascertain its safety for mucosal LP.

Low-level laser therapy

Low-level laser therapy (LLLT) is a controversial modality treatment that uses low-level lasers or light-emitting diodes to alter cellular function.

EFFICACY: One randomized trial found comparable clinical improvement rate for low level diode laser and dexamethasone mouth rinse for atrophic/erosive OLP.⁷²

SAFETY: Low-level laser has no major side effect.⁷²

LIMITATIONS & COMMENTS: Historically, this modality has been debatable and controversial for different applications. More evidence is needed for mucosal LP.

Tripterygium

“Tripterygium Hypoglaucum” tablet is a purified product of the effective ingredients of decorticated radix tripterygium hypoglaucum, which is extracted in boiling water and precipitated by alcohol. This purification technique is different from that of making “tripterygium glycosides”, and can reduce the toxic ingredients in the preparation process. The good thing about both traditional Chinese herbs is that they do not act like glucocorticoids and therefore can be used as alternatives to corticosteroids in different diseases or in conditions like facial addiction to topical corticosteroid.⁷³

EFFICACY: One randomized open label trial compared these two herbs with each other. It seems that tripterygium glycosides is significantly more effective than tripterygium hypoglaucum in healing the erosive-ulcerative lesions whereas tripterygium hypoglaucum has a better safety profile.⁷³

SAFETY: Tripterygium glycosides can cause menstrual disturbances (25%) and leukocytopenia (2%). Tripterygium hypoglaucum can cause fewer side effects.⁷³

LIMITATIONS AND COMMENTS: There was no placebo control or a topical or oral corticosteroid control in this study. Hence, none of them may be recommended for mucosal LP.

Ignatia

Ignatia is a homeopathic remedy that is derived from the bean of a small tree that is native to the Philippine Islands and China.

EFFICACY: There is only one placebo-controlled trial for ignatia. It reported a significant effect of ignatia on lesion size and pain score.⁷⁴

SAFETY: No side effects were reported for ignatia.⁷⁴

LIMITATIONS AND COMMENTS: The presentation of the data is not sufficient to conclude a definitive effect.

Hyaluronic acid

Hyaluronic acid (HA) is one of the chief components of the extracellular matrix. It has a relatively short half-life and that is why several efforts have been made to optimize its stability. It has been approved as a drug for corneal and epithelial wound healing.

EFFICACY: One double blind randomized trial compared (HA) 0.2% with placebo and found that HA 0.2% can be partially helpful, especially in short term periods (less than 4 hours), in relieving the symptoms. It also had no effect on erosion size after 28 days when compared with placebo. Additionally, 0.2% HA had no effect on the extent and severity of the OLP as described by Thongprasom's criteria.⁷⁵

What We Know: CLP

- The high quality evidence is extremely lacking for CLP. There is an emergent need for conducting randomized-controlled trials.
- Primary treatment options for mild to moderate CLP would be topical corticosteroids and immunomodulators but there is no strong evidence to support them. Only one study supports the additive effects of oral prednisone to topical hydrocortisone-17-butyrate.
- For generalized LP or resistant cases, systemic corticosteroids, immunosuppressive drugs, PUVA, or biologics can be administered. However, there is no supporting evidence for this.
- Life-long clinical follow-up is fundamental.

What We Know: Mucosal LP

- Currently, the main therapeutic goal in the treatment of mucosal LP is not immediate complete cure. The main focus should be on relieving pain and discomfort in the mouth during talking, eating, drinking, and genitalia during intercourse.
- Although topical corticosteroids are considered as the mainstay of mucosal LP therapy, only two of them have been proven to be more beneficial than placebo.
- Calcineurin inhibitors can be considered as second line therapy. Tacrolimus is more effective than clobetasol and triamcinolone in two RCTs. Cyclosporine and pimecrolimus are at least as effective as topical corticosteroids. Relapse can occur in many patients after tacrolimus and pimecrolimus treatment.
- Topical retinoids are more effective than placebo.
- Aloe vera may be beneficial in the treatment of mucosal LP. The only RCT that assessed vulvovaginal LP patients found aloe vera useful.
- Life-long clinical follow-up is fundamental.

SAFETY: It is a relatively safe therapeutic option at a 0.2% concentration.

LIMITATIONS & COMMENTS: The efficacy of HA is under question. It may only be considered as a supportive component of a combination therapy. It has to be applied in a frequent fashion to maintain its efficacy (e.g. 6 times a day). It warrants further investigation.

Treatment of Pemphigus

Deshan F. Sebaratnam, M.B.B.S. (Hons),
Dedee F. Murrell, M.A., B.M.B.Ch, F.A.A.D., M.D., F.A.C.D., and
Victoria P. Werth, M.D.

BACKGROUND

Pemphigus is a group of rare autoimmune bullous diseases caused by the dissociation of keratinocytes, leading to the formation of bullae and erosions. It is a chronic, potentially life-threatening condition characterized by widespread blistering of the skin and mucous membranes.

EPIDEMIOLOGY

The incidence of pemphigus has been estimated between 1 to 10 new cases per million people per year¹ with some genetic variance observed. For instance, the incidence is higher in Japanese, Indian, Arabic, and Ashkenazi Jewish populations compared to that observed in North America or Western Europe with HLA class II alleles potentially involved in the pathogenesis of pemphigus.² Sex distribution is equal across men and women, and the disease most commonly starts in adulthood.

ETIOLOGY

Pemphigus is an organ-specific autoimmune disease. The exact pathophysiologic mechanisms underlying the derangements in immunity have yet to be elucidated, however, the disease is characterized by the production of autoantibodies directed against desmogleins, transmembrane proteins located on desmosomes responsible for cell-to-cell adhesion, leading to acantholysis.

The clinical phenotype of pemphigus depends on the tissue distribution of the particular desmoglein that autoantibodies are directed against. Desmoglein 1 is distributed in the granular epidermal layer and limited to the skin, while desmoglein 3 is located in the basal epidermis and found in both the skin and mucous membranes. The clinical picture depends on which desmogleins are targeted in the autoimmune process.³ Rarely, additional target antigens have been identified in pemphigus, including desmocollins, acetylcholine receptors and other autoantigens.⁴ Triggering of apoptosis pathways is also important in pemphigus, with involvement of downstream phosphorylation signalling

pathways.⁵ Besides the humoral pathway generating autoantibodies, T-cell pathways are also involved in the epitopes that generate an immune response with derangements present in the normal immunologic regulatory pathways.⁶

Pemphigus vulgaris (PV) is the most common type of pemphigus, characterized by the presence of autoantibodies against desmoglein 3, which is why the oral mucous membrane is often involved initially. Involvement of desmoglein 1 and desmocollins via epitope spreading is also possible. Patients typically present with nonhealing oral erosions which progress to involve the skin after a period of months. Autoantibodies are directed against desmoglein 1 in pemphigus foliaceus (PF), so patients present with blistering and erosions limited to the skin with the mucous membranes spared.

Other forms of pemphigus exist, including paraneoplastic pemphigus, drug-induced pemphigus, pemphigus vegetans, pemphigus erythematosus and pemphigus herpetiformis. This review will be limited to the most common types of pemphigus – PV and PF.

DIAGNOSIS

Diagnosis of pemphigus is based on a combination of clinical features, histopathologic review and immunofluorescence (IF) studies. The clinical features of pemphigus include flaccid blisters, oral ulcers, and superficial erosions. Light microscopy of lesional biopsies demonstrates intraepidermal acantholysis, vesicle formation, and the upward growth of papillae lined by a single layer of epidermal cells. Confirmation of the diagnosis necessitates the use of immunofluorescence, because of the difficulty of differentiating pemphigus from other bullous diseases. Direct immunofluorescence of perilesional biopsies reveals intercellular epidermal deposits of IgG, with or without C3, and indirect immunofluorescence on monkey esophagus reveals antibodies to keratinocyte surface antigen in PV. Indirect IF can be done in dilutions to give an idea about the degree of activity of the pemphigus. Enzyme-linked immunosorbent assay (ELISA) measures the titration of

specific desmoglein 1 or 3 antibodies circulating in the serum. It is more sensitive than titers done on indirect IF. In some research laboratories, immunoblotting studies are available, which allow identification of particular antigens, and may prove useful for diagnosis and prognosis.

PROGNOSIS

Pemphigus is a potentially life-threatening condition with chronic blistering, capable of causing fluid depletion, secondary infection or sepsis, and in rare cases, death. Prior to the age of corticosteroids, mortality was approximately 70% as a result of sepsis.⁷ With the advent of corticosteroids, mortality is now 6%, with most deaths attributable to side-effects of steroid therapy.⁸ The literature provides a limited understanding of the prognostic factors in pemphigus, but PV is reported to have a worse prognosis than PF⁹ and in the setting of PV, disease limited to the mucosa is associated with a better prognosis than disease with combined mucocutaneous involvement.¹⁰

MANAGEMENT

The aim of management in pemphigus is to induce and maintain remission, which is defined as “the absence of new or established lesions while the patient is off all systemic therapy for at least 2 months”,¹¹ while minimizing the adverse effects of treatment. In stating this, it is important not to overtreat the patient; the presence of a few transient blisters means that the treatment is not too strong, as that is the source of most morbidity in the long-term management of pemphigus.

At present, treatment regimes are more ‘eminence-based’ than evidence based, and there is no consensus amongst international experts regarding the treatment of pemphigus,¹² although some countries have their own national guidelines.¹³ This is largely because of the fact that there have been less than a dozen well-designed, double-blind, randomized-controlled trials (RCTs) reviewing the treatment of the disease.¹⁴ The numbers of patients included in most of these RCTs was too low in most cases to have sufficient power to determine a statistically significant difference. Pemphigus is a rare condition in most countries, making patient recruitment a challenge, and therefore most clinical trials in AIBD tend to involve small cohorts of patients. Most studies are open and uncontrolled with patients of assorted disease severities often treated concomitantly with a number of therapies, making it difficult to evaluate the benefits of a given treatment.

There has also been a lack of suitable endpoints in clinical studies to measure the outcomes of intervention, although international consensus definitions of outcome measures for pemphigus have recently been developed.¹¹ Objective instruments, which quantify disease activity, such as the Autoimmune Bullous Skin Disease Intensity Score (ABSIS),¹⁵ and the Pemphigus Disease Activity

Index (PDAI),¹⁶ may provide a suitable endpoint in clinical studies, as well as quality-of-life instruments, which have become increasingly employed in the field of dermatology to evaluate disease status.¹⁷

Outcomes that have been previously used to assess disease control include effectiveness in preventing new vesicle formation, the healing of pre-existing lesions, the time taken to achieve disease control, and antibody titers. Long-term outcomes have included the proportion of patients able to discontinue treatment and the proportion of patients that relapse. Cumulative steroid dose has also been utilized as an outcome in the literature as a proxy for steroid-induced adverse events, as this is the major cause of mortality in pemphigus. Further research is warranted in developing standardized outcome measures to enable effective, evidence-based comparisons of the wide range of interventions employed in the management of pemphigus.

CORTICOSTEROIDS

Corticosteroid dosing

Systemic glucocorticoids are the cornerstone of treatment. The advent of corticosteroids in the 1950s was accompanied by a 45% reduction in mortality,⁷ but the long-term, high-dose courses of systemic corticosteroids often used to control pemphigus are associated with significant sequelae.¹⁸ There is no standardized approach to the administration of corticosteroids in pemphigus, although continuous oral administration is the most common. It has been put forward that corticosteroids should be initiated at a high enough dose to control disease and tapered thereafter once the majority of lesions have healed. The optimal dosing strategy has yet to be determined and it has also been argued that high dose, pulsed therapy may achieve faster disease control and offer the patient a reduced cumulative glucocorticoid dose.¹⁹

There has only been one RCT investigating steroid dosing regimens in pemphigus.²⁰ In this study, 22 newly diagnosed patients with greater than 50% of body surface area affected were randomized to low-dose (45-60 mg) (n=11) or high-dose (120-150 mg) (n=11) prednisolone and followed for 5 years. All patients were treated until remission, after which their steroid dose was tapered to 20 mg. From this point, either adjuvant cyclophosphamide 100 mg or methotrexate 15 mg weekly was randomly introduced and the prednisolone dose decreased to 2.5 mg per month. All patients had resolution of blister formation and were seronegative for autoantibodies at 3 months. There was no significant difference in the duration of treatment needed to achieve initial remission, the number of relapses or the timeframe to relapse, or the incidence of complications between the two groups, indicating that there was no short-term or long-term advantage to a high-dose regimen. However, the numbers in this small study were insufficient to perform adequate statistical analysis.

Fernandes and Perez report a retrospective, nonrandomized controlled trial involving 71 patients (41 PV/30 PF).²¹ Patients were assigned to cohorts receiving prednisone 1 mg/kg/day ($n=34$) or 2 mg/kg/day ($n=37$) based on clinical severity at presentation and followed for 5 years. Both cohorts were kept on prednisone for 4-6 weeks until remission, after which the prednisone dose was tapered. No statistical difference was observed between cohorts in terms of response to treatment, however, there was a significantly higher frequency of adverse events, particularly infection, in the 2 mg/kg/day cohort. Despite the retrospective, nonrandomized nature of the study, the results indicate that higher doses of corticosteroid are no more effective than lower doses, and are associated with higher rates of complications.

Overall, the limited evidence indicates that lower steroid dose regimens (at around 1 mg/kg/day) may be sufficient for initial control of pemphigus in most patients and may have decreased associated morbidity. At our institution, we commence therapy with 1 mg/kg/day of oral prednisone for pemphigus. Once the patient has reached the end of the consolidation phase, we begin to taper the prednisone slowly. At high doses, we give divided doses of steroids to reduce hyperglycaemic effects. We add a steroid-sparing drug (see below) and follow the steroid taper used by Werth's group from 40 mg to zero over about 4 months. Patients are tapered by 5 mg a week to 20 mg a week, then by 2.5 mg a week to 10 mg a week, then by 1 mg a week to 3 mg/week. If an 8:00 a.m. cortisol is normal at that point, then prednisone taper by 1 mg a week is continued. Using this combination and duration of treatments, most of our patients have been able to go into clinical remission on low dose steroid-sparing agents.

Pulse Corticosteroid Therapy

Pulse therapy refers to discontinuous intravenous infusion of high-dose glucocorticoids in a short burst. It is based on the rationale that the steroid pulses may cause rapid control of disease and decrease the need for long-term steroid use, thereby reducing the complications of long-term usage.²²

The only RCT evaluating the utility of pulse therapy in pemphigus had only 20 patients with newly diagnosed PV, or new disease activity randomized to oral dexamethasone 300 mg ($n=11$) or placebo ($n=9$) pulses three days per month.²³ Both treatment cohorts also received prednisolone 80 mg/day tapered over 19 weeks and azathioprine 3 mg/kg/day, with pulse therapy continued until the prednisolone dose reached zero. Patients were followed for 1 year. There was no significant difference between cohorts in the time to remission, duration or remission or relapse rate. The cumulative steroid dose was higher in the dexamethasone cohort as was the rate of adverse effects. No benefit was able to be demonstrated in the use of oral dexamethasone pulse therapy in addition to conventional treatment. With

only 20 patients in the study, we cannot conclude from this that there would be no benefit from oral dexamethasone pulse therapy.

Femiano et al. have reported an open, nonrandomized, controlled trial of 20 PV patients with participants receiving either a 125 mg/day tapering schedule of prednisone ($n=10$) or a 50 mg/day tapering schedule of prednisone plus i.v. bethamethasone 20 mg/day.²⁴ In this study, the cohort receiving the pulse therapy was found to have minimal differences in resolution of symptoms and oral lesions (30 vs. 25 days).

In addition, there have been a number of case series reporting the use of pulse steroids.

In 1995, Chryssomallis et al. first reported 8 patients with severe or recalcitrant treated with 6-10 pulses of i.v. methylprednisolone 8-10 mg/kg on alternate days plus oral prednisone 0.4-1 mg/kg/day and either azathioprine or cyclophosphamide.²⁵ All patients achieved disease control, healing at least 50% of lesions, but none could discontinue therapy, and one patient died of a cardiac arrest. Werth et al. reported nine PV patients who did not initially respond to prednisone, receiving i.v. methylprednisolone 250-1000 mg/day for 1-5 days in addition to adjunctive treatment.¹⁹ During the pulse therapy, six of nine patients improved and four of nine were able to discontinue treatment for an average of 2 years. A steroid-sparing effect was observed compared to a historic control group. Mignogna et al. reported 12 pemphigus patients treated with i.v. methylprednisolone 30 mg/kg for 3-5 days on cycles of 21 days.²⁶ In all patients, remission was observed by the third cycle, however nine of 12 cases relapsed during the 6-month follow-up and every patient had some adverse effect.

Toth et al. reported a retrospective series of 14 patients treated with 60 mg/kg oral prednisone and 200-300 mg pulse dexamethasone for 3 days monthly.²² Remission was established in five of 14 patients after one pulse treatment and in a further two out of 14 patients after 2 pulses, and was sustained for 2-15 months thereafter. Minor adverse effects were observed in approximately 60% of cases.

While these early case series of pulsed corticosteroids appeared promising, evidence from the more recent controlled trials have not demonstrated that pulsed steroids confer any clear additional benefit and that they may be associated with a higher incidence of side-effects. Notably, the case series described had patient cohorts with predominantly severe or recalcitrant disease while patients in the two studies were predominantly newly diagnosed, which may account for some of the observed dichotomy.

ADJUVANT IMMUNOSUPPRESSIVE THERAPY

Adjvant steroid-sparing therapies have been employed in the management of pemphigus, with the belief that they not only reduce the cumulative glucocorticoid dose but increase the efficacy of treatment. Common adjvant

therapies utilised include azathioprine, mycophenolate mofetil, cyclophosphamide and cyclosporine. These agents typically require 4-12 weeks to demonstrate any therapeutic effect, so their use is essentially in maintaining remission and allowing steroid taper, rather than inducing remission.

A recent RCT by Chams-Devatchi et al. of 120 newly diagnosed PV patients compared prednisone monotherapy (n=30) with prednisone plus adjuvant azathioprine (n=30), mycophenolate mofetil (n=30) or intravenous cyclophosphamide pulse therapy (n=30).²⁷ All four regimens induced complete remission in 70-80% patients with no statistically significant difference observed between them in terms of remission or side-effects. However, the mean cumulative steroid dose in the prednisone cohort was significantly higher than the mean in the adjuvant cohorts ($p=0.047$), suggesting a steroid-sparing role of adjuvant therapy. The authors proposed that azathioprine was the most efficacious steroid-sparing agent, followed by cyclophosphamide, then mycophenolate mofetil based on the mean cumulative steroid dose between cohorts.

A retrospective case series of 101 patients with moderate to severe PV by Olszewska et al. also compared prednisone monotherapy with adjuvant azathioprine, cyclosporine, and cyclophosphamide.²⁸ Patients were treated with oral prednisone 1.1-1.5 mg/kg/day (n=20) or prednisone combined with azathioprine 100 mg (n=16), cyclosporine 2.5-3 mg/kg (n=14) or cyclophosphamide 100 mg 1.1-1.5 mg/kg (n=51). Clinical remission was achieved significantly faster in the cyclophosphamide cohort, compared to other patients, and resolution of PV antibodies was faster in the cyclophosphamide cohort compared to the prednisone cohort. Disease activity was significantly lower in the cyclophosphamide cohort after 3 months of therapy, and significantly higher in the cyclosporine cohort at 12 months compared to the other participants. The safety profile was similar across cohorts. In this study, the authors proposed that cyclophosphamide should be the drug of choice in PV.

The majority of evidence for the use of adjuvant therapy has been based on case series as there have been limited RCTs published on the topic.

Azathioprine

The use of combined prednisone and azathioprine is commonly employed regimen in pemphigus and is usually well-tolerated.

In Chams-Devatchi's RCT, disease control was achieved in 80% of patients in the azathioprine cohort after 1 year, and the cumulative steroid dose was significantly lower than that of the prednisone monotherapy and prednisone plus mycophenolate mofetil cohorts.²⁷ However, another randomized trial comparing azathioprine with mycophenolate mofetil in 40 pemphigus patients failed to demonstrate any significant difference between the two therapies in terms of remission, relapse rates, cumulative

steroid dose or adverse effects according to the author's protocol.²⁹

Akhtar and Hasan reported a nonrandomized-controlled trial in 72 patients comparing prednisolone (n=40), prednisolone plus azathioprine (n=15) and betamethasone-cyclophosphamide pulse therapy (n=17).³⁰ The regimen consisted of prednisolone 30-120 mg/day given on a tapering schedule alone or in combination with azathioprine 100-150 mg/day. Treatment with azathioprine was more effective in terms of the proportion of patients achieving disease control, and the frequency of relapses and incidence of complications was lower in the azathioprine group.

The largest case series on azathioprine was a prospective, long-term study of 37 patients treated with methylprednisolone 80-200 mg plus azathioprine 2-3 mg/kg/day.³¹ In the follow-up ranging from 4-16 years, "complete clinical remission" was reported in all patients evaluated, although 66% of patients experienced relapses. At the time of evaluation, 24/37 patients were disease free, five of 37 had improved but were not disease free, and two of 37 had failed on this regimen.

Azathioprine has been shown to have a steroid-sparing role and it is put forward that it is therefore likely to reduce steroid-related complications. Its role in disease control has not been satisfactorily established, but based on the limited evidence in the literature it appears adjunctive azathioprine is beneficial. On the basis of this evidence and our experience, we check thiopurine methyl transferase levels and if not very low, we commence azathioprine early at 2.5 mg/kg/day while the patient is on high doses of prednisone, and monitor bloods for safety every 2 weeks initially.

Mycophenolate mofetil

Mycophenolate mofetil is a relatively recent drug, which functions as an immunosuppressant by inhibiting the proliferation of lymphocytes.

In Chams-Devatchi's RCT, 70% of patients in the mycophenolate mofetil cohort achieved complete remission after 1 year and the cumulative steroid dose was significantly lower than that of the prednisone monotherapy cohort, indicating a potential steroid-sparing role for the agent.²⁷ A multicenter RCT randomised patients with mild or moderate PV to oral corticosteroid plus either mycophenolate mofetil (2 or 3 g/day) or placebo for 52 weeks.³² The primary outcome, response rate at 48 to 52 weeks was no different. However, there were several differences in the secondary outcome measures. Compared to the patients receiving placebo, patients on either dose of mycophenolate mofetil achieved a faster therapeutic response, maintained their response for longer and had a longer time to relapse. There was also an observed steroid sparing role of the immunomodulator, collectively indicating a more durable therapeutic outcome. Another randomized trial comparing azathioprine with mycophenolate mofetil demonstrated

that mycophenolate mofetil was more effective than azathioprine in achieving disease control, with complete healing reported in 20/21 (95%) of mycophenolate mofetil patients compared to 13/18 (72%) of azathioprine patients.²⁹

The largest case series, reported by Mimouni et al. reported 42 patients treated with mycophenolate mofetil 35-45 mg/kg/day in combination with prednisone 1 mg/kg/day.³³ The patients included had either relapsed during prednisone taper or had experienced adverse effects on azathioprine. Remission was achieved in 27/42 patients with a steroid dose of less than 0.15 mg/kg/day after a median of 9 months. The therapy was well-tolerated with 77% of patients having no adverse effects.

Powell et al. reported 17 patients with severe, recalcitrant pemphigus treated with mycophenolate mofetil 2.5 g/day and prednisone 15-60 mg/day.³⁴ Within 3 months, eight of 17 patients had clinically inactive disease and four of 17 improved with ongoing lesion. Two patients were clinical failures, one patient withdrew because of poor disease control, and two withdrew after reporting paresthesias.

Chams-Davatchi described 10 patients with severe pemphigus vulgaris refractory to azathioprine, and multiple other adjuvants.³⁵ Patients were treated with 2000 mg/day mycophenolate mofetil for 6 months and a tapering schedule of prednisone. Nine of 10 patients had clinical resolution of lesions after a mean of 3.4 months and a steroid sparing effect was observed. Two patients relapsed during the trial and one patient failed to respond. Five patients relapsed within 3 weeks of discontinuing mycophenolate, indicating that courses of longer than 6 months are required for sustained remission.

Overall, the evidence suggests that mycophenolate mofetil serves a steroid-sparing role and there is some evidence to suggest it may be superior to azathioprine in terms of disease control. Case series report the successful use of adjuvant mycophenolate mofetil in patients with refractory disease with minimal side-effects observed, however treatment failures are also reported in a small proportion of these patients. As mycophenolate mofetil is significantly more expensive than azathioprine and the steroid-sparing difference is minimal in these studies, it is our practice to start with azathioprine and if there are side effects or lack of efficacy, to switch to mycophenolate mofetil later. If the patient has a contraindication to azathioprine, then we commence mycophenolate mofetil instead.

Cyclophosphamide

Cyclophosphamide is an alkylating agent used as an adjuvant in pemphigus. While there are case reports of successful cyclophosphamide therapy, there are also series, which suggest it has limited utility as a monotherapy³⁶ and the substantive evidence of its benefit is in combination with corticosteroids.

An RCT by Chrysomallis et al. compared prednisone monotherapy and the use of adjuvant cyclophosphamide

or cyclosporine.³⁷ Patients with newly diagnosed mucosal PV were randomized to either prednisone 40 mg (n=10), or prednisone with cyclophosphamide 100 mg/day (n=10) or cyclosporine 5 mg/kg/day (n=10) and followed for 5 years. There was no significant difference between the three cohorts in terms of time to remission or relapse rates. Combination therapy cohorts were reported to have a higher incidence of adverse events, although these were mild.

Cummins et al. reported 23 patients (20PV, 3PF) treated with oral cyclophosphamide 2-2.5 mg/kg and prednisone 1 mg/kg.³⁸ Five patients also received concomitant plasmapheresis. Seventeen of 23 patients achieved complete remission after a median of 8.5 months, although six relapsed subsequent to discontinuation of treatment after a median of 6 months. Adverse events occurred in at 14 of 23 patients including hematuria in five patients, infection, and one case of transitional cell carcinoma. Piampongsant reported 12 patients treated with prednisone 60-120 mg/day and cyclophosphamide 100 mg daily, on a tapering schedule.³⁹ Disease control was achieved in 9 of 12 patients on prednisone <15 mg/day plus cyclophosphamide 50 mg on alternate days or once a week, and 3 of 12 patients were able to stop treatment. No serious complications from cyclophosphamide therapy were reported. Fellner described five patients with newly diagnosed PV treated with oral cyclophosphamide 100-200 mg/day plus prednisone 200 mg/day.⁴⁰ All patients achieved disease control and four were able to discontinue medication.

A case series by Momeni et al. reported the use of oral cyclophosphamide with dexamethasone pulse therapy in 50 PV patients.⁴¹ Participants received oral cyclophosphamide 50 mg daily and i.v. dexamethasone 100 mg for 3 consecutive days repeated every 14 days, with i.v. cyclophosphamide 500 mg administered once at the onset of the study. At 10-year follow-up, 10 of 50 patients were free of lesions and 21 of 50 patients were in complete remission with the mean duration of remission of 5.7 years. One patient died from septicemia and Cushingoid features were observed in ten patients, but no serious side effects were otherwise reported.

In summary, adjuvant oral cyclophosphamide has been reported as effective in inducing remission in pemphigus. However, no studies have been performed demonstrating that the combination of steroid and cyclophosphamide is more efficacious than steroid monotherapy and the safety-profile of oral cyclophosphamide in the setting of pemphigus has not been fully elucidated.

Pulsed Cyclophosphamide

Pulsed intravenous cyclophosphamide has been reported to be more effective than oral cyclophosphamide in a number of autoimmune conditions, offering improved clinical outcomes and fewer side effects than daily oral therapy. It was thus anticipated that this modality may

also be effective in pemphigus. Three RCTs, one nonrandomized control trial and numerous case series have been reported, however, no studies to date compare oral and pulsed cyclophosphamide.

In Chams-Devatchi's RCT, 73.3% of patients in the pulse cyclophosphamide cohort achieved complete remission after 1 year and the cumulative steroid dose was significantly lower than that of the prednisone monotherapy cohort, indicating a potential steroid-sparing role of the modality.²⁷ It was not found to be superior to either azathioprine or mycophenolate mofetil in terms of disease control.

Rose et al. conducted an open RCT with 22 newly diagnosed pemphigus patients (16PV, 6PF) comparing combined methylprednisolone and azathioprine therapy with combined pulse i.v. dexamethasone and cyclophosphamide therapy.⁴² The methylprednisolone/azathioprine cohort were treated with methylprednisolone 2 mg/kg/day and azathioprine 2.0-2.5 mg/kg/day therapy (n=11) and the dexamethasone-cyclophosphamide cohort were treated with i.v. dexamethasone 100 mg on 3 consecutive days with cyclophosphamide 500 mg on day one, repeated every 2-4 weeks, in addition to oral cyclophosphamide 50 mg (n=11). At 24 months, remission was reported in five of 11 patients in the methylprednisolone/azathioprine cohort and one of 11 patients in the dexamethasone-cyclophosphamide cohort, with three of 11 patients in each cohort in remission having ceased therapy. Progression of disease was observed in one of 11 patients in the methylprednisolone/azathioprine cohort and six of 11 patients in the dexamethasone-cyclophosphamide cohort. No results of the study were statistically significant.

Another open, randomized trial compared dexamethasone-cyclophosphamide pulse and daily oral cyclophosphamide against cyclophosphamide pulse and daily oral prednisolone.⁴³ In Group A, fifteen patients received 100 mg of dexamethasone i.v. on three consecutive doses with a single dose of cyclophosphamide 500 mg i.v. repeated every 4 weeks as well as daily cyclophosphamide 50 mg (and oral prednisolone if disease activity was not controlled after two weeks). In Group B, thirteen patients received i.v. cyclophosphamide 15 mg/kg/day every 4 weeks along with daily oral prednisolone 1.5 mg/kg/day on a tapering regime. The total period of therapy was 12 months and at the conclusion of the study, there was a statistically significant difference in the time to initiation of a cutaneous response and the time to achieve remission in Group B. However, there was no difference in terms of time to initiation of a mucosal response and the re-epithelialization of lesions, nor any difference between cohorts in terms of autoantibody titers. In both groups the titers were significantly reduced from pretreatment levels. Relapse rates were >60% in both groups after cessation of therapy, indicating the need for maintenance therapy in this setting.

Akhtar and Hasan reported a nonrandomized, controlled trial comparing prednisolone (n=40), prednisolone

plus azathioprine (n=15), and pulsed betamethasone-cyclophosphamide pulse therapy (n=17), described previously in the discussion of azathioprine.³⁰ The regimen of the betamethasone-cyclophosphamide cohort consisted of pulsed i.v. betamethasone 100 mg/day for 3 days and cyclophosphamide 500 mg on day one, plus cyclophosphamide 50 mg orally daily. Twelve of 17 patients in the pulse cyclophosphamide cohort were considered treatment failures and required additional steroids. An increased susceptibility to infection was seen in the betamethasone-cyclophosphamide group compared to other arms and four of 17 patients died.

The results of these trials differ considerably from the numerous case series in the literature reporting similar protocols of pulse cyclophosphamide: pulse i.v. dexamethasone 100 mg/day for 3 days and cyclophosphamide 500 mg on day one, plus cyclophosphamide 50 mg orally daily. Pasricha et al. reported 300 pemphigus patients on cyclophosphamide pulse therapy for over 12 years. It was reported that 190/300 patients were 'disease free' on no medication, with remission continuing over 2 years in 123 patients.⁴⁴ Kaur & Kanwar reported 50 pemphigus patients treated with pulse therapy over 2 years.⁴⁵ Lesions were reported to resolve within days of commencing treatment and remission was induced in 28 of 50 patients. Kanwar et al. later reported on the long-term efficacy of this regimen in 36 patients (32PV, 4PF).⁴⁶ All patients were able to discontinue therapy and remain free of disease over a range of 0.5 to 12 years. Sacchidanand et al. reported 46 patients with advanced pemphigus (44PV, 2PF) of which 70% achieved clinical remission after three pulses.⁴⁷ Bhat et al. reported a case series of 26 patients (25 PV, 1PF) treated with an i.v. cyclophosphamide 15 mg/kg bolus monthly and daily prednisolone 1 mg/kg/day in which 82% of patients were free of all lesions after 12 months.⁴⁸

These case series offered predominantly positive outcomes, reporting rapid response to treatment and high rates of remission. However more recent controlled trials have not demonstrated any evidence to support the use of pulse cyclophosphamide therapy in pemphigus, although there is evidence that it serves a steroid-sparing role. It is our practice to only use pulse cyclophosphamide if less toxic treatments are ineffective.

Cyclosporin

Two RCTs and a number of case series have presented the use of cyclosporine in pemphigus.

Ioannides et al. reported an RCT of 33 patients with newly diagnosed pemphigus (29PV, 4PF).⁴⁹ Patients were randomized to treatment with prednisone 1 mg/kg (n=17) or prednisone and cyclosporine 5 mg/kg (n=16) and followed for 4-6 years. Multiple endpoints were employed to evaluate clinical response including the proportion of patients responding to therapy, the time required to achieve disease control, the proportion of patients who relapsed,

partial and complete remission rates, and cumulative steroid dose. No significant difference was observed between the two cohorts, although the incidence of adverse effects was higher in the cohort receiving cyclosporine. The RCT failed to demonstrate any advantage of adjuvant cyclosporine in the management of pemphigus. Similarly, the RCT of Chrysomallis et al. described previously in the discussion of cyclophosphamide failed to demonstrate any benefit of adjuvant cyclosporine in the time to achieve disease control, the proportion of patients responding, or treatment or relapse rates³⁷. However, the incidence of adverse events was significantly higher in the patients receiving cyclosporine compared to the other two cohorts.

Lapidoth et al. reported a study of 16 PV patients treated with prednisone 60-80 mg/day and cyclosporine 5 mg/kg/day and compared the outcome with a historic control group of 15 patients, treated with prednisone 120 mg/day on a tapering schedule.⁵⁰ The combined therapy cohort achieved clinical remission in a shorter timeframe than the historic control group, and the cessation time for new blister formation was also significantly shorter in the combined therapy cohort. The cohort receiving cyclosporine also had significantly shorter hospital admissions and a lower mean cumulative steroid dose, suggesting a steroid-sparing role of cyclosporine.

Barthelemy et al. published a study of nine PV patients treated with different regimens of cyclosporine and prednisone.⁵¹ The four patients treated with cyclosporine alone demonstrated no clinical improvement after 2 weeks. In four patients who showed no clinical improvement after 2 months of treatment with prednisone (>1 mg/kg/day), the addition of cyclosporine induced the clearing of lesions within 3 weeks, but three of four patients relapsed upon tapering of cyclosporine. One patient treated with prednisone 0.6 mg/kg/day and cyclosporine 6-8 mg/kg/day improved under the combined therapy but relapsed when the steroid dose was tapered.

Mobini et al. described a group of 6 PV patients with severe recalcitrant disease successfully treated with high dose prednisone and cyclosporine 1-3 mg/kg/day.⁵² Clearing of 'most lesions' occurred 16-20 weeks after cyclosporine therapy was initiated and discontinued after 1-2 years with no relapses reported over a 5-year follow-up.

Given the small number of RCTs evaluating cyclosporine in pemphigus, it is difficult to make firm conclusions from this evidence. Some of the studies were evaluating the wrong outcome measure for a steroid-sparing drug (i.e. time to disease control), as that occurs early because of the steroid therapy. The important outcome measure for a steroid-sparing agent is the proportion of patients eventually achieving complete remission on minimal therapy and this was not used as the primary outcome in these studies. Hence, whether cyclosporine is useful in pemphigus is still an open question. Our practice has been to use other steroid-sparing agents first, but cyclosporine should not be completely ruled out on the basis of the above.

Methotrexate

No controlled trials have been conducted investigating the efficacy of methotrexate in pemphigus. Early case series reported methotrexate as effective in disease control, however the therapy has been abandoned in recent years because of concerns about adverse effects. However, this may have resulted from the high dosages employed in combination with high dose corticosteroids.

In a series of nine patients with active PV, Smith and Bystryn reported the use of methotrexate 10-17.5 mg/week in combination with prednisone 20 mg/day.⁵³ In six of nine patients, steroid therapy could be discontinued within 6 months without any flare in disease activity, however all patients relapsed once methotrexate therapy was ceased. Adverse events were mild.

Mashkilleyson reported 53 patients with PV treated with prednisone 60-200 mg/day and methotrexate 25-50 mg/week.⁵⁴ Treatment was reported as 'effective' in 42 of 53 patients, 'ineffective' in nine of 53 patients and two patients withdrew because of adverse events. There were no changes in transaminases and liver biopsies performed after every cumulative 1.5 g of methotrexate were unremarkable. A steroid-sparing effect was observed. The most common adverse effect was infection. In this case series, 28 of 185 patients died, but the number of participants receiving methotrexate was not reported.

There is insufficient evidence to draw conclusions regarding the role of adjuvant methotrexate in pemphigus. Anecdotally, in clinical practice in Australia, methotrexate is used by dermatologists who report some success. Now that outcome measures have been defined, it would be good to see RCTs of methotrexate with prednisone versus placebo with prednisone, in a country such as Iran or India where there are many PV patients, to see if methotrexate were useful as a steroid-sparing agent in PV.

Chlorambucil

One small retrospective case series has been reported investigating chlorambucil therapy.⁵⁵ In the study, nine pemphigus patients (7PV, 2PF) were treated with chlorambucil and prednisone and six of nine patients demonstrated clinical improvement. The study suggests that chlorambucil may be a potential adjuvant in pemphigus when other immunosuppressants fail, but no recommendation can be made of its utility on this small series alone.

Gold

Gold is one of the oldest therapeutic agents, exerting anti-inflammatory properties and influencing humoral and cellular immunity. As it has a delayed onset of action, it is normally administered as an adjuvant therapy. One controlled study and a number of case series were identified.

Auad et al. reported a blinded, controlled trial of adjuvant gold in 30 PF patients.⁵⁶ Patients were initially

stabilized on corticosteroids, then gold 3 mg/day or placebo was administered. Nine of 30 patients did not complete the trial, and intention to treat analysis was not performed. The results of 10 patients treated with gold and 11 in the placebo cohort were reported, with a mean follow-up of 4 years. At 12 months, a steroid-sparing effect was seen with mean steroid dose of 37 mg/day in the placebo group and 5.5 mg/day in the gold arm. Four patients in the gold arm experienced mild complications, including diarrhea, and proteinuria.

Sutej et al. reported a prospective case series of six PV patients, four of whom had new onset disease.⁵⁷ Patients were treated with intramuscular gold thiomolate 50 mg and prednisone. All patients improved, with four of six patients tapering steroids below 15 mg/day, and 2 of 6 patients able to discontinue steroids. The regimen was well tolerated.

Pandya and Dyke reported 26 pemphigus patients with mild disease treated with intramuscular gold over 10 years.⁵⁸ Patients were treated with intramuscular gold thiomolate 50 mg weekly until disease control was established, and monthly injections thereafter for 4 months. Four patients were treated with gold monotherapy and 22 were treated with combined prednisone and gold. Response to therapy was reported in 22 of 26 (85%) patients, with a reduction of blisters and ability to taper steroids to <20 mg/day. Remission was reported in 11 of 26 patients who were able to discontinue steroids and four of these patients were able to discontinue all treatment. Four of 26 patients did not respond. There was no mortality, but adverse effects were noted in 11 of 26 patients, including proteinuria, eosinophilia, and "cutaneous reactions."

Iranzo et al. reported a case series of 13 patients with refractory PV treated with prednisone and gold.⁵⁹ Intramuscular auruothiomalate 50 mg weekly was administered with prednisone 7.5-100 mg, with 3 patients receiving concomitant intravenous immunoglobulin 400 mg/kg/day for 5 consecutive days once a month. Complete long-standing remission was achieved in seven of 13 patients and partial remission in seven of 13, with the remaining two of 13 ceasing treatment because of adverse effects (proteinuria and a cutaneous abscess with severe granulopenia). In 11 of 13 patients, the prednisone dose was halved.

Poulin et al. reported 13 PV patients treated with prednisone and intramuscular gold thiomolate or aurothioglucose 50 mg administered weekly.⁶⁰ In the retrospective series, seven of 13 patients achieved complete resolution of lesions and ceased all treatment after a mean of 18.3 months, although two of seven subsequently relapsed. Thus, five of 13 patients had remission at a mean follow-up of 48.8 months. Two patients demonstrated no clinical benefit from gold and three of 13 patients responded to the treatment, but therapy was stopped because of adverse effects – proteinuria, eosinophilia, mild leukopenia, and urticaria – all resolving upon cessation of gold.

Penneys et al. reported on the long-term follow-up of 18 patients treated with gold.⁶¹ The treatment regimen was the

same as that used by Poulin described above. Eight of 18 patients had clinical resolution of lesions and were able to stop all treatment after a mean of 37.3 months of gold therapy. Remission had been sustained in these eight patients during a follow-up period of 8-34 months. Seven of 18 patients improved, but required maintenance therapy. Two patients discontinued gold because of adverse events, and one patient was lost to follow-up. Adverse events reported included nephrotic syndrome, proteinuria, dermatitis, erythema nodosum, and agranulocytosis.

Gold may be considered as a possible treatment option when other adjuvants cannot be employed. The case series in the literature indicate that the majority of patients on gold therapy demonstrate clinical improvement, with many able to stop treatment, and a steroid-sparing effect has been reported. At the same time, adverse effects are common, albeit relatively mild, and often precede clinical improvement which needs to be considered with using gold therapy.

Dapsone

Dapsone has been evaluated in one RCT of 19 recalcitrant PV patients reported by Werth et al.⁶² Patients were randomized to receive maintenance steroids plus either dapsone 125-150 mg/day (n=9) or placebo (n=10). In the dapsone cohort, five of 9 patients were able to taper their steroid dose below 7.5 mg/day compared to three of 10 in the placebo cohort, although this was not statistically significant. The authors presented some trends favoring the use of dapsone, but statistical significance was never reached. This did not exclude a beneficial effect because of the low power of the study. Adverse events included paraesthesia and methemoglobinemia.

Heaphy et al. reported the use of dapsone in a retrospective case series of nine PV patients who were steroid-dependent or had poor disease control.⁶³ Patients were receiving glucocorticoids and immunosuppressants in addition to dapsone titrated to 125-150 mg/day. After eight months, seven of nine patients were able to reduce their prednisone dose by 84% to <7.5 mg/day and two of seven were able to discontinue steroids. No response was seen in two of nine patients who had poor disease control at baseline.

Basset et al. reported a case series of nine newly diagnosed patients receiving dapsone 200–300 mg/day.⁶⁴ Five patients, all with mild to moderate disease, responded with at least a 50% decrease in the extent of their disease within 15 days of starting therapy. Four patients did not respond. Three patients discontinued dapsone because of adverse events, including hemolytic anemia, toxic hepatitis, and methemoglobinemia.

Dapsone appears to benefit some PV patients in the maintenance phases of their disease, however as there is little evidence to support the use of dapsone in pemphigus, it is difficult to evaluate its utility.

Tetracyclines/Nicotinamide

The evidence for the use of tetracyclines and nicotinamide in pemphigus is derived from small case series.

Calebotta et al. reported a prospective series of 13 hospitalized patients with PV treated with tapering regimens of tetracycline 2 g/day and prednisone 0.5-1 mg/kg/day and compared the study group with a historic cohort of seven pemphigus patients treated with prednisone and azathioprine.⁶⁵ All patients in the study cohort achieved cessation of blister formation within 5.5 days compared to 23.7 days in the control cohort. The study cohort also had fewer new lesions after 2 weeks, could taper their steroid doses faster, and had short hospital admissions that were all statistically significant.

Alpsoy et al. reported 15 patients with pemphigus (11PV, 4 PF) treated with tetracycline 2 g/day and nicotinamide 1.5 g/day over 2 months.⁶⁶ Five patients were newly diagnosed and 10 had previously been treated with corticosteroids and/or immunosuppressants. All patients had active disease. At 2 months, two of 15 had complete healing, four of 15 had 50% of lesions healed, and nine of 15 had no response. Three of 15 patients had mild gastrointestinal upset.

Chaffins et al. reported 11 pemphigus patients (6PV, 5PF) treated with nicotinamide 1.5 g/day and tetracycline 2 m/day with five of 11 on concurrent prednisone (2.5-30 mg/day).⁶⁷ After 8 weeks of treatment, five of 11 had complete resolution, 4 of 11 had >50% of lesions resolved, and two of 11 had no response. Four patients experienced mild gastrointestinal upset and one patient developed a morbilliform eruption. Gaspar et al. reported 10 patients (7PV, 3 PF) with active disease treated with minocycline 100 mg/day as an adjuvant.⁶⁸ Nine of 10 patients were concurrently treated with prednisone 10-40 mg/day and five patients concurrently received azathioprine 100-200 mg/day. Assessed subjectively, four of 10 patients had complete lesion resolution, two of 10 improved and four of 10 had no response, and a steroid-sparing effect was observed. Candidiasis occurred in nine of 10 patients and one of 10 developed hyperpigmentation.

The case series present inconsistent evidence regarding the use of antibiotics and nicotinamide in pemphigus. They could be considered as adjuvant treatment in mild cases, but further research including controlled trials is warranted to elicit their utility in this setting.

Plasmapheresis

Plasmapheresis is hypothesized to remove pathogenic autoantibodies and has been used in refractory cases of pemphigus. The utility of plasmapheresis is controversial with the results of one RCT ostensibly opposing those of small case series.

Guillaume et al. randomized 40 previously untreated pemphigus patients to prednisolone monotherapy

(0.5-2 mg/kg/day) (n=18) or prednisolone plus 10 large-volume plasma exchanges (55 mL/kg/exchange) over 4 weeks (n=22).⁶⁹ No differences were observed between cohorts with respect to clinical improvement, cumulative steroid dose or autoantibody titer. Four patients in the plasmapheresis cohort died of sepsis or thromboembolism.

These results differ to the outcomes reported in the case series and reports on plasmapheresis.

Tan-Lim and Bystryn reported a retrospective case series, comparing 11 patients (9PV, 2F) treated with plasmapheresis (1000-2000 mL/exchange; 5-12 exchanges over 10-24 days), corticosteroids (70-240 mg/day) and immunosuppressants (azathioprine or cyclophosphamide), with 11 patients (9PV, 2F) treated with steroids and immunosuppressants alone.⁷⁰ The average autoantibody titer decreased by 83% after 3 weeks of treatment in the plasmapheresis compared to a decrease of 18% in the historic control.

Roujeau et al. described a retrospective case series of 10 patients (2 PF, 8 PV) treated with massive volume plasmapheresis (3000-5000 mL/exchange).⁷¹ Patients received treatment with prednisone 0.1-2.5 mg/kg, and concurrent cyclophosphamide, azathioprine, or chlorambucil. Plasmapheresis was administered 2-3 times per week with 3-20 sessions per patient over 1-16 weeks. Rapid improvement was observed in six of 10 patients with no new blister formation after four treatments, however, three of six subsequently relapsed. Transient improvement was seen in two of 10 patients and no improvement observed in two of 10. Adverse events included thrombocytopenia, hypocalcaemia, urticaria, fever, hypotension, and two patients suffered acute hepatitis. Sondergaard et al. have reported the use of plasmapheresis in eight patients (7PV, 1PF) in combination with prednisone 30-120 mg/day and adjuvant therapy.⁷² At baseline, two of eight patients were lesion-free, three of eight were newly diagnosed and three of eight had pre-existing disease. In four of eight cases, pemphigus had been resistant to conventional therapy. Patients were treated with massive volume plasmapheresis (1500-3000 mL/exchange) 1-2 times per month for 5-73 months. All patients were in clinical remission within 2 months of therapy and remained in remission for 40-94% of the treatment period. A significant steroid-sparing effect was demonstrated and side-effects were rare and transient.

The role of plasmapheresis in pemphigus is controversial. The RCT by Guillaume et al. provides the best quality of evidence, although it doesn't correspond to the case reports in the literature. Some have argued that concurrent immunosuppressive agents are required to prevent rebound antibody synthesis during plasmapheresis,⁷⁰ which may explain the poor efficacy of plasmapheresis in the trial. Plasmapheresis may be considered for rapid control of severe or recalcitrant pemphigus but only in conjunction with immunosuppression to reduce rebound of autoantibodies.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIg) is being increasingly employed in the treatment of recalcitrant pemphigus. There have been two RCTs and several case series describing its use.

Amagai et al. have recently published a double-blinded, multicenter RCT of 61 pemphigus patients randomized to infusions of IVIg 400 mg/kg/day ($n=21$) or 200 mg/kg/day ($n=20$), or placebo ($n=20$) over 5 consecutive days.⁷³ A particular protocol was established and the success of therapy was based on the time until they had to deviate or 'escape' from the protocol. A dose-response relationship was observed amongst the three cohorts with the time to escape from the protocol significantly prolonged in the 400 mg cohort compared to placebo. Both the 200 mg and 400 mg cohorts were reported to have significant decreases in pemphigus activity scores and autoantibody titers from baseline, while no decrease was observed in the placebo cohort. No significant difference was observed between cohorts in terms of safety profile at 85-day follow-up. Due to the short-term nature of the study and outcome measure being time to escape from the protocol, rather than the proportion of cases in complete remission on no therapy or minimal therapy, it is still difficult to be sure that IVIg has a high cost-benefit ratio compared to other options. Another randomized-controlled crossover trial of IVIg was conducted in a single patient with severe PV comprising of two phases of 6 months of treatment with either IVIg or placebo infusion with prednisolone and azathioprine therapy maintained throughout the study.⁷⁴ Although this study was clearly limited by having a single subject, the mean dose of prednisolone was significantly lower during the treatment phase of the cross-over and the mean subjective patient disease scores and pemphigus autoantibody titers also improved. Ideally there should be more studies of IVIG conducted along these lines.

The largest case series is reported by Ahmed in which 21 patients with severe refractory PV treated with IVIg 2000 mg divided into 3 doses administered over 3 consecutive days, given at 4 week intervals until all lesions healed.⁷⁵ Improvement was observed after 4.5 months on average and the mean number of cycles administered was 18 (ranging from 14-34). It was reported that in all 21 patients, prednisone and adjuvant therapy could be discontinued, with remission achieved for an average of 20 months (ranging from 13-73). Following treatment, participants were reported to receive significantly lower doses of prednisone, fewer side recurrences and relapses, fewer and shorter hospital admissions and improvements in quality of life compared to before IVIg therapy. Another series by Baum et al. employed a similar treatment protocol to Ahmed in 12 patients with severe PV.⁷⁶ In 10 of 12 patients, treatment with IVIg allowed a reduction in prednisone dose compared to baseline, with six of 12 achieving clinical remission after 6 cycles. A partial response was observed in four of 12 patients and no response reported in two of 12. The results are concordant with the other series published in the literature.

IVIg appears to be an effective and safe treatment in recalcitrant pemphigus patients who have failed conventional therapy. Although expensive, it has a demonstrable corticosteroid-sparing effect and has been reported to have a rapid effect on disease activity, albeit transient at times. It appears that IVIg functions well as an adjuvant therapy in recalcitrant pemphigus, with repeated courses necessary to sustain benefit.

Immunoabsorption

Immunoabsorption is a relatively new treatment, which unlike plasmapheresis, specifically removes particular plasma components such as pathogenic immunoglobulins. The evidence for this therapy is derived solely from case series. Lüftl et al. reported a series of nine pemphigus patients (7PV, 2PF) treated with immunoabsorption in addition to their regular immunosuppressive therapy.⁷⁷ Evaluation by ELISA revealed a 30% reduction of pathogenic IgG antibodies after a single immunoabsorption treatment, and all patients demonstrated clinical improvement. Eming et al. reported 4PV patients and 2 PF patients treated with immunoabsorption adjuvant to their regular immunosuppressive medications.⁷⁸ Immunoabsorption was performed for 4 consecutive days every 4 weeks, representing one treatment cycle, with immunoglobulin 10g administered each cycle. The authors reported that a single immunoabsorption cycle reduced anti-Dsg1 and anti-Dsg3 antibodies by an average of 50-70% with all patients demonstrating rapid clinical improvement. Schmidt et al. reported five patients (4PV, 1PF) treated with 3 days of immunoabsorption, representing one cycle, with pulse dexamethasone and cyclophosphamide and oral methylprednisolone administered between cycles to minimize antibody resynthesis.⁷⁹ A single cycle was reported as reducing ELISA readings by 80-90% and all patients were in clinical remission at follow-up 13-116 weeks after initiating treatment. A similar immunoabsorption protocol was employed by Shimanovich et al. in a series of nine PV patients, with oral methylprednisolone and either azathioprine or mycophenolate mofetil employed instead of dexamethasone/cyclophosphamide therapy.⁸⁰ A single cycle was reported to reduce autoantibody titers by 75% and patients remained free of clinical disease for up to 26 months after treatment was discontinued.

These small case series are promising, but to date have focused their outcome measures on autoantibody levels with clinical outcomes assessed before the newer disease extent scales were developed. Further studies are warranted, ideally evaluating the clinical effects of immunoabsorption objectively.

Rituximab

Rituximab is an anti-CD20 humanized monoclonal antibody causing transitory B-cell depletion reserved for

patients with pemphigus that is unresponsive to conventional therapies or to patients in whom these drugs are contraindicated. Several case reports and a number of small series describe patients treated with pemphigus on a regimen of four weekly infusions of rituximab 375 mg/m.²

Joly et al. prospectively studied 21 patients (14PV, 7PF) treated with rituximab in addition to their regular immunosuppressive therapy.⁸¹ At 34 months, 18/21 (86%) patients were disease free and eight of these patients were no longer on systemic therapy. A steroid-sparing role was demonstrated and autoantibody titers had decreased in those patients who had achieved remission. Cianchini reported 12 patients (10PV, 2PF) with severe pemphigus treated with rituximab.⁸² All patients experienced disease control 1 month after treatment, with 4 of 12 (33%) having complete remission for up to a year. Antibody titers were shown to decline over 6 months and no adverse effects were observed. Antonucci described five PV patients who achieved complete remission for 12 months after rituximab treatment associated with a decline in antiepidermal antibodies.⁸³ Goh et al. reported a prospective study of 5 PV patients treated with rituximab.⁸⁴ At 13 months, one of five had complete remission with cessation of steroids, two of five achieved remission while continuing on medication and two of five were considered to have a partial remission.

Most of the patients in these case series have responded to rituximab with resistant lesions often cleared in 1-4 months. Rituximab may be a valuable treatment for recalcitrant pemphigus but further studies are warranted and further monitoring for long-term safety.

Pimecrolimus

Pimecrolimus is a topical immunomodulator with a calcineurin inhibitory effect encumbering T-cell and mast cell activation as well as the synthesis of a number of cytokines. The efficacy of the agent has been established in inflammatory disorders, most notably atopic dermatitis, but also more resistant problems, such as oral lichen planus,⁸⁵ and there has been one double-blinded, controlled trial investigating its efficacy in pemphigus.⁸⁶ Eleven patients with confirmed PV under treatment with prednisolone and azathioprine who had bilateral symmetrical oral lesions had all right or left-sided lesions randomized to treatment with either pimecrolimus 1% cream or placebo for 30 days. Overall, 31 lesions were treated with pimecrolimus and 31 were treated with placebo and at the conclusion of the study, there was a significant difference in the epithelial index of lesions in favor of the pimecrolimus. These results and encouraging and future studies could evaluate the efficacy of pimecrolimus with larger cohort numbers as well as lesions at other sites.

Topical epidermal growth factor

The efficacy of topical epidermal growth factor (EGF) has been evaluated in a double-blinded RCT of 20 PV patients.⁸⁷ Patients had similar, symmetrical lesions treated with either epidermal growth factor 10 µg/g in silver sulfadiazine cream or silver sulfadiazine cream alone. Lesions treated with topical EGF healed in a median of 9 days compared to control lesions which healed in a median of 15 days, with

What We Know

- The best evidence-based algorithm for the management of pemphigus is yet to be established.
- Systemic corticosteroids are the mainstay of treatment. Regimens of oral corticosteroid at around 1 mg/kg/day appear to be as effective as higher doses and much safer.
- Azathioprine and mycophenolate mofetil appear to be the adjuvant therapies of choice based on their steroid-sparing effects and safety-profiles. Oral cyclophosphamide may be considered as an alternative, as it has a good efficacy but unfavorable side-effect profile.
- Adjuvant cyclosporine is of limited use in pemphigus.
- There is insufficient evidence to assess the utility of methotrexate, gold, dapsone, and tetracyclines in pemphigus.
- Plasmapheresis, IVIg, immunoabsorption, rituximab, topical pimecrolimus and topical epidermal growth factor are all promising therapies in pemphigus. Further studies are warranted to elucidate their exact role in the management of pemphigus.
- Further studies are warranted to ascertain the best approach to management in pemphigus, ideally as blinded, multicenter controlled trials with large patient cohorts and valid, objective outcome and disease extent measures.
- Low dose (1mg/kg/d) prednisone is as effective as higher doses of prednisone in inducing remission of pemphigus
- Adjuvant mycophenolate mofetil (MMF) shortens the time to complete remission on therapy and reduces steroid requirements
- Adjuvant azathioprine was steroid sparing in one study and no different in effectiveness to MMF in other studies
- IVIG appears to be beneficial in uncontrolled studies and one placebo-controlled study but needs further confirmation; it has a good safety profile.
- Rituximab appears effective in some recalcitrant cases of PV but has not been tested in by RCT
- Most studies in PV do not reach adequate power to give statistically significant results

TABLE 17-1—Therapies in Pemphigus and Their Evidence

Treatment	Evaluation	Level of Evidence	Strength of Recommendation
Oral corticosteroids	Optimum dosing unknown; but low-dose regimens ($\leq 1\text{mg/kg/day}$) show equivalent efficacy and better safety ²⁰ <i>First line treatment</i>	1B	I
Pulse i.v. steroids	No advantage demonstrated of adjuvant therapy over placebo ²³ <i>Consider in severe/recalcitrant disease</i>	1B	I
Azathioprine	Demonstrated steroid-sparing role ²⁷ Superiority over mycophenolate mofetil controversial ²⁹ <i>May be used adjuvantly for steroid-sparing effect</i>	1B 1B	I I
Mycophenolate mofetil	Demonstrated steroid-sparing role ^{27,32} Superiority over azathioprine controversial ²⁹ <i>May be used adjuvantly for steroid-sparing effect</i>	1B 1B	I I
Oral cyclophosphamide	No advantage demonstrated over steroid monotherapy ³⁷ <i>Consider if azathioprine/mycophenolate mofetil are unsuitable</i>	1B	I
Pulse i.v. cyclophosphamide	Demonstrated steroid-sparing role ²⁷ <i>Consider in severe/recalcitrant disease</i>	1B	I
Cyclosporin	Adjunctive cyclosporin has no demonstrated advantage in pemphigus ^{37,49} <i>Cannot be advocated in pemphigus</i>	1B	I
Methotrexate	Early case series promising, but concerns exist regarding adverse effects ^{53,54} <i>Limited data available to establish role of therapy</i>	4	III
Chlorambucil	One small retrospective case series suggested the drug may be useful ⁵⁵ <i>Limited data available to establish role of therapy</i>	4	III
Gold	Many patients demonstrate clinical improvement and steroid-sparing role reported ⁵⁶ <i>An alternative to traditional adjuvants</i>	2B	II-1
Dapsone	Small RCT evaluating use of adjuvant dapsone did not reach significance ⁶¹ May benefit patients in maintenance phase of disease ^{62,63} <i>An alternative to traditional adjuvants</i>	1B 4	I III
Tetracyclines/ Nicotinomide	Variable efficacy reported ^{65–68} <i>An alternative to traditional adjuvants in mild pemphigus</i>	4	III
Plasmapheresis	No advantage demonstrated over steroid monotherapy ⁶⁹ <i>Further studies warranted; results of RCT contrary to earlier work</i>	1B	I
IVIg	Demonstrated role in decreasing disease activity and antibody titres ^{73,74} <i>Consider if traditional adjuvants are unsuccessful</i>	1B	I
Immunoabsorption	Shown to decrease antibody titres with many patients showing clinical improvement ^{77–80} <i>Further studies warranted evaluating clinical improvement</i>	4	III
Rituximab	Demonstrated steroid sparing role with efficacy demonstrated in recalcitrant pemphigus ^{81–84} <i>Consider if traditional adjuvants are unsuccessful</i>	4	III
Pimecrolimus	Significant improvement in oral lesions over placebo ⁸⁶ Further studies warranted evaluating cutaneous efficacy	1B	I
Topical epidermal growth factor	Improved lesion healing observed ⁸⁷ <i>Further studies warranted.</i>	1B	I

the difference found to be significant. Further studies are required to confirm these promising results before making an assessment of topical EGF in pemphigus.

CONCLUSION

As a rare disease, there is a paucity of good-quality evidence regarding interventions in pemphigus (Table 17-1). Well-designed, randomized-controlled trials are scarce and because of the previous deficits in uniform outcome measures in pemphigus, it is difficult to compare the efficacy of modalities across different studies. Further studies using the consensus definitions for outcome measures and assessment tools are necessary to ascertain the best approach to management in pemphigus. Ideally, these should be double-blind, randomized-controlled trials with large patient cohorts, using valid, objective outcome measures that can provide an evidence-based approach to the treatment of pemphigus.

Treatment of Dystrophic Epidermolysis Bullosa

David T. Woodley, M.D., Gene Kim, M.D., and Mei Chen, Ph.D.

INTRODUCTION

Dystrophic epidermolysis bullosa (DEB) belongs to a family of inherited bullous diseases in which the blisters heal with scars.¹ The pathogenesis of DEB involves the anchoring fibrils, structures that emanate from the epidermal-dermal junction (EDJ) basement membrane zone (BMZ), and attach to the high papillary dermis. These structures consist of a skin specific collagen called type VII collagen (C7).²⁻³ Normal anchoring fibrils with normal functioning are necessary for adherence between the epidermis and dermis. Approximately 25 – 30% of the normal complement of functioning anchoring fibrils is necessary to keep the epidermis adhered to the dermis.⁴ When anchoring fibrils fall below this percentage, the patient experiences skin fragility and subepidermal bullae over trauma-prone extensor surfaces that heal with milia and scar formation.

There are two ways that anchoring fibrils and their function can be perturbed and lead to clinical skin disease. The first occurs in DEB in which there is a gene defect in the *COL7A1* gene that encodes for the C7 alpha chain, a large molecule of 290,000 daltons. The second arises in patients with autoimmune dysregulation who produce IgG autoantibodies to type VII (anchoring fibril) collagen.⁵⁻⁶ The IgG autoantibodies deposit on anchoring fibrils and leads to their dysfunction or destruction by mechanisms that are not well understood. These patients have acquired EB, so-called epidermolysis bullosa acquisita (EBA). Whether it is genetic DEB (inherited by autosomal dominant or recessive patterns) or an acquired autoimmune bullous disease, such as EBA, these anchoring fibril-centered diseases have similar phenotypes – skin fragility, subepidermal bullae in trauma-prone areas of skin, erosions, milia formation, and scars. Disease severity is variable, but in general, EBA is a

less severe phenotype than recessively inherited DEB with two abnormal alleles.

With regard to therapy, there is very little “evidence-based” therapy for either DEB or EBA.

THERAPY FOR EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa is a disease that has been described prior to the turn of the last century. However, it is a very rare disease. For that reason, there has never been a single controlled therapeutic trial of any medication or device for EBA. To further complicate matters, although all EBA patients have IgG autoantibodies that bind to C7 and anchoring fibrils, the clinical phenotype is anything but uniform. The most common presentation is a relatively noninflammatory, mechanobullous disease that is reminiscent of genetic DEB. However, in a subset of patients, the disease can be highly inflammatory and mimic bullous pemphigoid or cicatricial pemphigoid.⁷⁻⁸ To date, there is no good explanation why there are these variable phenotypes of EBA. Nevertheless, designing a blinded, placebo-controlled therapy trial for EBA is simply unfeasible and has never been done. Therefore therapy for EBA has been “non-evidence based” and has relied simply on anecdotal reports and small case series. Based on these reports, the currently available treatment for EBA is unsatisfactory. Nevertheless, EBA patients may benefit from treatment with the following¹²⁻²²:

1. Immunosuppressive agents
2. Dapsone
3. Colchicine
4. Photophoresis
5. IVIG
6. Biologics (such as rituximab)

Systemic prednisone has very limited value in the noninflammatory, mechanobullous form of EBA. These patients should be advised to avoid trauma to minimize trauma-induced vesiculation and scarring.

THERAPY FOR RECESSIVE DYSTROPHIC EPIDERMOLYSIS BULLOSA

Recessive dystrophic epidermolysis bullosa (RDEB) is a genetic disease caused by a defect in the gene that encodes for a skin-specific collagen called C7. The patients are born with an incurable skin disease, which is manifest by extreme skin fragility, blisters, erosions, and scarring. Other findings include dystrophic fingernails, fibrotic adherent digits, small pearl-like epidermal cysts (milia), mouth and esophageal erosions, poor dentition, and stenosis of the upper one-third of the esophagus caused by chronic wounding and healing at that site. In the third decade of life, RDEB patients frequently develop aggressive and often fatal squamous cell carcinomas in their chronic wounds²³⁻²⁵. There is no current cure for RDEB.

C7 in skin is organized into structures called anchoring fibrils. These structures are large and range in size from 300 nm – 800 nm. They are localized at the interface between the epidermis and dermis and are known to be critical for normal adherence of the epidermis onto the dermis.²⁶

For some time in the past, the prevailing hypothesis in RDEB was that the dermal fibroblasts (or other cell type) synthesized too much collagenase, leading to the degradation of type VII (anchoring fibril) collagen. Therefore, clinicians focused on therapy that could decrease the local amount of collagenase in the skin with the hope that anchoring fibrils would not be degraded. One known collagenase inhibitor is phenytoin (Dilantin). In one small study, systemic phenytoin was given to RDEB patients, and it appeared that these patients developed fewer new lesions, healed older lesions more rapidly, and had overall, better epidermal-dermal adherence with fewer wounds.²⁷ Nevertheless, a larger controlled study comparing phenytoin to placebo showed that the phenytoin was no better than placebo²⁸.

The idea that RDEB was caused by some type of intrinsic increase in collagenase was dispelled when several investigators showed that RDEB was caused by defects in the gene that encodes for C7, the COL7A1 gene. This discovery opened the possibility for gene therapy as an approach of curing RDEB. In theory, the keratinocytes taken from an RDEB patients' skin biopsy could be placed into tissue culture, engineered to correct the gene defect, grown into large sheets, and then transplanted as sheets back onto the patient. Cultured keratinocyte autografts have been successfully transplanted back onto severely burned patients, both adults and children, with success.²⁹⁻³¹ Nevertheless, these keratinocyte sheets are thin and fragile,

and considerable attention needs to be paid to preparing the transplant wound site, applying the cultured autograft, carefully and gently bandaging the patient, and then immobilizing the patient post-transplantation. While feasible, it is logically difficult and some percentage of the transplanted skin is lost.

Both human keratinocytes and human dermal fibroblasts can make C7.³²⁻³³ Thus, it is possible to gene-correct either RDEB keratinocytes or fibroblasts. RDEB keratinocytes and fibroblasts exhibit abnormal morphology, substratum attachment, cell motility, and proliferative potential.³⁴ When these cells are gene-corrected to synthesize and secrete C7, all of these cellular parameters normalize. The cells behave and look like normal skin cells.³⁴ Engineering human fibroblasts offers advantages over keratinocytes, primarily because of their relative ease in culturing and handling. Fibroblasts can be grown with an additional cell for co-culture and passaged over 30 doublings, while keratinocytes are much more finicky and can often only be passaged five to eight times. Therefore, because of these advantages, gene corrected fibroblasts have also become a target for treatment of RDEB.³⁵⁻³⁶ In fact, it has been shown by us and by others that if you intradermally inject gene-corrected RDEB fibroblasts into RDEB skin that has been transplanted onto an immunosuppressed animal, the cells take up residence in the transplanted skin upper dermis, and act like small C7 factories that synthesize and export the protein into the extracellular space of the transplanted skin.³⁵⁻³⁶ Within the extracellular space, the fibroblast-derived C7 will bind to the BMZ between the epidermis and dermis and form anchoring fibrils. The new anchoring fibrils in the RDEB graft then induce good adherence of the epidermis to the dermis and the phenotype of the RDEB graft (skin fragility and blistering) is reversed³⁵⁻³⁶. We have recently shown that gene-corrected RDEB human fibroblasts injected into the vein of an immunosuppressed mouse will migrate to exogenously induced wounds. There, they set up residence in the dermis of the mouse's healing wound and synthesize and export human C7³⁷. We have called this "Cell Therapy" for RDEB.

Recently, the research team of Dr. John McGrath in Great Britain has tried "Cell Therapy" for patients with RDEB with some success.³⁸ Patients received fibroblast injections of normal dermal fibroblasts from a relative, an unrelated donor, or, as a control, themselves. All of the patients tested had RDEB, but made some endogenous C7 at their EDJ. When patients were injected intradermally with normal dermal fibroblasts, the C7 at their EDJ increased, whereas there was no increase when they were injected with their own fibroblasts. In addition, the investigators noted that there was improved epidermal-dermal adherence in the patients treated with normal dermal fibroblasts. While this was encouraging, there was one finding that was both puzzling and less straightforward. When the investigators determined the source of the increased C7 at the EDJ, they found that it came from the patients' cells and was

actually mutated C7 rather than normal C7. The investigators speculated that the injection of normal dermal fibroblasts stimulated the patient's keratinocytes and fibroblast to synthesize and secrete more mutated C7, which homed to the EDJ. That is, it did not appear that the injected normal fibroblasts were contributing C7 to the patient's EDJ. So, while there was a positive therapeutic result, the underlying mechanism toward that result was not what had been expected and was somewhat disappointing.

Using RDEB skin equivalents grafted onto hairless immunosuppressed mice, it was also shown that viral vectors expressing the full-length C7 alpha chain could be intradermally injected into the RDEB skin.³⁹ Both fibroblasts and endothelial cells in the RDEB skin grafts took up the injected viral vectors. These RDEB endogenous cells then expressed normal C7 and secreted it into the local skin environment. In the extracellular spaces in the high papillary dermis, the extracellular C7 bound to the basement membrane at the EDJ of the RDEB skin and produced anchoring fibrils. We called this therapeutic strategy "**Vector Therapy**." Similar to "**Cell Therapy**," vector therapy also resulted in a great amount of linear C7 and anchoring fibrils at the EDJ of the RDEB skin and greatly improved epidermal-dermal adherence.

Vector Therapy

Vector therapy has also been shown to be beneficial in an RDEB-like animal model. This murine model consists of knockout mice unable to make C7.⁴⁰ These mice have a severe blistering disease of their skin and oral mucosa. The mice only live for a few days. Nevertheless, when these animals are injected intradermally with a lentiviral vector expressing the normal human C7 alpha gene, new blistering decreases, the mice live longer and the mice have human C7 and human anchoring fibrils at their EDJ. Their RDEB phenotype is essentially reversed.

One potential advantage of vector therapy is that the patient's own endogenous cells become the papillary dermal "cell factories" synthesizing and secreting normal C7, and no foreign cells are used. Donor-recipient HLA matching issues become moot. While an effective therapy in animal models, this therapy does involve injecting a foreign virus into the patient and has the potential for an untoward immune response. It also has an unlikely but possible side effect of the viral vectors recombining into an active virus and infecting the patient.

Another therapeutic strategy to consider is simply to administer the C7 protein to patients.⁴¹ We know that normally, C7 is synthesized and secreted into the extracellular space of the skin by keratinocytes and fibroblasts. Once this large matrix molecule is in the extracellular space, there are extracellular mechanisms by which the C7 binds to the BMZ in the EDJ. Presumably, this happens by protein-to-protein interactions and adhesion. The BMZ is rich in type IV collagen and laminin-5, and C7 has binding

domains for both of these matrix molecules.⁴²⁻⁴³ Once C7 molecules are selectively concentrated at the BMZ, they are capable of organizing themselves into anchoring fibril structures. Using the RDEB-like mouse model mentioned above, we demonstrated that we could reverse their RDEB phenotype by injecting the animals intradermally with human C7 protein.⁴⁴ The injected human protein became incorporated into the C7-null mice skin at the EDJ and created human anchoring fibrils. Not only did the knock-out RDEB mice now have human C7 and anchoring fibrils at their EDJ, but they lived longer and no longer had skin bullae. We call this approach "**Protein Therapy**."

In summary, we have in vitro studies and in vivo animal studies that demonstrate the feasibility of treating RDEB patients with cell therapy, vector therapy or protein therapy. However, except for the small study by the McGrath group detailed above using cell therapy, there are no other human RDEB trials that have shown a therapeutic benefit for RDEB patients. Therefore, strong evidence-based medicine treatments for RDEB are lacking. Nevertheless, promising clinical trials are currently underway. The group at Stanford University, led Dr. Paul Khavari and Dr. Alfred Lane are pursuing ex vivo therapy for RDEB patients and plan to transplant these patients with gene-corrected, cultured, autologous, keratinocyte sheets. The group in England headed by Dr. John McGrath is continuing to study cell therapy with more patients and using various modifications of their originally published protocol. Investigators at the University of Minnesota and Columbia University are performing clinical trials with RDEB patients in which the patients are treated with bone marrow and stem cell transplants. Although not yet published, it appears that at least one RDEB child was treated very successfully by this approach. Unfortunately, others had serious side effects including death. Lastly, the investigators at the University of Southern California are pursuing protein therapy and have designed a clinical study that will be initiated this year. They believe that there are lower intrinsic risks associated with protein therapy because it does not require exposure to viral vectors or foreign cells and does not carry the associated risk of bone marrow and stem cell transplantation. Protein therapy may also prove to be the most practical because it obviates the need for transplantation of cultures, meticulous wound care, and patient immobilization. However, there are many questions that still need to be answered regarding this and other C7-based therapies. It may be that RDEB patients with no endogenous C7 will produce antibodies to the newly introduced C7 during protein therapy (or vector therapy or cell therapy). The Federal Drug Administration has given protein therapy "orphan disease" status, which should allow it to be approved for use in humans with less regulatory hurdles. Clinical trials are necessary to validate these treatment options and determine what the effects of any newly formed antibodies to C7 will be.

What We Know

- DEB can be inherited or acquired
- A paucity of normal function anchoring fibrils is the common denominator
- DEB is very rare so no FDA-approved medications
- No known cure for inherited or acquired DEB
- No evidence-based studies to support DEB therapy
- For hereditary DEB gene therapy, cell therapy, Vector therapy and Protein
- Therapy is all-possible and works well in an RDEB-like knockout mouse model
- Protein therapy for hereditary DEB is probably the safest treatment to try first
- Therapy for acquired EB (EBA) is based solely on case reports

Treatment of Alopecia Areata

Maria Hordinsky, M.D., Ana Junqueira Bertin, M.D., and Anna Levin, M.D.

INTRODUCTION

No drug is currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of alopecia areata, a complex genetic, immune-mediated disease that targets anagen hair follicles.¹ Alopecia areata is clinically characterized by round or oval patches of hair loss, loss of all scalp hair (alopecia totalis), loss of all body hair (alopecia universalis) or ophiasis pattern hair loss. Both males and females of all ages can be affected and there is no known race or ethnic preponderance. In alopecia areata, the hair follicle is not destroyed and maintains its potential to re-grow hair should the disease go into remission. It is estimated that alopecia areata affects between 4 and 5 million individuals in the United States.² Treatments have been evaluated in randomized trials and as with any autoimmune disease, spontaneous remission is common.

There is currently no cure for alopecia areata and no universally proven therapy that induces and sustains remission.³ Many therapies are available and current treatment choices are frequently based on disease extent, duration, and age of the patient.⁴ The option of not being treated is an alternative way of dealing with this disease.^{5,6}

EPIDEMIOLOGY

The prevalence of alopecia areata in the United States, as determined from the First National Health and Nutrition Examination Survey conducted from 1971 through 1974 was 158 per 100,000 persons, or roughly 0.1 to 0.2% of the population.⁷ From several studies published primarily in the American and British literature, the presence of severe nail abnormalities, atopy (asthma, allergic rhinitis, and atopic dermatitis), onset of extensive disease in children less than 5 years of age, as well as alopecia totalis or universalis lasting more than 2 years, have all been implicated as negative prognostic indicators.^{8,9}

Surveys from other parts of the world such as Kuwait, Northern India, Chandigarh India, Singapore, and Korea have revealed similar as well as slightly different associations.¹⁰⁻¹⁵ In a study from Kuwait, associations were similar to those reported in the western literature. Similar findings were also reported from Chandigarh, India except that

the association of atopy with a younger age of onset and severe alopecia areata was not confirmed. Different associations were reported from studies completed in Kuwait and Northern India. In a study of 10,000 consecutive new patients surveyed in Kuwait, a female preponderance was observed and infants constituted the largest group and in the study from Chandigarh, the age of onset, a positive family history for alopecia areata and associated atopic disorders were noted to have no influence on the extent and severity of the disease.

ETIOLOGY AND DIAGNOSIS

Alopecia areata is a complex genetic, immune-mediated disease that targets anagen hair follicles.¹⁻³ Transplantation studies in severe-combined immunodeficient (SCID) mice established that T-cell immunity is critical in the pathophysiology of this disease.¹⁶

A hallmark of alopecia areata is the histopathologic presence of peribulbar lymphocytes around anagen follicles. There is also some evidence to suggest that immune privilege is lost in alopecia areata.^{17,18a,18b} The peribulbar infiltrate in alopecia areata is frequently referred to as a "swarm of bees," particularly in patients with active disease. In patients with long-standing disease, this inflammatory process may be less obvious. Recent studies have demonstrated the expression of cytomegalovirus UL16-binding protein (ULBP) expression in lesional scalp of patients with active disease providing evidence for the involvement of both innate and acquired immunity in the pathogenesis of alopecia areata.¹ Nerves have also been implicated in the pathogenesis of alopecia areata and stressful life events and psychiatric disorders have been studied as they relate to both the onset and progression of alopecia areata.^{19,20} Genes, the immune and nervous systems continue to be active areas of research in alopecia areata.

Clinically, alopecia areata is quite straightforward to diagnose. Other hair diseases in the differential diagnosis for patchy disease include Tinea capitis and trichotillomania. The differential diagnosis for extensive alopecia areata includes popular atrichia as well as an ectodermal dysplasia. If the diagnosis is not straightforward, examination of a 4-mm scalp biopsy specimen may be beneficial.²¹

SEARCH METHODOLOGY

Searches were performed for the terms “alopecia areata,” “alopecia totalis” and “alopecia universalis with both “AND treatment” and “AND therapy” as modifiers on MEDLINE/PubMed, AMED and PsychINFO with no date limitations and searching all fields. The 2008 Cochrane Review “Interventions for alopecia areata” was also used as a reference for information up to 2008, followed by a search of the terms “alopecia areata,” “alopecia totalis” and “alopecia universalis” without any modifiers from 2007 onward for a comprehensive search of recent literature that was not covered in the Cochrane Review. Searches were also performed for these terms without modifiers on clinicaltrials.gov and the World Health Organization Clinical Trials Registry Platform (<http://apps.who.int/trialsearch>) for upcoming studies.³ The search was performed in October 2009 and a modified search again in September 2009.

TREATMENTS FOR ALOPECIA AREATA

Assessing efficacy of treatments for alopecia areata is complicated by the fact that there are few published randomized controlled trials. There are several uncontrolled trials and reports with non-ideal criteria to evaluate treatment progression and long-term follow up is not included in most of the published works. The definition of “success” varies in different studies with most but not all focused on cosmetically acceptable hair regrowth. Lastly, until recently the criteria to analyze hair regrowth and extent differ among most of the studies. The treatments that will be reviewed in this chapter are presented in Table 19-1. In 1999 and 2004, the Alopecia Areata Investigational Assessment Guidelines were published and were subsequently applied to up to 30% of new investigations providing some standardization to the description of disease extent characterization and response to therapy.^{22,23} Treatments for alopecia areata that will be reviewed in this chapter include the medications and devices noted in Table 19-1.

TOPICAL THERAPIES

Anthralin

The use of anthralin as a treatment for alopecia areata was first described in 1979, in a study in which 21 of 24 patients with patchy alopecia areata and three of eight patients with alopecia totalis developed induction of hair growth with once daily anthralin application.²⁴ It was hypothesized that the irritant contact dermatitis induced on the affected skin was the cause of hair growth. When a low concentration regimen was used on 10 patients, and was unsuccessful and no patients achieved significant hair growth, it was suggested that a higher concentration requiring induction of more irritation was necessary for a therapeutic benefit.²⁵ In a 1987 study, 68 patients with severe alopecia areata

TABLE 19-1 Treatments for Alopecia Areata

Topical

1. Anthralin
2. Calcineurin Inhibitors
 Tacrolimus
 Pimicrolimus
3. Corticosteroids
4. Minoxidil
5. Photodynamic Therapy (PDT)
6. Prostaglandin Analogues
7. Sensitizers
8. Targretin Gel
9. Topical Psoralen plus Ultraviolet Light (PUVA)
10. Narrowband Ultraviolet Light (NBUVB)

Systemic Medications

1. Corticosteroids
2. Cyclosporine
3. Minoxidil
4. PUVA
5. Sulfasalazine

Intralesional Steroids

Biologics

Devices

Combination Therapies

“Natural” Treatments

1. Aromatherapy
2. Onion Juice
3. Topical Garlic

Miscellaneous – There are Several

1. Isoprinosine, Thymopentin, Nitrogen Mustard, Azathioprine, Capsaicin, Vitamin D analog Calcipotriol, Intralesional Interferon alpha-2, Croton Oil, Sodium Lauryl Sulfate, Benzyl Benzoate, Phenol, Staphylococcus-Streptococcus vaccine, Dapsone, Griseofulvin, Topical Tretinoin, Relaxation, Acupuncture.
2. Aromatherapy
3. Cryotherapy
4. Hypnosis
5. Antidepressants

applied higher concentrations of anthralin (0.5% - 1%), and had a more positive response, with 25% of subjects achieving an acceptable cosmetic response, and 71% of responders maintaining hair growth for the duration of therapy. Adverse effects were typical of an irritant dermatitis and included erythema, scaling, and pruritus in the treated areas.²⁶

More recent studies have focused on the molecular mechanisms of action of anthralin, such as its possible immunomodulating qualities.²⁷ In 2005, a study of 31 patients with patchy alopecia areata, compared the efficacy of 0.5% topical anthralin to 20% topical azelaic acid. An overall similar efficacy rate of 53.3% of the azelaic acid group and 56.2% in the anthralin group was documented suggesting a “shared” irritant quality.²⁸ To date, no randomized controlled trials have been performed to evaluate

the efficacy of anthralin, and available study results are limited by study design and patient population size.

Calcineurin Inhibitors

Topical Tacrolimus and Pimecrolimus

Tacrolimus and pimecrolimus have been used for many years as immunosuppressant medications in organ transplantation and in T-cell mediated autoimmune diseases.²⁹ They exert anti-inflammatory and immunomodulatory activities inhibiting transcription following T-cell activation of several cytokines. Application of topical tacrolimus in rat and mouse models of alopecia areata suggested that the use of this drug could be effective in treating alopecia areata.^{30,31} There are however no randomized clinical trials using these treatments for human alopecia areata but the results of two open-label studies have provided some useful information.

In 2004, 17 patients were enrolled in a study for 30 weeks.²⁹ Tacrolimus ointment 0.1% was applied twice daily in the affected scalp for 24 weeks. After stopping the treatment, the subjects were observed for 6 weeks. Only 11 patients completed the study, six discontinued participation, two because they found the greasy ointment to be inconvenient to use. Of these 11 subjects who completed the study, only one showed hair regrowth, the others experienced no change or even further loss. The authors suggested that this lack of efficacy could be related to insufficient penetration of the current ointment formulation and the selection of the patients.

A pilot study with pimecrolimus 1% cream versus placebo including 15 patients, revealed a similar type of response as was seen with tacrolimus. Even though all the enrolled patients had alopecia areata with duration of less than 2 years, the efficacy of Pimecrolimus was no better than placebo.³²

Although there is a theoretical concern, there is no evidence to suggest an increased risk of cutaneous or visceral cancer in patients applying topical pimecrolimus or tacrolimus.³³⁻³⁵ Notably, tacrolimus is not atrophogenic and at concentrations that had efficacy similar to 0.13% clobetasol, it did not cause atrophy of the skin.³⁶

Topical Corticosteroids

A variety of topical corticoids with different potency/category and different types of vehicles are available and are frequently used to treat AA. In 1972, Kligman and Leyden tested the topical application of 2.5% dexamethasone using penetration enhancer vehicles to treat 26 patients, including patients with alopecia totalis and patchy type of alopecia areata. Group 1 (10 patients) applied the solution to one or more areas of alopecia, leaving at least one untreated as control. Sixty percent of these patients had definite signs of regrowth in 1 month. Group 2 (22 patients)

were treated first with oral prednisone (beginning at 30 mg daily and gradually reducing the dose till 0 for 5 weeks) and after the oral steroid course, the ones who showed signs of regrowth, 18 of the 22, received the topical dexamethasone formulation to apply three times a day. In 17 cases the hair growth initiated by the oral steroid was maintained by the topical application.³⁷

In a 1992 review, Fiedler et al. have reported promising clinical results using topical steroids for AA. Application of 0.05% betamethasone dipropionate cream twice daily, was shown to work well, particularly well in children, even in some with 100% hair loss. According to the investigators, at least 3 months of uninterrupted treatment was necessary to assess hair regrowth.³⁸

Pascher et al. demonstrated significant responses in patchy AA with the use of topical 0.2% fluocinolone acetonide cream. These authors reported hair regrowth in six of nine patients with alopecia totalis. The results were surprisingly different between different ages. Children younger than eleven obtained 100% regrowth, adolescents younger than 16 obtained 50% and adults only 33%.³⁹

The use of clobetasol propionate 0.05% under occlusion for 6 weeks in patients with alopecia universalis, using a half-side technique also commonly called a half head study, was associated with almost a 29% response rate. However, three patients relapsed in the 6-month follow-up period. Occurrence of hair regrowth only in the treated half of the scalp clearly showed that the efficacy of this treatment is a result of a local and not systemic effect of the drug. In the total of 28 patients, six did not conclude the study because of side effects or lack of compliance.⁴⁰

Topical 0.25% desoximetasone cream was also tested in a 12-week course and when compared to placebo showed a moderate hair regrowth response in alopecia areata patients. There was a trend toward more regrowth with the topical, but the rate of complete hair regrowth was not statistically significant when compared with placebo.⁴¹

In more recent trials, investigators focused on finding the most appropriate vehicles to use for the management of alopecia areata. Mancuso et al. in a randomized clinical trial, demonstrated that betamethasone valerate foam was effective and well tolerated by patients with mild to moderate AA. In a 12-week treatment study in which one group of patients with mild-to-moderate alopecia areata applied betamethasone valerate (BVF) cream and the other, betamethasone dipropionate lotion (BDL), a regrowth score (RGS) >3 was observed in 61% of patients in the BVF group compared to 27% in the BDL group ($P<0.03$).⁴²

The efficacy and safety of clobetasol propionate 0.05% foam to treat moderate to severe disease has also been examined. In a 12-week within patient study, (right versus left side of scalp) regrowth of at least 50% was noted seven of 34 of the treated sites compared to one of 34 on the non-treated side.⁴³

According to Fiedler, in 15 years of using topical betamethasone dipropionate twice daily, no systemic side effects

were seen even in children as young as 2 years of age and older who were receiving long-term maintenance therapies.⁴⁴ Nonetheless, careful monitoring of the growth curve in children as a marker for hypothalamic-pituitary-adrenal axis suppression is advised. Side effects at the sites of application can occur. These are considered to be in large part reversible and include folliculitis, atrophy, and hypertrichosis on the face or neck.⁴⁴

Minoxidil

This vasodilating antihypertensive drug was noted in the 1980s to have a prominent side effect of hypertrichosis. Upon this discovery, several case series and reports were described in which minoxidil was used topically for the treatment of alopecia areata with some success.⁴⁵ This led to a modified double blind crossover study, comparing 1% topical minoxidil with placebo in 30 patients with patchy alopecia areata and alopecia totalis. A cosmetically acceptable response was seen in 16 patients, none of whom experienced adverse effects. It was also noted that those patients with more extensive disease were less likely to respond.⁴⁶ In a subsequent study by Vanderveen et al. 15 patients with alopecia totalis or universalis applied either 1% or 5% topical minoxidil. None achieved hair regrowth despite blood levels similar to a group of patients with androgenic alopecia for whom the treatment was more successful.⁴⁷ Vestey et al. also found no significant difference in a prolonged double-blind trial of 1% minoxidil in hair growth of 50 patients with extensive alopecia areata.⁴⁸

A larger study evaluating a 1% topical solution on 24 patients with patchy alopecia areata and 24 patients with alopecia totalis or universalis was more promising. Twenty five patients saw terminal hair growth, and of those, 11 saw cosmetically acceptable results. Hair growth in this study was not associated with disease severity or extent, and began approximately 2 months after treatment was started. Notably, no systemic side effects were found.⁴⁹ Similarly, in a study of 54 patients, 7 with alopecia totalis and 47 with patchy disease, 28 patients applied topical minoxidil and 26 patients received a placebo formulation, 50% of the treated group achieved cosmetically acceptable regrowth.⁵⁰ However, these results were again contradicted by a double-blind crossover trial of 15 patients with alopecia totalis studying 3% topical minoxidil versus placebo. After 16 weeks, the results showed no cosmetically acceptable hair regrowth in patients with extensive well-established alopecia totalis. The results showed only some vellus hair growth which was not deemed cosmetically acceptable.⁵¹ These inconsistent conclusions continued in a 3-month double-blind crossover study of 1% topical minoxidil on 23 patients with extensive alopecia areata, 13 of whom showed an increase in terminal hair growth, but only one achieved a cosmetically acceptable result.⁵²

To further examine the effectiveness of minoxidil, a study was completed evaluating 5% minoxidil solution in

47 patients with severe alopecia areata. Notably, 85% of patients had terminal hair regrowth after 48-60 weeks of treatment. Although for most of these subjects, the hair growth was not cosmetically acceptable, these results were significantly better than with a 1% solution.⁵³ Furthermore, a study of 66 patients also with extensive scalp hair loss resulted in terminal hair growth in 38% of patients with 1% solution and 81% of patients who applied a 5% solution. An observation from this study was that occlusion of the area must be maintained for optimal results. It was also noted that recurrence of hair loss was frequent upon cessation of treatment.⁵⁴

Multiple other studies have shown modest, if not dramatic benefits that minoxidil may have in the treatment of alopecia areata. A 3% solution has also been studied. One double-blind evaluation of 30 patients with extensive alopecia areata who applied either 3% minoxidil twice a day for 64 weeks or placebo for 12 weeks followed by 3% minoxidil, the remainder of the weeks showed no statistically significant difference at 12 weeks. At 64 weeks, 45% showed a cosmetically acceptable result but none of those patients had 100% hair loss at baseline. Hypertrichosis of the face was noted as an adverse experience in five of the subjects.⁵⁵⁻⁵⁶ In another double-blinded, placebo controlled trial of 1 year's duration, patients with extensive disease who applied 3% topical minoxidil did achieve better hair growth, but only three of the 11 minoxidil-treated patients achieved a cosmetically acceptable result. In this study, there were no significant adverse experiences.⁵⁵ A randomized, double-blind, controlled study of 21 patients with alopecia totalis or universalis using 3% topical minoxidil was unimpressive; no significant cosmetically acceptable results were achieved, although transient regrowth of vellus hair was present in eight patients. Long-term efficacy over 3 years showed maintenance of results but no additional cosmetically acceptable growth in those who did not show it initially, and none of the patients went into complete remission during treatment.⁵⁷⁻⁵⁸

Photodynamic Therapy (PDT)

Photodynamic therapy involves the administration of a photosensitizer, followed by its activation with light to generate a therapeutic effect. 5-Aminolevulinic acid (ALA) is a photosensitizer precursor that is transformed by cells into protoporphyrin IX (PpIX), which can in turn be activated by red light.⁵⁹ The knowledge that ALA is primarily metabolized to PpIX in activated lymphocytes, and that this photosensitizer has been shown to induce apoptosis in cell culture and tumors, created a reasonable link to explore the role of PDT in AA.⁶⁰⁻⁶²

In 1987, Da Monfrecola et al. reported hair regrowth in patients with alopecia areata after PDT using a topical formulation of the photosensitizer haematoporphyrin.⁶³ Despite the interesting possible link between this therapeutic approach and alopecia areata, only one randomized

clinical trial is available for review. Bissonnette et al. investigated the effect of PDT in AA, trying to clarify the “theoretical hypothesis” that ALA-PDT could improve AA by inducing apoptosis around the hair follicles. In a group of six patients, ALA lotion at 5%, 10% and 20% as well as the vehicle alone were applied separately to different areas of the scalp—followed 3 hours later by exposure to red light at each treatment session. A significant increase in erythema and pigmentation was observed in the concentrations used, suggesting that PpIX was being activated. With fluorescence microscopy, bright red fluorescence was seen only in the epidermis and sebaceous glands, and was not seen around the hair follicles and after 20 twice-weekly treatment sessions, no significant hair regrowth difference between the vehicle and the three ALA-treated sites was observed. It was thus concluded that the use of PDT was ineffective in the treatment of alopecia areata.⁵⁹ Nevertheless the authors had some considerations related to factors that could be implicated in the final results. They suggested that number of treatments, number of patients, length of period between drug application and light exposure and low level of the PpIX synthesized (not enough to be detected) could be explanations to explain the negative findings. The use of oral ALA was discussed as a future perspective to overcome the obstacles because Divaris et al. showed phototoxic damage to hair follicles and sebaceous glands after systemic use of ALA.⁶³

Prostaglandin Analogues

Prostaglandins and specifically Prostaglandin F2 alpha analogs bind to cell surface receptors activating phospholipase C. This enzyme orchestrates a variety of responses in cells such as stimulating gene expression and division. Latanoprost and bimatoprost are phenyl substitute analogues of prostaglandin F2 alpha, and are widely used in an ophthalmic solution to lower intraocular pressure in glaucoma.

In 1997, the first data relating eyelash regrowth to this type of drug was published. A retrospective trial done by Johnstone et al. reported that in 43 patients receiving latanoprost monocularly, hypertrichoses of eyelashes occurred in all of the eyes treated, using the contralateral eye as a control.⁶⁴ After this work some case reports were seen reinforcing this relationship but none were related to patients with alopecia areata.⁶⁵

In 2002, a macaque model was used to elucidate the effect of latanoprost for hair regrowth using animals with androgenetic alopecia. Latanoprost was applied topically using 50 ug/mL and 500 ug/mL compared to placebo. The smaller concentration caused minimal hair regrowth while 500 ug/mL induced moderate to marked hair regrowth with 5-10% conversion of vellus hairs to intermediate or terminal hairs.⁶⁶

After several additional studies, a case report of an 11-year old girl with bilateral loss of eyelashes assumed

to be related to alopecia areata was published. She was prescribed Latanoprost and demonstrated pronounced lash growth of eyelashes on all four lids after 8 weeks of use.⁶⁷

Ross et al., were one of the first to publish a study of prostaglandin analogues for alopecia areata. This was a 16-week randomized, right-left, investigator blinded study in adults with severe eyebrow AA. The randomly assigned subjects treated one eyebrow with topical latanoprost (3 mcg) for 12 hours daily over 12 weeks. In a total of eight patients, seven did not show any regrowth. One patient did have a positive result; however, it was bilateral and was most likely the result of administration of prednisone therapy during the treatment period.⁶⁸

In 2008, another trial to assess the effect of cutaneous application of latanoprost for alopecia areata was published. Bimatoprost was also tested and both drugs were used in the same concentration as they are used for glaucoma. The drugs were applied directly to the affected eyelid margins of patients with alopecia areata. None of the patients presented appreciable regrowth. It was concluded that the method of drug delivery was yet to be elucidated.⁶⁹

One year later the use of topical latanoprost was again assessed, but at this time in the eyebrows and eyelashes. In 26 patients, only one showed partial regrowth.⁷⁰

Instilled bimatoprost ophthalmic solution was also explored in an open label prospective study to evaluate eyelash regrowth in alopecia areata patients. No appreciable regrowth was seen in patients with 95% to 100% eyelash loss at baseline. Patients with up to 30% and 40% eyelashes present at baseline did experience additional eyelash growth, suggesting that patients with less extensive eyelash loss may benefit from this therapeutic option.⁷¹

Sensitizers

Three different topical sensitizers have been used to treat alopecia areata with some evidence of efficacy. These three include dinitrochlorobenzene (DNCB), diphenycyprone (DPCP), and squaric acid dibutyl ester (SADBE). The theory of immunomodulation was proposed by Happle et al. in 1986, when he showed that skin treated with topical sensitizers showed changes in the peribulbar CD4/CD8 lymphocyte ratio.⁷² In 2006, Herbst et al. reinforced and complemented the theory providing evidence that long-term treatment with a contact sensitizer, allows for the recovery of the hair follicle by driving autoreactive T cells into activation-induced cell death.⁷³

DNCB was first used for alopecia areata in 1976, but because of concerns over the mutagenic properties of the drug in *Salmonella enteritidis* serotype Typhimurium and its absorption through the skin with ultimate excretion in urine, its use has in large part been discontinued.⁷⁴ Because SADBE is stated to be relatively unstable in acetone solution, DPCP is the most commonly used sensitizer in clinical practice.⁷⁵⁻⁷⁶ Happle et al. enthusiastically introduced the use of DPCP for the treatment of alopecia areata when

they reported that 67% of treated patients had a satisfactory response to this treatment.⁷⁵ In a larger study of 139 patients completed by the same investigator, a response rate of 50.4% was subsequently reported.⁷⁷ However, some years later a review of 17 reported cases series concluded that though 50-60% of patients may achieve a response to DPCP, the range of reported responses was very wide, between 9 to 87%.⁷⁸ In a follow-up study, Gordon et al. included a total of 32 patients and demonstrated that only nine patients maintained regrowth without further DPCP treatment for an average of 19.8 months, while nine had poor regrowth with continued use of the drug and 5 discontinued the treatment.⁷⁹

Micali et al. studied the use of SADBE for alopecia areata and demonstrated an 80% rate of regrowth in less severe forms and 49% in more severe cases. The failure rate was found to be higher in patients with the more severe form (29%), compared to a 7% rate only for patients with mild AA.⁸⁰ The same investigator later studied 54 patients with extensive alopecia areata treated with SADBE. Data collected were compared with those of a matched control group of 54 patients who did not receive any treatment. At the end of therapy, the treatment group showed a statistically significant ($p<0.001$) improvement. At follow-up, there was no significant change in the previous relapse rate (treated 44% vs. control 52%).⁸¹

A review of AA treatments in 2003 presented the evaluation of the 17 most significant controlled trials from 1983 to 2001, using DPCP and SABDE studies to test the efficacy of treating AA. The response rate of treatments represented by cosmetically acceptable hair regrowth varied from 29% to 78%. The investigators suggested that these differences could be explained by the different extent and durations of alopecia areata present in the patient populations prior to the treatment in each study and by the different treatment methodologies.⁸² In yet another retrospective chart review of patients from 1996 to 1999, 33% were found to attain cosmetically acceptable or total regrowth with topically applied SADBE.⁸³

An Indian study in 2006 involved 70 patients treated with SADBE for 4 months. The overall success rate was 43%. For subjects with <50% of scalp involvement the rate was 68%, however for those with > 50% involvement the success rate was 29%. Additionally 81% of the responders (21 in 26) had relapse occurrence.⁸⁴

In a study completed in Greece, 64 patients with alopecia areata were sensitized with 2% DPCP and treated with graduated concentrations adjusted to maintain erythema and pruritus on the scalp for 48 hours. The follow up was 2 years. A total of 83.3% of the subjects responded to therapy, although a significant difference in responses was noted and varied between regrowth of vellus hair, sparse pigmented terminal hairs, and terminal hairs in patches of alopecia, as well as regrowth of terminal hair on the entire scalp. Relapses were noted to occur in approximately 70% of the patients.⁸⁵

The side effects of topical immunotherapy need to be considered. Although the desired reactions inherent to the treatment include a mild dermatitis, undesired side effects are noted in 2-5% of patients and include vesicular and bullous reactions at the initiation of treatment before appropriate individual concentrations are determined, dissemination of allergic contact dermatitis, urticaria or erythema multiforme-like reactions, and pigmentary disturbances such as postinflammatory hyperpigmentation. Notably, no long-term side effects have been reported after 18 years use of DCPC and 21 years of SADBE treatments worldwide.⁸²

Targretin Gel

In 2009, a phase I/II randomized bilateral half-head comparison study was performed to evaluate the efficacy of bexarotene gel for alopecia areata. Bexarotene is a synthetic retinoid that target the retinoic acid X receptor, which has been shown to have immunomodulatory effects beneficial in cutaneous T-cell lymphoma. In this study, 42 patients were included, 34 with patchy disease, 3 with alopecia totallis, and 5 with alopecia universalis. One percent bexarotene gel was applied topically to half of the head twice daily for 6 months; 12% achieved 50% or greater regrowth on the treated side, and an additional 14% achieved similar results bilaterally. This study, like many others, was limited by an inability to differentiate drug-induced and spontaneous growth, but the results suggests that bexarotene is a well-tolerated treatment that warrants further study.⁸⁶

Topical Psoralen plus Ultraviolet A Light (PUVA)

The use of psoralens and ultraviolet A light (PUVA) for alopecia areata is based on the concept that PUVA therapy may influence the inflammatory infiltrate that surrounds affected hair follicles. There are many uncontrolled studies of both oral and topical PUVA for alopecia areata. Both oral and topical have been tried. In this section, results of topical studies will be emphasized.

Weissman et al. were the first to report encouraging results from the use of topical methoxsalen and UVA radiation of the scalp. The range of hair regrowth in this study varied from 15% to 90% in a small group of five patients.⁸⁷ Lassus et al. subsequently reported on 41 patients who were treated with topical or oral methoxypsonalalen and UVA. They reported good to excellent results in 73% of patients.⁸⁸

Claudy et al. reported treatment failure to local UVA radiation and topical methoxsalen but positive results for oral methoxsalen and total skin surface irradiation in two consecutive studies in 1980 and 1983.⁸⁹ In a small group of patients treated with oral methoxsalen and total skin surface irradiation, 64.7% of the patients had a complete

or more than 90% regrowth. During a follow-up period of 18.6 months, three patients experienced a relapse.

Mitchell et al. in a study of 22 patients demonstrated almost a 46% positive response to treatment with topical methoxysoralen and UVA in which 36% had excellent hair regrowth and 9% had good regrowth. In a follow-up mean period of 8.3 months, 8 of 9 responders experienced a relapse, with the investigators concluding that this approach does not change the long-term course of AA.⁹⁰ In two retrospective reviews of clinical experience the response rate was also found to be low (6.3-13.1% after at least 3 months treatment) and according to the investigators, no better than spontaneous improvement.⁹¹⁻⁹²

In a 2005 report of 149 patients, 124 patients with alopecia areata and 25 patients with alopecia totalis/universalis treated with topical 8-methoxysoralen and UVA were reported to have different treatment responses. Of the alopecia areata totalis/universalis patients, 44% showed only vellus hair regrowth and 56% had good (>50% scalp hair regrowth) and excellent results (>80% scalp hair regrowth). Three patients experienced relapses in the follow-up period. In contrast, patients with patchy alopecia, 85% demonstrated good or excellent hair regrowth; 11% had fine white hair regrowth and 4% no response.⁹³

Psoralen-UVA-Turban is a modification of PUVA bath therapy in which a dilute Psoralen solution is administered selectively to the scalp of patients. Twenty patients were treated with 8-methoxysoralen at a dilution of 0.0001% (1 mg/mL), applied for 20 minutes to the scalp followed by UVA radiation. Treatments were performed 2 or 3 times a week. Hair regrowth was observed in 15 patients, a 75% of overall success rate. Six patients experienced total regrowth (4 with patchy disease and 2 with alopecia totalis/universalis). Nine patients (5 with patchy disease and 4 with alopecia totalis/universalis) or 45 % had partial regrowth. Five patients did not respond to this treatment. Analyses on the different responses according to the type of alopecia areata revealed that 100% of patient with patchy disease achieved some kind of regrowth while only 55% of the patients with alopecia totalis/universalis did. The conclusion was that this treatment was effective, particularly for patchy alopecia areata.⁹⁴⁻⁹⁵ In general, regrowth is usually detected after 20-40 sessions, with the maximum effect developing within 1 year.⁹⁶

Narrowband Ultraviolet Light (NBUVB)

Despite positive results with other autoimmune diseases such as psoriasis, the use of UVB phototherapy for alopecia areata has been only minimally studied. This therapy was first described in 1961, when a Kromayer lamp was used to treat 32 patients with extensive alopecia areata weekly or every other week. Twenty five patients achieved hair regrowth within 3 months, and full regrowth occurred in 14 of the 25, however, several reported relapse upon discontinuation of treatment.⁹⁷ A later evaluation of

multiple dermatoses including eight patients with alopecia areata used a novel monochromatic excimer light (MEL) light delivery system and resulted in 4 individuals achieving complete hair regrowth with a mean of 5.1 well-tolerated sessions.⁹⁸ However, an additional study which included eight children with alopecia areata, narrowband UVB phototherapy failed to produce results in any of the subjects, perhaps due to different delivery methods or the age of the patients.⁹⁹

SYSTEMIC THERAPIES

Corticosteroids

Since interest in the responsiveness of alopecia areata to systemic corticosteroids began in the 1950s, (Dillaha, Shelley) there have been many investigations done to examine the safety and efficacy of this therapy, as well as appropriate dosing regimens.¹⁰⁰⁻¹⁰¹ Numerous small studies on the effectiveness of systemic steroids administered orally or intramuscularly and long treatment periods led to enthusiastic publications.¹⁰²⁻¹⁰³ Later it was suggested that extensive disease is not as amenable to treatment as less extensive disease and the detrimental effects of prolonged systemic therapy including striae and truncal obesity, among others, in addition to the likelihood of disease recurrence, upon discontinuation of therapy led to less enthusiasm for this approach.¹⁰²⁻¹⁰³

Interest then grew for pulse dosing as a way to minimize adverse effects. Preliminary trials of various regimens obtained similar results, showing that such dosing had the capability of temporarily arresting and possibly putting into remission active alopecia areata, especially patchy multifocal disease. The treatments appeared to be well tolerated and safe. However, those with prolonged disease duration or extensive distribution seemed to respond to a lesser degree to this therapy than those with recent onset (<12 months). Recurrence of hair loss occurred in many patients with this dosing regimen as well.¹⁰⁴⁻¹⁰⁸ Similar results were found in children treated with pulse therapy.¹⁰⁹⁻¹¹⁰

In an open study of 45 patients, IV pulse of 250 mg methylprednisolone was administered twice a day for three consecutive days to patients at 1, 3, 6, and 12 months. All patients had disease duration of less than a year, the extent of which varied. Twenty patients had patchy disease, 10 ophiasis pattern hair loss, 6 alopecia totalis and 9 alopecia universalis. This treatment stopped hair loss in half the patients and lasted at least 12 months in 54% of responders. Minimal side effects were experienced, and patients with multifocal alopecia areata experienced the greatest benefit while those with ophiasis and universalis patterns obtained a less pronounced improvement.¹¹¹

The first randomized, placebo-controlled study published in 2005 included 43 patients with extensive disease who received either a placebo control or 200 mg of oral prednisolone weekly for 3 months. Patients were

followed monthly for 3 months subsequent to completion of the study. None of the treated patients had been diagnosed with the disease for greater than 2 years. Of the 23 patients in the treated group, eight experienced significant regrowth while none of the patients in the untreated group did. However, two of the patients who achieved regrowth experienced a relapse during the follow-up period. The results of this study supported a role for systemic corticosteroids, particularly pulse dosage, in the treatment of alopecia areata.¹¹²

The question of which systemic regimen is most effective with the fewest side effects in both limited and extensive disease was addressed by Kurosawa et al.¹¹³ Fifty-one patients with patchy disease and 38 patients with alopecia totalis/universalis were randomly divided to receive either pulse therapy, low-dose daily dexamethasone, or monthly intramuscular injections. The response rate and relapse rates were significantly better in the pulse therapy and intramuscular steroid groups, however 23% of those receiving intramuscular steroid injections and 7% of those who received pulse therapy were observed to have temporary impairment of adrenocortical function.

To confirm these findings, Nakajima et al. studied a larger population of 139 patients with severe disease, 90% with disease duration of less than 1 year, and 72.7% with hair loss affecting >50% of the scalp.¹¹⁴ Among the group with a disease onset of <6 months, 59% had a response rate of 75% or greater while only approximately 16% of patients with a longer duration since disease onset had a similar response. Furthermore, among the recent onset patients, those with <50% hair loss had a response rate of 88%, while those with 100% hair loss only responded in 21% of cases. These results reaffirmed the variable success rates of this treatment with different types of alopecia areata.

Overall, the evidence suggests that systemic therapy with corticosteroids is an important part of the management of active disease, especially in specific groups of patients. The risks and benefits of this treatment must however be weighed individually for each patient as there are significant side affects associated with systemic steroid therapy and relapses are likely. Furthermore, long-term outcome studies remain to be completed.¹¹⁵

Cyclosporine

Several case reports have been published on the effectiveness of systemic and topical cyclosporine.^{116,117} In one of the first studies, six patients received oral cyclosporine (two with patchy alopecia areata, two with alopecia totalis, and one with alopecia universalis). Scalp hair regrowth was seen in all subjects by the fourth week. Cosmetically acceptable regrowth was experienced in three of the six patients; however, all experienced a relapse within 3 months of discontinuation of therapy.¹¹⁸ In a slightly larger study of fifteen patients who received oral cyclosporine for 6-12

months (eight with alopecia universalis, two with alopecia totalis, and five with patchy alopecia areata), twelve experienced vellus hair growth. Of those, seven went on to develop terminal hair after 3-8 months; two patients experienced full hair regrowth. Side effects were minimal except for one patient who withdrew from the study because of hypertension and another who experienced gingival hyperplasia. Unlike corticosteroids, responsiveness to therapy did not appear to correlate to type or severity of disease.¹¹⁹

Interest in the topical application of cyclosporine also evolved, however a study by Gilhar et al. showed no beneficial response in any of 10 patients with alopecia areata and alopecia universalis who used a topical formulation of cyclosporine A in an oil preparation for 12 months.¹²⁰ A placebo-controlled study of 43 patients revealed development of terminal hairs in a group receiving topical cyclosporine, but no patient experienced complete scalp hair regrowth. Side effects were minimal, with occasional itching or irritation and no evident laboratory abnormalities.¹²¹

These findings provide encouraging data to support the further study of cyclosporine in randomized, controlled, large studies to fully evaluate the efficacy and safety of this treatment. Future studies could also focus on a preferred dosage and delivery system.

Minoxidil

Because minoxidil is limited by its cutaneous solubility and absorption, the efficacy of employing an oral route was evaluated in a 1987 study of 65 patients with extensive, treatment-resistant alopecia areata.¹²² Despite a more rapid and extensive response, only 18% patients obtained a cosmetically acceptable response. It was concluded that oral minoxidil was unlikely to be effective as a single agent in the treatment of severe disease. Specifically, a total of 65 patients were entered into a study to determine the safety and efficacy of low-dose (5 mg every 12 hours) oral minoxidil in the treatment of severe AA. Patients included were 27 men and 38 women, ranging in age from 13 to 55 years (mean, 31 years). Extent of scalp hair loss at baseline was 75% to 100% in 44 (68%) patients, 25% to 74% in 19 (29%), and 0% to 24% in two (3%). Thirty-four patients of the 65, were treated in a previous study with topical 5% minoxidil. They had experienced either no response to treatment or no additional response in the preceding 3 to 6 months. These patients were subsequently enrolled in this same study with oral minoxidil. Cosmetic response was defined as sufficient terminal hair regrowth so that the patient no longer needed a wig or cap to conceal any residual alopecia. Fair response was defined as extensive, but not cosmetic, regrowth. Slight response was defined as sparse terminal hair regrowth. Nonresponse was defined as vellus or no regrowth. Scalp biopsies were performed at baseline and at 6 months. Serum minoxidil levels were monitored at each

visit for the first 12 to 18 months of treatment. Strict adherence to a 2-g sodium diet was required for the duration of treatment. The mean duration of treatment was 53 weeks (range, 20 to 115 weeks).

Response to oral minoxidil was seen in 52 (80%) of the 65 patients, in 21 (100%) of 21 patients with baseline scalp hair loss less than 75%, and in 31 (70%) of 44 patients with baseline scalp hair loss greater than or equal to 75%. Cosmetic response was seen in 12 (18%) of the 65 patients, in eight (38%) of 21 patients with less than 75% scalp hair loss, and in four (9%) of 44 patients with greater than or equal to 75% scalp hair loss. Cosmetic regrowth was maintained during treatment in all 12 patients, although minor episodes of hair loss occurred in some. Serum and tissue levels showed no correlation with each other or with response to treatment. Thirty-three patients discontinued taking oral minoxidil, 19 because of lack of efficacy, and 14 for personal reasons. Seven of these patients reported onset of hair loss within 2 to 8 weeks after discontinuation of treatment.

Oral minoxidil and topical 5% minoxidil produced similar percentages of responders. The mean time to regrowth was similar in both studies. Comparison of the 34 patients who were treated in both studies showed that hair regrowth progressed more rapidly and was more extensive with oral than with topical 5% minoxidil. Cosmetic response was enhanced with oral minoxidil (12/65 [18%]) vs topical 5% minoxidil (6/47 [13%]). The mean time to a cosmetic response was also shortened with oral (34.8 weeks [range, 12 to 61 weeks]) vs topical 5% minoxidil (62 weeks [range, 16 to 158 weeks]).

Oral minoxidil at the dose studied was relatively well tolerated and was used in an attempt to bypass the barrier to percutaneous absorption and the limitations of minoxidil solubility. Although efficacy was enhanced, only 18% of the patients achieved a cosmetically meaningful response. Mean tissue levels of minoxidil were similar for fair and cosmetic responders versus slight and nonresponders. These data suggest that even if topical minoxidil preparations are improved such that absorption and solubility limitations are overcome, minoxidil as a single therapeutic agent is expected to be cosmetically effective only in a minority of patients with severe AA.¹²³

PUVA

As noted previously, the use of Psoralens and UVA (PUVA) for AA is based on the concept that the PUVA therapy may eradicate the inflammatory infiltrate that surround the affected hair follicles. In 1980, a group reported 41 patients who were treated with either topical or oral methoxsalen and UVA. Good to excellent results were obtained in 73% of their patients.¹²⁶ Claudio et al. reported treatment failure to local UVA radiation and topical methoxsalen and positive results for oral methoxsalen and total skin surface

irradiation. For oral methoxsalen and total skin surface irradiation, 64.7% of the patients had a complete or more than 90% regrowth in a small group of 17 subjects total. In a follow-up mean of 18.6 months, three patients relapsed.¹²⁴

Several relevant features of PUVA need be considered before choosing this therapeutic approach. Systemic PUVA can induce nausea, vomiting, possible burning of the scalp, pigmentary alterations, photo aging, squamous cell carcinoma, and photosensitization of the cornea and the entire skin. Local PUVA or PUVA-bath can avoid the systemic effects as systemic burden of 8-MOP and the duration of photosensitivity in the skin is shorter following local application, but the available epidemiologic data do not support conclusions that PUVA-bath per se is less carcinogenic than oral PUVA therapy. All forms of PUVA therapy with 8-MOP irrespective of the route of administration of Psoralen, are expected to contribute to a small, dose-dependent increase in non-melanoma skin cancers.¹²⁵

Sulfasalazine

Sulfasalazine was developed in 1938 for the treatment of rheumatoid arthritis. Its anti-inflammatory drug composed of sulfonamide and salicylate.¹²⁶ This drug promotes inhibition of the chemotaxis of inflammatory cells and the production of antibodies, acting as an immunosuppressive and immunomodulatory agent.

Ellis et al. were the first group to report the use of sulfasalazine for AA. They reported 23% of cosmetically acceptable hair regrowth in a group of 30 patients. The results, however, were in large part anecdotal.¹²⁷

In 2007, an isolated case report showed one patient who showed 50% hair and eyelash regrowth after 7 months on sulfasalazine on progressive doses from 1 to 3 mg daily. The patient however had to terminate the treatment because of adverse events such as dizziness and headache. All fibers including eyelashes were shed within a few months after discontinuing the medication.¹²⁸

Thirty-nine AA patients with persistent (recalcitrant to other therapies) disease were treated with 3g of sulfasalazine for 6 months and evaluated using the SALT score in a prospective trial. A good response occurred in 25.6 %, moderate response in 30.7% and poor or no response in 43.5% of the patients. Recurrence was observed in 12.8% of the responders (3 with moderate and 2 with good response). 5.1% of the patients experienced dizziness and headaches and 20% dyspepsia.¹²⁹

An open label uncontrolled trial in 2008 included 22 AA subjects with recalcitrant or severe AA on a regimen of 1 mg to 3 mg daily. The treatment duration ranged from 6 to 24 months. Overall rate response achieved 68.2%. 27.3% of the patients experienced complete hair regrowth, 40.9% partial hair regrowth and 31.8% no hair regrowth. Side effects were observed in 31.8% of the subjects, and

included gastrointestinal distress, rash, laboratory abnormalities, and headache.¹³⁰

Combination therapy with sulfasalazine and systemic corticosteroids has been reported to be successful. A series of six case reports demonstrated the efficacy of using sulfasalazine 1 to 3 g/day along with oral methyl prednisolone 1 mg/kg/day for 3 months. After this period, complete recovery was seen and the corticosteroid was tapered. After an additional 7 months of therapy with sulfasalazine alone, patients were followed for another 16 months, maintaining full scalp hair growth.¹³¹

INTRALESIONAL CORTICOSTEROIDS

Local injection of corticosteroids into lesions of alopecia areata has been the preferred treatment since the late 1950s after this approach was described in several German and Spanish studies.¹³²⁻¹³⁶ This method theoretically provides increased delivery of an anti-inflammatory medication drug directly to the affected area while minimizing systemic corticosteroid side effects. In a smaller study comparing the effectiveness of intralesional triamcinolone hexacetonide in 11 patients to triamcinolone acetonide in 17 patients, results were encouraging, showing a majority of patients in both groups responding with a linear rate of hair growth for at least 9 months after the injection.¹³⁷ These results were reaffirmed by a larger study in 1973 of 84 patients treated with intralesional injections of triamcinolone acetonide, in which 71% of patients with patchy alopecia areata patients and 28% with alopecia totalis maintained hair regrowth at 12 weeks. Side effects from this treatment included atrophy at injection sites, which in the previously described study resolved without further sequelae in the months subsequent to treatment. The treatment was well tolerated by patients.¹³⁸ In a study of 62 patients in Saudi Arabia who received 1 monthly intralesional injection of triamcinolone acetonide complete regrowth was noted in 63% of patients at 4 months. Results revealed an increased likelihood of success in younger patients with fewer, smaller, and newer lesions.¹³⁹ In a study of 58 patients, it was suggested that the application of topical tretinoin in combination with intralesional corticosteroids had an additional positive effect on hair growth compared to the use of intralesional corticosteroids alone.¹⁴⁰

BIOLOGICS

Biologics reported to date to have some type of effect in AA are Etanercept, Infliximab, Alefacept, Adalimumab, and Efalizumab. Etanercept (Enbrel, Amgen, Inc) is a soluble TNF receptor that works by binding circulating TNF. The administration is a subcutaneous injection. Infliximab (Remicade, Centocor, Inc) is an intravenous anti TNF antibody that kills cells having surface TNF. Efalizumab (Raptiva, Genentech) is an anti -CD11a that works by inhibition the interaction by T cells and antigen presenting cells

as well as by inhibition of T cell migration from blood. This biologic though tested for the treatment of alopecia areata has since been recalled and is not available.

Alefacept (Amevive, Biogen Inc, Cambridge, MA) was designed to bind CD2, inhibit antigen presenting cell interaction with T cells and selectively reduce CD45RO+ cells. It can be administered intravenously or intramuscularly.¹⁴¹ Adalimumab is a fully humanized anti TNF-alpha monoclonal antibody

Despite the hopes for a role of biologics in the treatment of AA in 2005, a case report revealed for the first time recurrence of alopecia areata in a man with history of previous AA and rheumatoid arthritis while being treated with Etanercept for more than 2 years.¹⁴² Later additional case reports appeared describing patients developing alopecia areata while receiving biologic therapy.¹⁴³

Strober et al. studied the safety and efficacy of Etanercept in a prospective open label study in the treatment of moderate to severe AA. Seventeen patients were enrolled and they received the maximum dose of the drug approved by the Food and Drug Administration. After between 8 to 24 weeks of treatment with 50 mg subcutaneously twice a week, none of the participants showed significant hair regrowth, suggesting lack of efficacy with this approach.¹⁴⁴

In 2006 Tosti et al. additional cases of alopecia areata occurring during treatment with biologics. In one case, AA occurred during a course of Infliximab therapy in a patient with no previous history of AA. In a second case report, during a course of therapy with Efalizumab in a patient with previous patchy type disease the patient developed an extensive and refractory AA after the treatment.¹⁴⁵ In contrast, Hefferman et al. described improvement in four patients after Alefacept therapy and in a case report in 2008, complete regrowth of scalp and body hair after a single 12-week treatment course with Alefacept in a patient with Universalis type of AA was reported.¹⁴⁶⁻¹⁴⁷

In 2006, a single successful case of monotherapy treatment with Efalizumab for Universalis type of AA was published. 90% of hair regrowth was achieved after 6 months of treatment. Regrowth of body hair was slower but significant. Of note, during this period the patient's Hashimoto's thyroiditis was also treated with levothyroxine.¹⁴⁸

In 2008 the first randomized, double blind, placebo-controlled multi-center study for AA was performed with a biologic. The safety and efficacy of Efalizumab in the treatment of AA was assessed. Sixty-two patients were enrolled in a 12-week period treatment. Unfortunately, a response rate response of 8% was observed for both Efalizumab and placebo treated groups.¹⁴⁹

DEVICES/LASERS

No randomized controlled trials were found that addressed laser therapy for AA, however some reports and clinical trials are available for evaluation. Gundogan et al. were the first to reveal positive effects of a 308 nm xenon chloride

excimer laser for AA. The investigators reported that in two cases of patchy AA, after 11 and 12 sessions and within a 9 and 11-week period, there was excellent regrowth with no relapse in a follow-up period of 5 and 18 months.¹⁵⁰ It was postulated that the laser acted on the inflammatory peribulbar infiltrate perhaps through a T cell apoptotic effect.¹⁵¹

In 2004 a study involving nine patients, five with patchy AA and four with totalis or universalis, reinforced this hypothesis. Using the same type of device, lesions were treated for a maximum of 24 sessions with initial fluencies of 50mJ/cm² increased from 50 mJ/cm² every two sessions. Each treated lesion had an untreated lesion as a control. All patients with patchy disease developed moderate to excellent hair regrowth while no hair regrowth was observed in the patients with alopecia totalis or universalis. Side effects were limited to mild erythema and hyperpigmentation.¹⁵²

Another type of laser device has also been reported to be successful in alopecia areata. In one study with 16 patients, 34 resistant patches of AA were treated to assess the effect of the pulsed infrared diode laser (904 nm). It was used in 4 sessions, once a week. Regrowth was seen in 94% of the patches, with the majority of fibers expressing a normal color.¹⁵³ It was suggested that this type of laser improved microvascular circulation and reduced inflammation.¹⁵⁴ Even without exactly understanding the mechanism of action, it was suggested that this device might either alter the cellular membrane or change the previously exposed "hidden antigen".

Al-Mutairi in two consecutive trials tested the effect of 308-nm excimer laser for AA. In the first study 18 adults, AA subjects with patchy disease were treated. Regrowth was observed in 41.5% of patches. Most of lesions that responded were on the scalp, lesions on the extremities were not that responsive. All the lesions on the scalp that did not respond were in patients with bronchial asthma. In the second trial 9 children with patchy AA, as well two with alopecia totalis were treated. Regrowth was observed in 60% of the patches on scalp, while there was no notable response in the control patches and in lesions on the extremities. Reinforcing the previous observation, the four scalp lesions that did not show any regrowth were in patients with bronchial asthma. Four patients had relapse after 6 months post laser therapy. In general, in both studies the therapy was well tolerated.^{155,156}

More recently fractional photothermolysis laser therapy has been proposed to be beneficial to patients with alopecia areata.¹⁵⁷ This type of device produces a thermal damage called "microthermal treatment zones" (MZT) and characteristically spares the tissue surrounding each MZT. The stratum corneum is kept intact and there are "fractional" microscopic thermal columns, which are associated with wound healing. One single report of a patient with patchy disease treated with this device weekly for 24 weeks demonstrated that the patient could achieve complete hair regrowth in all lesions after 6 months of therapy. No relapse

was observed in 6 months follow up. The authors suggested that the mechanism of action was T cell apoptosis possibly associated to a decrease in the perifollicular lymphocyte infiltration.¹⁵⁸

COMBINATION THERAPIES

The success of systemic corticosteroids in managing alopecia areata increased interest in the idea of other therapies having an additional or synergistic effect when used in combination. In 1992, a randomized, controlled study of a 6-week prednisone taper with or without 2% topical minoxidil revealed that six out of seven combination treated responders were able to maintain hair growth versus one of six vehicle-treated responders. In a similar open trial, over 50% of patients using topical minoxidil were able to maintain hair growth at 6 months.¹⁵⁹

The combination of cyclosporine, an immunomodulator, and corticosteroids has also been studied. A small study of eight patients showed that only 25% responded to cyclosporine with low dose prednisone and several experienced severe side effects including edema, hypertension, abnormal liver function tests, and abnormal lipid levels.¹⁶⁰ However, the use of methylprednisolone pulse therapy with oral cyclosporine in another limited study showed promising results; three out of six patients with alopecia totalis and three out of 12 of patients with alopecia universalis showed hair regrowth on at least 70% of the affected area with no significant relapses after at least nine months of followup. Furthermore, side effects were minimal (mild acne, mild increase in blood pressure, etc.) and the treatment was well tolerated.¹⁶¹ One larger, but also uncontrolled study was similarly encouraging, with 38 of 43 patients with severe alopecia areata experiencing significant hair regrowth. However, nine of the responders relapsed during the followup period of 12 months, and three of the original 46 patients discontinued the study due to intolerable adverse effects. Over half of the patients in the study experienced some form of adverse effects, most commonly gastrointestinal disturbance, edema, acne, and weight gain.¹⁶²

Another agent evaluated in combination with corticosteroids for the treatment of alopecia areata is methotrexate. One retrospective study showed that 11 of 16 patients with alopecia totalis or universalis treated with combination therapy (as opposed to 3 of six patients treated with methotrexate alone) had total hair growth. Of the six who later stopped the methotrexate, three experienced a relapse. No limiting adverse effects were observed.¹⁶³ Despite the uncontrolled nature of this study, the dramatic results indicate that future studies would be warranted in a controlled setting, and that this may potentially be an effective treatment for patients with severe disease.

Also, psoralen plus UVA (PUVA) treatment, a treatment suggested to modify the immune response of the skin, has been studied for its effectiveness in alopecia areata when used in combination with corticosteroids. In

six patients with alopecia totalis and three with universalis, all achieved terminal hair growth after 2 months of treatment with minimal side effects; two patients experienced a relapse three months after termination of treatment.¹⁶⁴

A combination of 5% minoxidil with 0.5% anthralin was evaluated in 51 patients with severe treatment resistant alopecia areata who were not responsive to one or both drugs. An acceptable cosmetic response was observed in 11% of the 45 patients that completed this study, and 80% of responders maintained the growth they had. It was concluded from this study that despite the small number of subjects who were successful with this treatment, the results were superior to the use of either drug alone for these resistant patients. The synergistic effects of the two drugs could be attributed to enhanced absorption of minoxidil in the presence of an irritant dermatitis.¹⁶⁵ Another combination therapy that has shown some success for chronic severe alopecia areata is the use of topical diphenylcyclopropenone and 5% minoxidil.¹⁶⁶ The evidence for these treatments may be valuable to consider when establishing a treatment plan for patients with recalcitrant or extensive alopecia areata. Despite the limited data, these may prove to be excellent treatment options once studied more thoroughly.

"NATURAL" TREATMENTS

Modalities such as yoga, multivitamins, use of herbs, acupuncture, aromatherapy, homeotherapy are considered unconventional or alternative medicine. These therapies are more popular than ever.^{167,168}

In 1981, Rhodes et al. published a case report of regrowth in a patient with alopecia areata induced by *Primula abconia*.¹⁶⁹ The patient was first sensitized with the leaf and then applied the leaf to one side of the scalp twice a week. Hair regrowth started 1 month later and was evident 2 months later. No further evaluations of the case or investigation of the mechanism of action of the plant was performed but the result is similar to what has been described with sensitization therapy.

Eighty-six patients participated in a randomized double-blind controlled trial of aromatherapy.¹⁷⁰ In a randomized, double-blind controlled trial of 7 months' duration with follow-up at 3 and 7 months, patients massaged onto their scalp essential oils (thyme, rosemary, lavender and cedar wood) in a mixture of carrier oils (jojoba and grape seed) or only the carrier oils. Nineteen of 43 patients showed some improvement in the treatment group compared with six of 41 patients in the control group.

Onion juice (*Allium cepa L.*) has been tried to treat alopecia areata. The idea of testing this "natural" treatment came from the fact the onions and garlic belong to same genus *Allium* and garlic has been used as a topical therapy for AA as part of folk medicine.¹⁷¹ The onion juice was applied topically, twice daily, and compared to tap water applications to a group of patients with patchy disease. In

the onion juice group regrowth was seen in 73.8% of the patients at 4 weeks, 86.9% at 6 weeks whereas in the control group (tap water) the hair regrowth was apparent in only 13% of the patients at 8 weeks. This was statistically significance ($P<0.0001$). It was postulated that that onion juice might induce an immunologic reaction and stimulate hair regrowth through antigenic competition as onions belong to the genus *Allium* and are rich in sulphur and phenolic compounds.

A double-blind randomized controlled study was performed to evaluate the efficacy of topical garlic gel combined with betamethasone valerate cream in the treatment of patchy alopecia areata.¹⁷² Again, the authors proposed the study based on anecdotal data. Both groups applied topical betamethasone cream 0.1% in isopropyl alcohol twice daily for 3 months. The "active" group also rubbed garlic gel 5% on the patches of AA under dressing and left this on for 1 hour, twice daily for 3 months and the control group did the same but with a placebo gel. Hair regrowth was observed in both groups, but good and moderate responses were significantly better in the garlic/active group ($P=0.001$). The response could have occurred because of the corticoid application, but an additive efficacy of garlic was demonstrated. The mechanism of action suggested by the authors was the same for the genus *Allium*/onion juice hypothesis.

MISCELLANEOUS

Other unique therapies have been investigated for the treatment of alopecia areata. In studies with relatively small numbers of patients, isoprinosine, thymopentin, azathioprine, nitrogen mustard, and capsaicin have all been studied as potential therapies for alopecia areata. All have shown some efficacy but results need to be supported by randomized, placebo-controlled trials. In contrast, treatments that have shown no benefit or proven efficacy include the use of the vitamin D analog calcipotriol, intralesional interferon alpha-2, croton oil. Sodium lauryl sulfate, benzyl benzoate, phenol, staphylococcus-streptococcus vaccine, dapson, griseofulvin, topical tretinoin, and relaxation.¹⁷³⁻¹⁸⁹

Other treatments of interest include cryotherapy, hypnosis, and the administration of antidepressants. Cryotherapy was attempted in 112 patients with extensive alopecia areata. Liquid nitrogen was applied lightly to the affected areas once weekly for 4 weeks. Results were encouraging, with 97.2% of patients achieving new terminal hair growth. In the 6-12 month follow-up period, relapses only occurred in three of 66 patients. Side effects were mild and included those typically associated with cryotherapy, including mild swelling, itching, and sensitivity. Hair growth was also attained in the placebo group but only in 35% of patients, a statistically significant difference. This treatment may be a promising, simple, and convenient option once more studies can confirm its efficacy and safety, as well as comparing results in patients with different disease severity.¹⁹⁰

As some patients report flares of alopecia areata coinciding with episodes of stress, some studies have focused on the psychological aspects of alopecia areata. Hypnotherapy was attempted in one study on five patients with chronic recalcitrant disease; after 10-12 weekly sessions of hypnotherapy, only one had a significant increase in hair growth.¹⁹¹

What We Know

- There is a high proportion of spontaneous recovery among alopecia areata patients, with 34% to 50% of the patients recovering within 1 year without treatment and up to 90% of patients with limited scalp involvement are said to experience spontaneous regrowth within 2 years. Differences in the response to treatments are observed between patients with limited scalp involvement and patients with alopecia totalis and universalis. Patients with limited scalp involvement patients generally respond favorably to a variety of treatments.²⁻⁴
- A review of treatments for alopecia areata is a valuable and helpful tool in the decision making process for the selection of an approach to manage patchy or extensive disease in children or adults. Several studies since 1994 have incorporated the recommendations for clinical trials from the National Alopecia Areata Foundation providing standardization and a better ability to compare study design and results. The finding of important genes in alopecia areata has led to investigators discussing studying drugs that target specific pathways.
- New drug treatment opportunities based on the results of a genome-wide association study, which implicate T-cell and NK-cell activation pathways are leading to new approaches in future clinical trials of alopecia areata. Special attention is being given to the UL 16-binding protein (ULBP3) gene cluster on chromosome 6q25, as these genes make the NKGD-activating ligand or signal, which can trigger the NKG2D receptor, initiating an autoimmune response.¹ ULBP3 expression has also been found in hair follicles in scalp biopsy specimens from patients with active disease.
- Future treatment approaches for alopecia areata will most likely include the study of drugs that block the NKGD-activating ligand and NKG2D receptor interaction, halting activated T cells or modifying the inflammatory cytokine network. Many drugs currently being used or being evaluated for other autoimmune diseases, which work through these mechanisms might prove to be very effective in alopecia areata. New clinical trials will take into consideration past experiences and the utilization of the Severity in Alopecia Scoring Tool, to standardize the description of disease extent and response to therapy.

This, however, was a very small sample size and is likely not adequate to draw conclusions from. A subsequent study of 28 patients with refractory, extensive alopecia areata showed scalp hair growth of 75%-100% in 12 patients after 3 to 8 sessions of hypnotherapy, total growth occurred in nine of these. However, other treatments were not discontinued for the duration of hypnotherapy and their effect cannot be excluded.¹⁹² A larger, randomized, controlled study to confirm these results and to evaluate the long-term efficacy would be useful to confirm hypnotherapy as an effective adjunct treatment.

Antidepressants have also been studied in the hope that ameliorating some of the anxiety associated with this disease would result in hair regrowth. An evaluation of imipramine in a double blind, placebo-controlled study showed clinically significant hair regrowth in five of the seven patients, who were treated, with none in the placebo group showing regrowth.¹⁹³

SSRIs in particular have also been of interest to investigators. In one case, series investigators used citalopram in four female patients diagnosed with anxiety or depression. Overall mood improvement and objective hair regrowth was evident after 30-45 days of treatment.¹⁹⁴ A double-blind, placebo controlled study of paroxetine in 13 patients with alopecia areata and an additional psychiatric diagnosis has been completed. Two of the eight patients receiving paroxetine achieved complete regrowth of hair; four had partial regrowth; one patient from the placebo group had regrowth of hair.¹⁹⁵ In another reported case, paroxetine in a woman was administered to a patient with moderate alopecia areata and a diagnosis of major depression. In conjunction with intralesional triamcinolone, hair regrowth began in the fifth week of treatment and psychiatric health improved.¹⁹⁶ For patients with a simultaneous psychiatric condition, the use of an antidepressant may serve to improve hair growth as well as mental health, however larger studies are necessary because the sample sizes of currently available studies are not sufficient.

Treatment of Female Androgenetic Alopecia

20

Alireza Firooz, M.D., Masoumeh Hassani, M.D.,
Shahab Babakoohi, M.D., and Farzam Gorouhi, M.D.

INTRODUCTION

Female pattern hair loss (FPHL) as a distinctive entity was first described about 30 years ago. The term “androgenetic alopecia” is a debatable term because hair loss does not necessarily only occur in women with hyperandrogenemia. Although balding has been observed in hyperandrogenic women who often have other manifestations of androgen excess like hirsutism or menstrual disorders, or severe and recalcitrant acne, However some studies have detected normal androgen levels in many women with pattern hair loss.^{1,2} Genetic susceptibility also has not been recognized as a leading factor in many patients.³ Thus, the term FPHL is preferred.⁴

EPIDEMIOLOGY

Female pattern hair loss may begin at any time after menarche or adrenarche and its frequency and severity usually increases with age, from 3-6% in women aged less than 30 years to 29-42% in women greater than 70 years.^{5,6} In some such cases, the clinical impact of hair loss has considerable societal and psychological costs for patients.⁷

CLINICAL MANIFESTATIONS

Female pattern hair loss usually presents with progressive thinning and loss of hair over the crown and frontal scalp. The frontal hairline is usually preserved in patients with FPHL. The affected zone varies from merely a small area to the entire scalp. In contrast to its frequent involvement in male pattern hair loss, vertex is rarely affected in FPHL.⁸ Several classification methods of pattern hair loss have been suggested, which all have limitations.^{4,9,10} FPHL can be observed in men as an uncommon presentation of hair loss.⁸

DIAGNOSIS

The diagnosis of FPHL is based on the clinical pattern of hair loss. Laboratory evaluation of women presenting with hair loss should be pursued after ruling out any other possible differential diagnoses like telogen effluvium,

diffuse, or reverse ophiasis alopecia areata, etc. Screening tests usually include CBC, work-up for iron deficiency, and hypothyroidism. In a subset of women who show other features associated with androgen excess such as hirsutism, menstrual irregularities, or difficult-to-treat acne, testosterone, dehydroepiandrosterone sulfate (DHEAS) and sex hormone binding globulin (SHBG) should also be measured as a screening tool for making the diagnosis of possible underlying disorders.⁸

TREATMENT

Many different forms of treatment and a variety of protocols have been tried for FPHL. The most commonly used include antiandrogens (topical or systemic) and topical minoxidil.⁸

Question: How do antiandrogens and minoxidil compare in efficacy and safety to placebo in the treatment of FPHL?

METHODS

Inclusion Criteria

Since no published systematic review on this topic existed, the main sources of evidence were individual RCTs. Only RCTs concerning treatment of FPHL in women were included. The studies reporting less than 10 patients were excluded. The search became limited to full-text articles in English.

Search Methodology

To locate all studies apropos of FPHL in women, a preliminary search was carried out in the following databases (to November 2008): Ovid MEDLINE, PubMed MEDLINE and Cochrane Central Register of Controlled Trials (CENTRAL).

Search strategy to locate RCTs in Ovid and PubMed MEDLINEs was based on the Cochrane Highly Sensitive Search Strategy for identifying randomized trials in MEDLINE: sensitivity- and precision-maximizing version (2008 revision), using following key (filter) words in their special format for each MEDLINE:

- Randomized controlled trial OR Controlled clinical trial OR randomized OR placebo OR clinical trials as topic OR randomly OR trial AND humans.
- Search strategy to locate FPHL in women in all databases was androgen* OR male pattern OR female pattern OR hereditary AND alopecia OR hair loss OR baldness AND female OR woman OR girl).

After initial search, the titles and abstracts of extracted articles were re-examined. If it was determined that a clinical trial had not been relevant to nonsurgical interventions in FPHL treatment in women, it was excluded before appraisal. Two researchers assessed the included studies independently of each other to determine the articles which were completely related to the subject and were accurately performed methodologically. In addition, references of relevant articles and reviews were checked manually in search of additional sources.

Data Collection

The features considered in the assessment of quality and correctness of studies according to Jadad criteria¹¹ were:

1. Application of randomization methods to divide participants into groups.
2. Allocation concealment method of study, which is considered sufficient if the intervention in each participant cannot be predicted.
3. Blinding: Has blinding been employed in study or not and who has become blinded (i.e., participant, physician, results assessors, analyzer, or health care provider)?
4. How many participants have been excluded and have the participants been analyzed based on primary group to which they were assigned in randomization or not?
5. Intention to treat analysis; proper and enough follow up.

In the process of selecting the relevant studies, disagreements among authors were resolved by reaching consensus.

Next step was extraction of necessary data, which was also performed independently by two authors, and exchange of ideas between all authors solved disagreements. According to the assessments, a description of quality for each selected article was issued and a Critical Appraisal Topic (CAT) form was provided for each article.

Data Analysis

The gathered data were entered into Review Manager (RevMan) software, version 5.0.25 (Copenhagen: The

Nordic Cochrane Centre, 2010) for statistical analysis. Inverse variance method was used to pool the data. Statistical heterogeneity was assessed using I^2 statistic. If substantial heterogeneity (I^2 statistic > 50%) existed between studies, we would explore the reasons for heterogeneity; such as disease severity, dosage, and duration of treatment as well as disease subtypes. The data were pooled and analyzed when I^2 statistic was less than 80%. The effects of therapeutic methods in different studies were compared using a random effects model. For dichotomous results, relative risk (RR), and 95% confidence interval (CI) were reported. For continuous results, weighted mean of difference (WMD, CI 95%) were reported.

RESULTS

Included Studies

Figure 20-1 shows the number of articles obtained from the preliminary search, number of articles included for systematic review, and the number of excluded articles and the reason for exclusion. No additional articles were identified by hand searching. Table 20-1 shows the characteristics of 12 articles included in this systematic review as well as the summarization of their main findings.¹²⁻²³ Assessment of methodologic quality of these studies based on the Jadad assessment scale is presented in Table 20-2. In 11 of these 12 studies, patient selection was based on physical examination and distinctive features of female pattern hair loss and only one study exclusively included hyperandrogenic women. Various methods were used for assessing the effect size of interventions in these studies that makes any comparison impossible.

Premenopausal Women

In seven studies, patient selection was only based on the distinctive features of female pattern hair loss and patients were not screened for hyperandrogenism. In 6 studies with a total of 1378 patients, topical minoxidil (1 ml) 1%,¹⁷ 2%,¹²⁻¹⁶ and 5%¹⁶ were compared to placebo. Minoxidil vs. placebo were applied twice daily for 24 weeks¹⁷, 32 weeks¹²⁻¹⁵, or 48 weeks¹⁶. Minoxidil was superior to placebo in all but one trial.¹³ Figure 20-2 demonstrates efficacy of Minoxidil 2% in comparison with placebo after pooling the data of 5 trials.¹²⁻¹⁶ In the only minoxidil dose-finding trial, minoxidil 5% was more effective than minoxidil 2%; however, the difference was not statistically significant.¹⁶

In a double-blind, randomized, placebo-controlled study on 40 women with diffuse or androgenetic alopecia, 1 mL of a 0.1% melatonin or placebo solution was applied on the scalp once daily in the evening for 6 months.²⁰ The trichograms showed a significant increase in anagen hair rate in occipital hair of those with androgenetic alopecia treated with melatonin compared with the placebo group. The increase in anagen hair rate in frontal hair in women

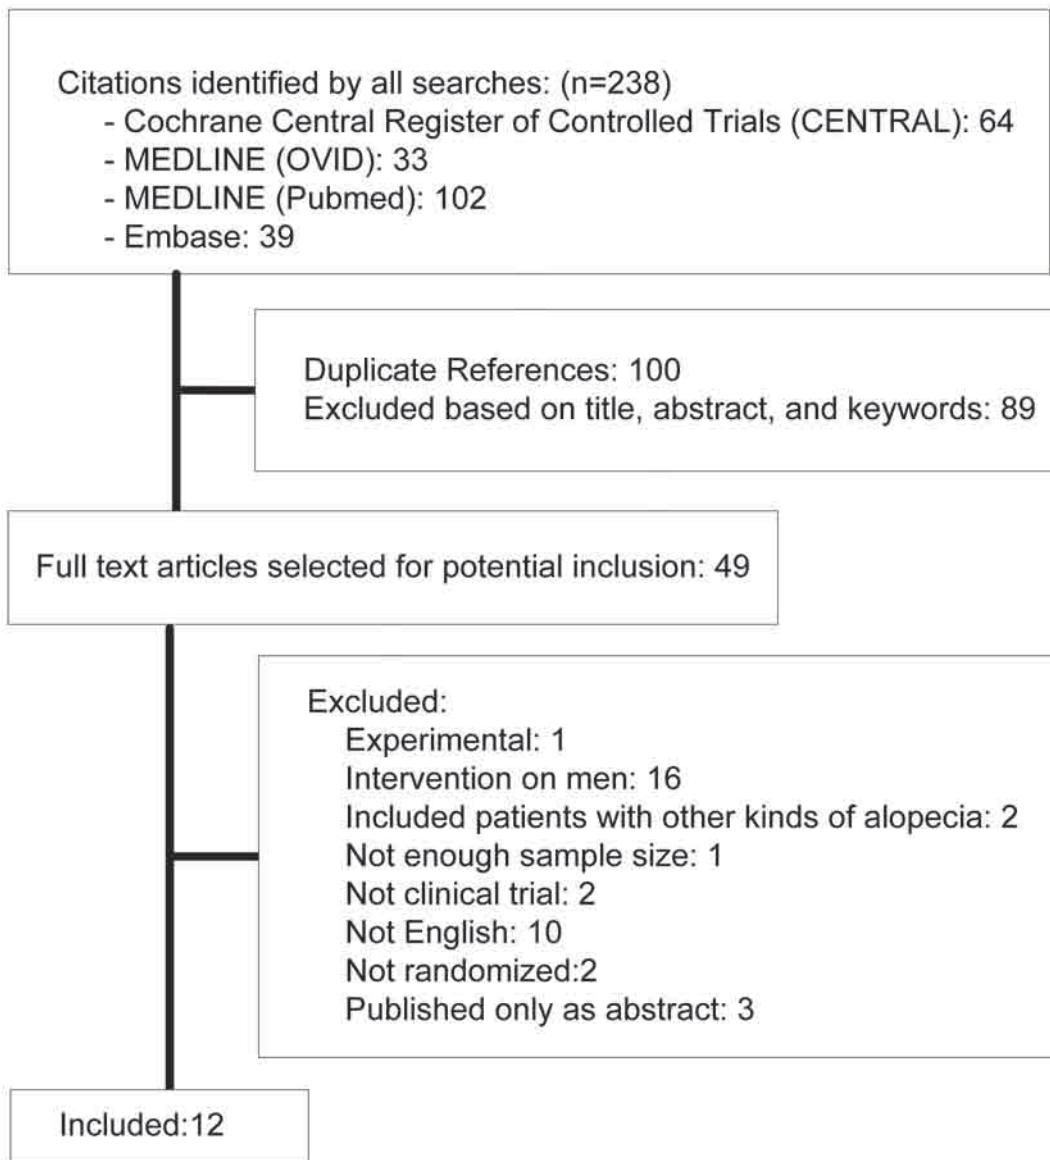

FIGURE 20-1 Flow Diagram

with androgenetic hair loss was not significantly different from the placebo group.

Vexiau P, et al.¹⁸ studied 66 patients, 18-34 years of age, randomly assigned into two groups, with 33 receiving morning and evening local applications (2 mL)

of topical minoxidil 2%. In addition, combined oral contraceptive for 21 of every 28 days and 33 patients were treated with cyproterone acetate 50 mg/day for 20 of every 28 days plus Diane for 21 of every 28 days for 1 year. Based on phototrichogram data, the minoxidil group was

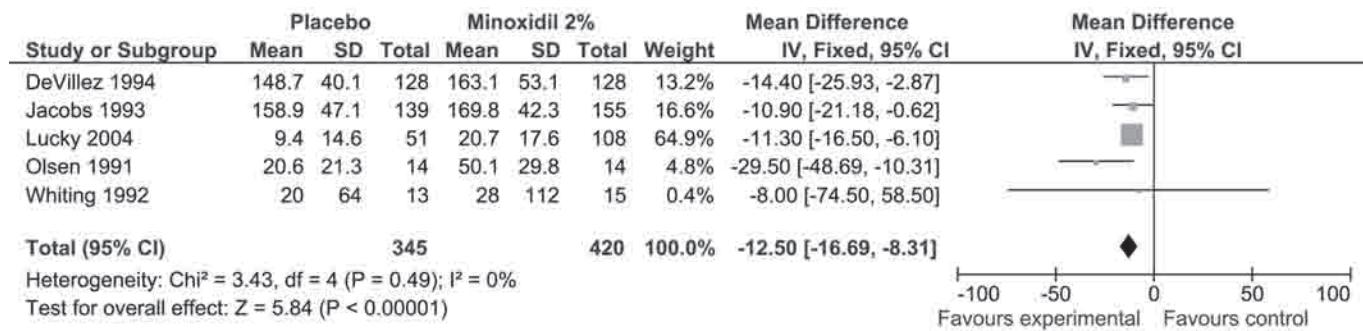

FIGURE 20-2 Forest plot of comparison: Minoxidil 2% vs. placebo, outcome: Hair count. The data of DeVillez 1994 and Jacobs 1993 studies were calculated using Hair count at 32 weeks. For the rest, Change from baseline hair count data were used.

TABLE 20-1—Characteristics of 12 Randomized-Controlled Trial for Treatment of Female Pattern Hair Loss

[†]No withdrawal from the beginning of study reported.

superior to the cyproterone group. This was seen in the increase in hairs of diameter >40 µm and the total number of hairs in the minoxidil group. However, in subgroup analysis, the minoxidil group was more effective in patients with isolated alopecia and in the absence of menstrual cycle irregularities and other signs of hyperandrogenism. The cyproterone acetate was also more effective when menstrual cycle irregularities and other signs of hyperandrogenism were present and when the BMI was elevated.

Carmina and Lobo,¹⁹ randomized 48 women with alopecia and increased serum androgens (testosterone, free testosterone, DHEAS) higher than the mean \pm 2 SD to one of three treatments. Twelve were treated with cyproterone acetate 50 mg/day from day 5 to day 15 of the cycle, and ethynodiol diacetate 25 µg from day 15 to day 25 of the cycle, 12 were treated with flutamide 250 mg/day, 12 were treated with finasteride 5 mg/day, and all for 1 year. Twelve patients who were recruited for the study refused any treatment and were observed without any treatment for 1 year. Thirty normal ovulatory women, matched for age and weight, were used as controls. After 1 year, only patients treated with flutamide was modestly superior to the control group, whereas finasteride and cyproterone were not effective.

Postmenopausal women

Three studies only included 282 postmenopausal women:²¹⁻²³

In one study, oral administration of finasteride 1 mg/day for 12 months did not increase hair growth or slow the progression of hair thinning in postmenopausal women with androgenetic alopecia.²¹

In the second study, estradiol valerate 0.03% was applied as 15 drops on the affected area of the scalp, every day for 4 weeks, and then every other day for 12 or 24 weeks.²² The results suggested that estradiol valerate was significantly more effective than placebo regarding anagen/telogen ratio. Furthermore, a 12-week course of estradiol valerate did not differ significantly from a 24-week course.

Additionally, 30 µl/cm² of fulvestrant 70 mg/mL solution, twice daily for 16 weeks was not associated with any statistically significant differences in favor of its use over placebo.²³

Another study,¹⁷ also included women 20 years of age and older with the average of 56-57 years old; however, the results have not been presented according to menstrual status and therefore, postmenopausal women cannot be identified.

DISCUSSION

Female pattern hair (FPHL) loss is a common disease. The role of androgens in this disease is not clear. In one study, only 40% of women with FPHL had elevated serum androgens.¹ In another study, patients with alopecia had lower serum levels of androstenedione and dehydroepiandrosterone sulfate (DHEAS), lower salivary testosterone, and

higher levels of sex hormone-binding globulin than patients with hirsutism, but total testosterone was not significantly different.² So the term FPHL has replaced the older term of androgenetic alopecia.⁸ Few RCTs for the treatment of FPHL were found in our search in English literature.^{12–23} The response to treatment may differ in patients with hyperandrogenism, and in postmenopausal women.

Premenopausal Women Without Hyperandrogenism

Seven RCTs have included women with FPHL without any evaluation of hyperandrogenism.^{12–17,20} The diagnosis in these studies were only based on the clinical pattern of hair loss. In five of these studies, twice-daily application of 1 mL of minoxidil 1%^{12,17} or 2%^{13–15} was compared with placebo. The duration of treatment was 24 weeks in one RCT¹⁷ and 32 weeks in three RCTs.^{12–14} In all of these studies, except one¹³, minoxidil was more effective than placebo in reduction of hair loss and increase in hair growth. No follow-up after discontinuation of treatment was reported in any of them.

In one dose finding RCT¹⁶, minoxidil 5% induced more hair regrowth than minoxidil 2% after 48 weeks, but the difference was not statistically significant. In men with male pattern hair loss minoxidil 5% was proved more efficacious than 2%.²⁴

No serious systemic side effect has been reported with topical application of minoxidil. It may cause redness and itching of scalp in approximately 5% of women. This dermatitis is usually a nonspecific irritant contact dermatitis, although rare cases of true allergic contact dermatitis with minoxidil have also been reported.²⁵ Hypertrichosis of face and body may occur, which is more frequent with 5% minoxidil and in patients with dark complexion.⁸ It usually subsides after discontinuation of treatment.

The mechanism of action of minoxidil in FPHL is not completely understood. Several mechanisms have been proposed including vasodilation, angiogenesis, enhanced cell proliferation, and DNA synthesis, potassium channel opening, antiandrogen effect, collagen synthesis suppression, and immunosuppression.²⁶

Although a 1-year prospective study did not find any adverse pregnancy outcome in women using topical minoxidil,²⁷ it is considered as pregnancy category X and should not be used by pregnant or lactating women.

In one RCT including 66 women with FPHL,¹⁸ treatment with 1 mL minoxidil 2% applied twice daily plus combined oral contraceptive for 21 of every 28 days was compared to cyproterone acetate 50 mg/day for 20 of every 28 days, plus Diane for 21 of every 28 days. The duration of treatment was 12 months and no follow-up was reported. Hair counts in phototrichography showed better response to minoxidil. In subgroup analysis, response to minoxidil was better in patients who had normal menstruation

cycle, but in the group treated with cyproterone, more hair growth was observed in patients who had an abnormal menstruation cycle. Patients included in this study were not assessed for the level of serum androgens.

One RCT did not find any significant difference between topical melatonin 0.1% solution, applied once mL daily and placebo after 6 months in frontal area, which is androgen dependent. Although melatonin was more effective in the occipital area.²⁰ Interestingly, the same study showed more efficacy of melatonin compared to placebo in the frontal area, but not in the occipital area in women with diffuse hair loss. In vitro studies have shown a positive effect of melatonin on hair matrix cell proliferation and hair growth, and an induction of anagen phase.²⁰

Premenopausal Women With Hyperandrogenism

Only one RCT has included exclusively patients with definite evidence of hyperandrogenism who had serum level of DHEAS, testosterone, and free testosterone more than twice of standard deviation of mean in normal controls.¹⁹ Forty eight patients were treated in three equal groups with cyproterone acetate 50 mg/day from day 5 to day 15 of the cycle, and ethinyl estradiol 25 µg from day 15 to day 25 of the cycle, or with flutamide 250 mg/day, or with finasteride 5 mg/day and 1 group was left untreated as control. The duration of treatment was 1 year. At the end of the study, only patients treated with flutamide showed significant improvement compared to the control group. Flutamide is a strong competitive inhibitor of androgen receptors and has been used successfully for the treatment of hirsutism. Considering the risk of hepatotoxicity of flutamide,²⁸ and the prolonged duration of treatment for FPHL, flutamide cannot be a suitable option in the treatment of FPHL. Finasteride is a selective inhibitor of 5α-reductase type II and has been approved for the treatment of male pattern hair loss at a dose of 1 mg daily.⁸ Although a few case reports have shown the efficacy of finasteride in FPHL patients with or without hyperandrogenism, or postmenopausal women,^{29–31} this RCT and also another RCT in postmenopausal women²¹ could not show any superiority of finasteride over placebo.

Postmenopausal Women

Three RCTs have exclusively evaluated postmenopausal women with FPHL. In these studies, oral finasteride 5 mg daily for 12 months²¹, topical estradiol valerate 0.03% for 12–24 weeks²², and topical fulvestrant 70 mg/mL for 16 weeks²³ were compared with placebo. None of them showed any significant difference between these treatments and placebo. Fulvestrant is a ‘pure’ oestrogen receptor antagonist, which causes telogen follicles to enter anagen, thereby causing hair growth.²³

What We Know

- The only treatment shown to be effective in FPHL is topical minoxidil. It seems the effect of minoxidil is not related to age or androgen level of patients and it may be effective in women with FPHL, both with and without hyperandrogenism, and in young and old, pre or postmenopausal. The maximum duration of treatment with minoxidil was 1 year in these RCTs, and none of them included a follow-up period after discontinuation of treatment. Therefore, it is not clear how long the effect of minoxidil lasts in FPHL. Similar studies in male pattern hair loss have shown that any beneficial effect of minoxidil is lost 4-6 months after discontinuation of treatment.
- In postmenopausal women with FPHL, treatment with antiandrogens such as estradiol, fulvestrant, and finasteride was not more effective than placebo. As the mechanism of action of minoxidil is not related to androgen levels, it may be the only treatment option in these patients, although no RCT evaluating minoxidil in postmenopausal women is available.
- In patients with FPHL and hyperandrogenism, treatment with antiandrogens seems logical. However, in the only available RCT, only flutamide was effective and finasteride and cyproterone did not show satisfactory results. In women with FPHL who have regular menses and no evidence of hyperandrogenism, there is no evidence to support use of anti-androgens.

One RCT evaluating topical minoxidil included women older than 20 years with a mean age of 56-57 years¹⁷, but data on postmenopausal women were not separately reported, so no conclusion could be drawn on the efficacy of minoxidil in postmenopausal women.

Treatment of Genital Warts

Tsu-Yi Chuang, M.D., M.P.H.

INTRODUCTION

Human papilloma virus (HPV)-induced genital wart is one of the most common sexually transmitted disease in the United States, behind chlamydia/gonorrhea, which affected 1.5 million new patients in 2007. Its prevalence has approached 24 million in the United States alone. Every year, 0.5~1 million new cases developed (CDC estimated 5.5 million people newly affected yearly). There is a 10% lifetime risk of infection in the general population.¹ Since 1976, 120 types of HPV have been designated and characterized in a defined manner, although many more HPV types have been recognized through polymerase chain reaction (PCR) amplification products. Nearly 40 HPV types are found in genital warts. Over 90% of cervical cancers are associated with genital warts and more than half induced by HPV-16 and -18.¹

TREATMENTS

There is no effective virus-specific therapeutic agent for genital warts. Destruction or abolition of visible lesion is the goal, not the elimination of virus. *Gardasil* and

Cervarix are HPV vaccines against HPV16/18/6/11 or HPV16/18, respectively. However, they are for prevention not treatment. No matter which treatment applied, recurrence is almost certain because of the skin surrounding visible lesion carrying subclinical HPV particles. In most occasions, remission, not cure, is the reasonable prospect. Genital warts may cause discomfort, irritation, pruritus, malodor, sometimes even bleeding, and some degree of emotional distress. Thus, most patients desire treatment. The treatment chosen is in part dictated by the size of the warts, their location, and patient's gender.

THERAPEUTIC REGIMENS AND MODALITIES

There are three categories of therapeutic agents and regimens: Cytotoxic agents, physical destruction, and immunomodulation. The effectiveness in treating genital warts is represented in percentage of clearance and recurrence, which, in turn, are estimated from multiple clinical trials. (See Tables 21-1 and 21-2). The strength of medical evidence, from Level 1 to 5, and the grade of

TABLE 21-1—Treatments for Genital Warts: Regimens, Rates of Clearance and Recurrence, Grades of Recommendation and Levels of Evidence

Therapeutic Regimens/ Modalities	Method of Application	Effect [†] : Clr/Rec	Grade [‡] / Evidence
<i>Cytotoxic Agents</i>			
Podofilox 0.5% gel, cream or solution	BID for 3 consecutive days with 4 days off, weekly for 4 weeks	70%/30%	A/1 (1a-)
Podophyllin 20-25% solution	Applied to lesions, wash-off 4 hours later, once-twice weekly for 4-6 weeks	60%/40%	A/1 (1a-)
Veregen ointment (15% Sinecatechins)	TID for up to 16 wks. Only for external genital warts and perianal warts.	55%/5%	A/1 (1a)
5-FU/adrenaline gel, inj.	Intradermal gel injection, once weekly for 6 weeks	60%/50%	A/1 (1b)
5-FU(5% fluorouracil), topical	QD for 5 consecutive days or 1-3 per week for 4 weeks; wash-off after 4 hours.	45%/60%	A/1 (1a-)
Isotretinoin, oral	1 mg/kg per day for 3-5 months	50%/10%	B/3 (3a)

TABLE 21-2—Oxford Evidence-Based Medicine (EBM) Levels for Treatment #

Grade*	Level of Evidence	Description of Clinical Evidence
A	1	Controlled trials
	1a	Systematic reviews (with homogeneity) of randomized controlled trials
	1a-	Systematic review of randomized trials displaying worrisome heterogeneity
	1b	Individual randomized-controlled trials (with narrow confidence interval)
	1b-	Individual randomized-controlled trials (with a wide confidence interval)
	1c	All or none randomized-controlled trials
B	2	Cohort studies
	2a	Systematic reviews (with homogeneity) of cohort studies
	2a-	Systematic reviews of cohort studies displaying worrisome heterogeneity
	2b	Individual cohort study or low quality randomized controlled trials (<80% follow-up)
	2b-	Individual cohort study or low quality randomized controlled trials (<80% follow-up/wide confidence interval)
	2c	'Outcomes' Research; ecologic studies
	3	Case-control studies
	3a	Systematic review (with homogeneity) of case-control studies
	3a-	Systematic review of case-control studies with worrisome heterogeneity
C	4	Case-series (and poor quality cohort and case-control studies)
	D	Expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'

(Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes, Martin Dawes since November 1998, updated by Jeremy Howick, March 2009). (Website: <http://www.cebm.net/index.aspx?o=1025>).* Four **Grades** of Recommendation for treatments, from A to D (graded by the U.S. Preventive Services Task Force, reflected the strength of evidence and magnitude of net benefit): e.g., Grade A is consistent with Level 1 evidence.

recommendation for treatment, from Grade A to D, are based on Oxford Evidence Based Medicine (EBM) Levels for Treatment from *the Oxford Centre for Evidence-Based Medicine*.

Cytotoxic Agents

Condylox (Podofilox) 0.5%²

Podophyllotoxin is the most active ingredient of podophyllin. Purified podophyllotoxin 0.5% solution, cream or gel is self-applied by the patient twice a day for three consecutive days of a week in 4-week treatment cycles. No more than 10 cm² of wart tissue should be treated at one time. Local adverse reactions including erythema, pain, burning, inflammation, and erosion have been experienced by more than 50% of patients. It is not recommended for perianal, vaginal, or urethral warts. Clinical clearance approaches 70% with a 30% recurrence rate, which is better than podophyllin. Several randomized-controlled trials confirmed its efficacy: Podofilox has a Grade-A recommendation for treatment and an evidence of Level 1a-.

Podophyllin 25%³⁻⁵

Podophyllin is applied to the lesions once weekly by the physician in the office/clinic and is washed off 4 hours later by the patient. A course of six consecutive weekly treatments is recommended. Podophyllin is available as a crude resin extract in 25% concentration in tincture of benzoin. It works better on large exophytic genital warts on moist surfaces. It is not very effective on dry surfaces. Like Condylox, it is not recommended for perianal, vaginal, cervical or urethral warts, but very effective for penile warts particularly warts on the glans and under prepuce. Powdering the warts after application of podophyllin is recommended for avoiding irritation to the surrounding "normal" skin. Applying large quantities of podophyllin should be avoided. This may cause systemic toxicity through absorption. Such potential toxicity and limitation in the use in certain types of genital warts makes podophyllin an unpopular choice of treatment. Its clearance rate is 60% with a 40% recurrence rate. This regimen has been tested in many randomized-controlled and case-controlled trials. Podophyllin gains a Grade A recommendation for treatment and a Level 1a- evidence.

Veregen (15% Sinecatechins) Ointment⁶

Veregen is applied on the skin of external genital and perianal areas three times a day for up to 16 weeks. It is intended for external genital warts and perianal warts, not for lesions inside vagina, cervix, urethra, rectum, or anus. Sinecatechins is a partially purified fraction of the water extract of green tea leaves from *Camellia sinensis* (L.) O Kuntze. Veregen ointment is thus a mixture of catechins

and other green tea components. The ointment has a 55% clearance rate and a low 5% recurrence rate. Veregen has a grade-A treatment recommendation and its evidence level is 1a, the highest rating among all clinical trials assessing the efficacy of treatment.

Efudex (5% fluorouracil) and 5-FU injection^{7,8}

Efudex cream (or solution) is recommended as a daily application for 5 consecutive days for 4 weeks or a mere two applications per week (an intermittent therapy) for 4 weeks. This results in an unimpressive 45% clearance rate and a relatively high recurrence rate of 60%. However, it is quite effective in flat penile warts, urethral and vaginal warts. It is prone to cause severe irritation/inflammation and painful erosions, so it is advised to wash it off after 4 hours. The recommendation for treatment is Grade A with Level 1a- evidence. Carac cream (0.5% fluorouracil) has been used for genital warts, assumed it is as effective as 5-FU, but with less irritation. However, it is hardly ever used.

Intradermal injection of a 5-FU/adrenaline gel, once weekly for 6 weeks, has shown a 60% clearance rate and a 50% recurrence rate. The recommendation for treatment is Grade A. Because of a dearth of randomized clinical trials, the evidence is Level 1b. It is not a commonly used regimen.

Isotretinoin, oral⁹

The use of oral isotretinoin has only been reported in a limited number of studies with mediocre effect (50% responsive rate and 10% recurrence rate). It is seldom used. Topical retinoids are not effective in genital warts.

Physical Destruction

Excision, surgical¹⁰

Surgical excision can efficiently eliminate genital warts (90% in effectiveness) particularly for large, exophytic or extensive lesions but cannot prevent it from recurring (25% recurrence rate). This method is often combined with electrosurgery. There were no randomized-controlled trials on surgical intervention, so the evidence level is slightly lower at 3a.

Cryosurgery (Liquid nitrogen)^{3,4,11}

Cryotherapy (mainly, liquid nitrogen) is more effective than podophyllin/podophyllotoxin, approaching 80% resolution and 30% recurrence. Three freeze-thaw cycles are applied to each lesion every month for 3 months resulted in a necrosis of wart tissue and formation of crusts, which usually fell off in 2-3 weeks. A zone of 1 mm beyond the

lesion is frozen. Cryotherapy is safe to use in pregnant patients. It is best for small, flat, or popular genital warts, not large exophytic lesions.

Laser vaporization¹²

The use of CO₂ laser in the treatment of genital warts has not been demonstrated to be more effective than simpler surgical or electrosurgical methods. The clearance rate is 80% with a recurrence rate of 30%. The CO₂ laser has the advantage of working on a bloodless field, healing rapidly with minimal scarring and focusing on lesions with precision. However, it might generate a smoke plume containing viral particles potentially infectious to the surgeon. Thus, surgeon should exercise precaution by wearing face mask and using smoke evacuator to remove the plume. Decontamination of the equipment after the surgery should be done. Laser treatment is recommended in vaginal, vulvar, and anal warts. It has been used for large and extensive genital warts with success.

A newer approach, photodynamic therapy with topical 20% 5-aminolaevulinic acid (ALA) solution applied to lesions under occlusive dressing and irradiation with helium-neon laser (100 J/cm² and a power of 100 mW), leads to clearance of condyloma acuminata in 100% (6% recurrence rate).¹² This therapy needs more clinical trials to confirm its efficacy. A recent randomized double-blinded prospective study on 175 patients treated with ALA-PDT plus CO₂ laser versus CO₂ laser alone showed no difference between them in controlling recurrence.¹³ The recurrence rate 12 weeks after either treatment was about 50%.¹³

Electrosurgery³

Electrocauterization/electrofulguration is quite effective: clearance therapy is 80% and cure at 55%. It is often used for recurrent warts or when other methods failed to result in "cure." HPV DNA is detected in the plumes generated during electrocauterization treatment just like during CO₂ laser treatment. This old-fashioned but time-honored treatment lacks randomized-controlled trials, thus its evidence level is lower at 3a just like surgery.

Trichloroacetic acid (TCA)¹¹

Trichloroacetic acid in 80~90% solution can be applied to genital warts weekly for 6 weeks. TCA causes tissue destruction. It is most effective on small, moist warts. It is effective in 75% of patients with a recurrence rate of 40%. The efficacy of treatment gained some support from a couple of randomized-controlled trials but its use has been limited because of its causing ulcerations and pain. It is safe for use in pregnant patients. TCA has a Grade-A recommendation for treatment and an evidence of Level-1a-.

Immunomodulation

Aldara(Imiquimod 5%)^{14,15}

Imiquimod, an immune response modifier that induces IFN locally at the site of application, has an efficacy of 55% and yields a low recurrence rate of 20%. Many high-quality randomized clinical trials earned it the highest evidence level (1a) and a grade-A treatment recommendation.

Aldara is a 5% imiquimod cream available in a box of 12 or 24 single-use packets. One packet can cover up to 30 cm² when applied appropriately. It is patient self-applied, three days (at bedtime) a week for 16 weeks. The treated areas should be cleansed the next morning. Response is slow, requiring 10 or more weeks in some patients to see results. The application might result in significant irritation, inflammation, and erosion. Imiquimod is often used for penile, perianal, and vulvar condyloma. It is not recommended for pregnant women.

IFN- α therapy^{16,17}

The efficacy of systemic and intralesional IFN- α therapy has been found to be ineffective in eradicating genital warts (a mere 35% clearance rate). Several randomized clinical trials have failed to confirm the efficacy of intralesional IFN- α . Some experts would no longer recommend a routine clinical use of this expensive regimen. However, IFN- α 2b cream has revived the hope of yet another immunomodulation therapy for genital warts. In clinical trials, IFN- α 2b cream is applied 3 times a week for 6 weeks and shows a 60% clearance rate and 10% recurrence. The treatment recommendation is Grade A and evidence level is 1a-. FDA is considering its approval.

Cidofovir 1% gel¹⁸

Cidofovir topical gel applied 5 days a week for 6 weeks has a 52% clearance rate and 20% recurrence rate. It has a Grade A treatment recommendation and Level 1b- evidence. It is expected to be approved by FDA by the end of 2009.

SPECIAL CONSIDERATION

Genital Warts in Children

Genital warts in children could arise from social nonsexual contact or serious, sexual abuse. Children can acquire genital warts through vertical transmission (from infected pregnant mother), particularly in children younger than 1 year of age. Infants might get genital warts from digital inoculation (from adults' infected fingers). In older children, autoinoculation through their own infected fingers might happen. Genital warts in children from nongenital source, like hand warts, tend to be small, digital, nonexophytic and limited in size and areas involved. However, through HPV

typing, many children's genital warts have the same types of genital HPV found in family members who had genital HPV infection. Even so, there needs to be solid evidence to determine sexual abuse. For instance, the HPV type in children's genital warts matched with the alleged abuser's HPV type. In abuse cases, other STDs should be screened for.

Genital warts in children often resolve without treatment in a majority of cases. Aggressive approach is discouraged. Nonintervention might be a reasonable approach. Topical therapy, such as podofilox, TCA, veregen, or imiquimod should be tried first.

Genital Warts in Pregnant Women

Genital warts have a tendency to enlarge and proliferate during pregnancy. Its removal is thus advocated. The use of podophyllin and podofilox is contraindicated during pregnancy. Laser, surgery, cryosurgery, and TCA are safe and effective in treating pregnant patients. Cesarean section should not be recommended solely for the reason of preventing infant's laryngeal papilloma.¹⁹

Genital Warts in Sexual Partners

Examination of sexual partners for clinical or subclinical HPV infection is highly recommended. The treatment, whichever chosen, should be discussed with patient's sexual partner, not just patient himself/herself. Transmission between partners ought to be prevented by exercising proper protection measures. Treatment for both patient and partner(s) is stressed.

HPV Vaccination

The HPV major capsid protein, L1, can spontaneously self-assemble into virus-like particles (VLPs) that resemble genuine HPV virions. Since these VLPs do not carry real copy of HPV DNA, they cannot induce squamous intraepithelial neoplasm or cancer. However, they can elicit an

What We Know

- Among all self-applied regimens, Condylox (podofilox) gel/cream/solution is the best and very easy to apply. Aldara cream is not better. Also, Aldara remains a problem to some patients as not every insurance plan covers it. This makes it a very expensive alternative. The new Veregen ointment has a very low recurrence rate but needs long-term follow-up data to prove its efficacy.
- Physical destruction is far better than self-applied regimens. However, the recurrence rate stays high. This makes the search for a better eradication modality a priority.

antibody response in vaccine recipients against infection by the HPV types exemplified in the vaccine. *Gardasil* is the first HPV vaccine against HPV16/18/6/11. It contains recombinant VLPs assembled from the L1 proteins of HPVs 16, 18, 6 and 11. Three shots (on day one, month two, and month 6) can accomplish nearly 100% prevention. This and another just approved HPV vaccine, *Cervarix*, against HPV 16/18, are recommended for females aged 9-25 and males aged 9-26.

Treatment of Nongenital Warts

Philip D. Shenefelt, M.D., M.S.

INTRODUCTION

Warts are benign proliferations of skin and mucosa caused by the human papilloma virus (HPV). More than 100 types of HPV have been identified. Although certain HPV types tend to occur at particular anatomic sites, warts associated with any HPV type may occur at any site. Frequent clinical manifestations of HPV infection include common warts, genital warts (see Chapter 21), flat warts, and deep painful palmoplantar warts (myrmecia). Less common manifestations of HPV infection include focal epithelial hyperplasia (Heck disease),¹ epidermodysplasia verruciformis, and plantar cysts. Warts are transmitted by direct or indirect contact. Predisposing factors that invite infection include disruption to the normal epithelial barrier. Common warts are usually asymptomatic, but they may cause cosmetic disfigurement or tenderness. Plantar warts on weight-bearing surfaces of the sole can be painful, and extensive involvement may impair ambulation. Malignant transformation in nongenital warts is rare but does occur and is known as verrucous carcinoma.²⁻⁴ Verrucous carcinoma is a slow-growing, locally invasive, well-differentiated squamous cell carcinoma that may be easily mistaken for a common wart. It can occur anywhere on the skin but is most common on the plantar surface of the sole. Although this type of cancer rarely metastasizes, it can be locally destructive and should be excised. Because of this entity, consider a deep incisional biopsy of any lesion that is extensive and not responsive to treatment. Treatment of warts can be difficult, with frequent failures and recurrences. Many warts, however, resolve spontaneously within a few years, as delayed cellular immunity to the wart virus takes effect.

EPIDEMIOLOGY

Warts are widespread worldwide and are estimated to affect approximately 7-12% of the population.⁵ They are more common in school-aged children with a prevalence of 10-20%.⁶ Increased frequency of warts also occurs among immunosuppressed patients and meat handlers. HPV is spread by direct skin-to-skin contact or indirect contact through fomites. It is hardy and can resist desiccation, freezing, and prolonged storage outside of host cells.

Autoinoculation also may occur when immune response is low, causing local spread of lesions. The incubation period for HPV frequently ranges from 1 to 6 months, but latency periods of up to 3 years or more are suspected to occur. With respect to race, common warts appear approximately twice as frequently in whites as in blacks or Asians.⁷ Focal epithelial hyperplasia (Heck disease) is more prevalent among American Indians and Inuit.¹ With respect to sex, the male-to-female ratio approaches 1:1. Nongenital warts can occur at any age. They are unusual in infancy and early childhood, increasing among school-aged children, and have a peak incidence at 12-16 years.⁸ The incidence of nongenital warts then generally declines slowly with age.

ETIOLOGY

Warts are caused by HPV, a double-stranded, circular, supercoiled DNA virus enclosed in an icosahedral capsid with 72 capsomers. Warts can infect any area on the skin or mucous membranes. The infection is confined to the epithelium and does not result in systemic dissemination of the virus. Replication occurs in differentiated epithelial cells in the upper level of the epidermis, although viral particles can be found in the basal layer. More than 100 types of HPV have been identified. They are numbered in the order of their discovery based on genotype, with at least 10% difference required in the nucleotide sequences compared to other types.⁹ They include those that cause common warts, most commonly HPV types 2 and 4, followed by types 1, 3, 27, 29, and 57. Deep palmoplantar warts (myrmecia) are most commonly associated with HPV type 1, followed by types 2, 3, 4, 27, 29, and 57. Flat warts are caused by HPV types 3, 10, and 28. Butcher's warts are associated with HPV type 7. Focal epithelial hyperplasia (Heck disease) is caused by HPV types 13 and 32. Cystic warts are associated with HPV type 60. A few HPV types are associated with the development of malignancies, including types 6, 11, 16, 18, 31, and 35. This malignant transformation is seen most commonly in patients with genital warts (see Chapter 3.24) and in immunocompromised patients. In patients with epidermodysplasia verruciformis, HPV types 5, 8, 20, and 47 have oncogenic potential.

DIAGNOSIS

Common warts, known as *verruca vulgaris*, appear as hyperkeratotic papules with a rough, irregular surface. They range from smaller than 1 mm to larger than 1 cm. While they can occur on any part of the body, they are seen most commonly on the hands and knees at sites of prior minor trauma. The diagnosis of warts is made primarily based on clinical findings.^{10,11} Paring of warts may reveal minute black dots, which represent thrombosed capillaries. Obtain a biopsy if the diagnosis is in doubt. In addition, immunohistochemical detection of HPV structural proteins may confirm the presence of virus in a lesion, but this has a low sensitivity. Viral DNA identification using Southern blot hybridization is a more sensitive and specific technique used to identify the specific HPV type present in tissue. Polymerase chain reaction may be used to amplify viral DNA for testing. Although HPV may usually be detected in younger lesions, it may not be detectable in older lesions. Filiform warts are long slender thread-like growths, usually seen on the face around the lips, eyelids, or nares. Deep palmoplantar warts (*myrmecia*)¹² begin as small shiny papules and enlarge to become deep endophytic, sharply defined, round lesions with a rough keratotic surface, surrounded by a smooth collar of callus. They tend to be more painful than common warts, especially those that occur on the plantar surface on weight-bearing areas, such as the metatarsal head and heel. When palmoplantar warts occur on the hand, they tend to be subungual or periungual. Flat warts or *verruca plana* are flat or slightly elevated flesh-colored papules that may be smooth or slightly hyperkeratotic. They range from 1 to 5 mm or more, and numbers range from a few to hundreds of lesions that may become grouped or confluent. While flat warts may occur anywhere, the face, hands, and shins tend to be the most common areas. They may appear in a linear distribution because of scratching or trauma (Koebner phenomenon). In men, they may be spread in the beard area by shaving. Regression of these lesions may be heralded by inflammation. Butcher's warts are seen most commonly on the hands of raw meat handlers. Their morphology is similar to common warts, with a higher prevalence of hyperproliferative cauliflower-like lesions. A mosaic wart is a plaque of closely grouped warts. When the skin surface is pared, the angular outlines of tightly compressed individual warts can be seen. Mosaic warts usually occur on the palms and soles. Focal epithelial hyperplasia (Heck disease)¹, is an HPV infection occurring in the oral cavity, often on the lower labial mucosa. It also can be seen on the buccal or gingival mucosa and rarely on the tongue. The lesions appear as multiple flat-topped or dome-shaped pink-white papules, usually 1-5 mm, with some lesions coalescing into plaques. They are seen most frequently in children of American Indian or Inuit descent. A cystic wart (plantar epidermoid cyst) appears as a nodule on the weight-bearing surface of the sole. The

nodule usually is smooth with visible rete ridges but may become hyperkeratotic. If the nodule is incised, keratinous material may be expressed. The etiology of these lesions is uncertain. One theory is that a cyst forms, originating from the eccrine duct, and secondary HPV infection occurs while another theory is that epidermis infected with HPV becomes implanted into the dermis, forming an epidermal inclusion cyst.^{13,14} Differential diagnoses for warts include acquired digital fibrokeratoma, actinic keratosis, arsenical keratosis, cutaneous horn, lichen niditus, hypertrophic lichen planus, molluscum contagiosum, prurigo nodularis, seborrheic keratosis, and squamous cell carcinoma.

SEARCH METHODS

A search was conducted using Ovid EBM Reviews - Cochrane Database of Systematic Reviews finding topical treatments for cutaneous warts¹⁵ and Ovid MEDLINE 1950 to December 2009, with extension by tracing article references back to the 1920s for treatment of warts. Of particular interest were randomized-controlled trials (RCT) and nonrandomized-controlled trials (NRCT), with case series (CS) and case reports (CR) also included for completeness.

EVIDENCE FOR TREATMENT EFFECTIVENESS

The studies reporting effectiveness of various nongenital wart treatments were rated in terms of the strength of the scientific evidence according to the American College of Cardiology and American Heart Association (ACC/AHA) guidelines grading schema.¹⁶ This involves 3 classes of recommendation 1, 2, and 3, and 3 strengths of evidence A, B, C. Recommendation class 1 is for treatments for which there is evidence or general agreement that the treatment is effective. Class 2 is for treatments where there is a divergence of evidence or opinion about the effectiveness of treatment. Class 3 is for treatments where there is evidence or general agreement that the treatment is not effective. Evidence strength level A is based on the results of multiple RCTs or meta-analyses of such trials. Level B is based on evidence from a single RCT or from NRCT studies. Level C is based on expert opinion, CS, several CR, or standards of care.

TREATMENTS

Many treatment modalities for warts are available, but none is uniformly effective.¹⁷⁻²³ It is recommended to begin with the least painful, least expensive, and least time-consuming methods, reserving the more expensive and invasive procedures for refractory extensive warts. As a rule of thumb, a single nonspread ing wart probably reflects a better cell-mediated immune (CMI) response to the wart virus, while multiple spreading warts reflects less CMI response.²⁴

Treatment options include benign neglect. Providing no treatment at all is certainly safe and cost effective, since 65% of warts may regress spontaneously within 2 years. Without treatment, however, warts may enlarge or spread to other areas. Treatment is recommended for patients with extensive, spreading, or symptomatic warts, or warts that have been present for more than 2 years. When warts resolve on their own, no scarring is seen. Scarring can occur as a result of different treatment methods that cause dermal injury such as strong acids, electrocautery, excision, laser, and less commonly cryosurgery. Hyperthermia involves immersing the involved surface in hot water (113° F or 45°C) for 30-45 minutes, 2-3 times per week, and has been reported to be effective in some cases in inducing wart resolution. Treatment failures and wart recurrences are common, especially among immunocompromised patients, who often are refractory to wart treatments. Normal appearing perilesional skin may harbor HPV, which helps explain recurrences. A quadrivalent vaccine (Gardasil) for HPV 6, 11, 16, and 18 has been developed and approved for prevention of genital warts (see Chapter 21), but so far no vaccine has been developed and approved for prevention of nongenital warts. See Table 22-1 for an overview of recommended first, second, and third line treatments for nongenital warts. For the most recent information on prescription medicines and their indications, interactions and adverse effects see the current Physicians Desk Reference²⁵ or similar source.

Psychological Treatment of Warts

Suggestion and the placebo effect have a long history of enhancing wart resolution both in folklore and in the medical literature. Our understanding of how CMI can be modified by the brain through psycho-neuro-endocrine effects on the immune system makes this approach biologically

plausible. There is case series supportive literature for suggestion²⁶ as evidence class 1C, and placebo has been supported by CS but is not supported by a small RCT,²⁷ placing it as evidence class 2B. There are no contraindications or adverse effects for appropriate suggestion. The same RCT²⁷ is one of several RCT that demonstrated the efficacy of hypnosis in inducing wart resolution, in this case being significantly superior to salicylic acid and placebo and control. Hypnosis for warts is evidence class 1B. Hypnosis has been used to treat warts refractory to other treatments.²⁸ Resolution rates have been reported from 27-55%, with prepubertal children more likely to respond than adults do. For warts resistant to hypnosis, a case series with resolution in 33 of 41 cases demonstrated the efficacy of psychosomatic hypnoanalysis,²⁹ with evidence rating of class 1C. Hypnosis and psychosomatic hypnoanalysis should be used only by those suitably trained and should be used with great caution in patients with psychosis. There are minimal adverse effects such as occasional posthypnotic mild headache.

Topical Agents for Nonprescription Home Use

Keratolytic agents cause cornified epithelium to swell, soften, macerate, and then desquamate. Salicylic acid (Compound W and similar) is available OTC in 5-40% concentration in creams, paints, gels, karaya gum, impregnated plasters, collodion, or sodium carboxy cellulose tape. Lactic acid may be a second keratolytic ingredient in some wart varnishes. By dissolving the intercellular cement substance, salicylic acid desquamates the horny layer of skin. Therapeutic effect may be enhanced by removal of some of the surface keratin prior to application. Dosing for adults and children is topically daily/bid for several weeks. No drug interactions are reported. Contraindications include documented hypersensitivity, prolonged use in diabetics or those with impaired circulation. Do not use on nevi or birthmarks. Do not use on genital area, face, or mucous membranes. Do not use on irritated skin or infected skin. Precautions are pregnancy category C. Fetal risk was revealed in studies in animals but not established or not studied in humans. It may be used if benefits outweigh the risk to the fetus. Also, avoid contact with normal skin surrounding warts. Immediately flush with water for 15 min if contact with eyes or mucous membranes occurs. Avoid inhaling vapors of the solvents. Side effects may include irritation and maceration of surrounding normal skin or contact dermatitis to colophony in collodion bases. Salicylic acid is a first-line therapy used to treat warts. It is available without a prescription and can be applied by the patient at home. The local inflammatory reaction created by the treatment attracts various inflammatory cells that may in turn help to develop CMI response. Cure rates in RCT from 70-80% are reported compared with about 30-50%

TABLE 22-1—Recommended Sequencing of Treatments for Warts Along with Evidence Categories for Each

Wart Type	First Line	Second Line	Third Line
Common	Salicylic acid 1A Liquid nitrogen 1C	Imiquimod* with occlusion 1C	Contact sensitizers** 1C Hypnosis 1B
Flat	Imiquimod* 1C	Topical retinoid* unrated	Liquid nitrogen 1C
Plantar	Salicylic acid 1A Liquid nitrogen 1C	Intralesional Immuno-therapy** 2C	Bleomycin* 2A Hypnosis 1B

*Off-label

**Considered experimental

in controls. It is evidence category 1A, with multiple RCT supporting its effectiveness.¹⁵

Adhesiotherapy consists of applying duct tape to the wart daily. This method is painless and inexpensive and has published reports of good success.^{30,31} Duct tape topical occlusion of warts overnight causes the cornified epithelium to swell, soften, and macerate. Removal of the tape causes gentle tape stripping of the macerated epidermis. Mild irritation might help to induce CMI against the wart virus. However, two RCT found no significant difference between duct tape and placebo occlusion, so it is currently evidence class 3B.^{32,33} Adding various topical home remedies such as raw minced garlic or banana inner peel, lemon slice, vinegar, lime juice, raw potato slice, tea tree oil, aloe, castor oil, dandelion stem milk, crushed chickweed, or strong calendula tea applied to the wart under duct tape or adhesive tape occlusion have so far not been tested by RCT to determine if they surpass the placebo effect. Raw garlic cloves have been shown to have antiviral activity and can be rubbed onto the wart nightly, followed by occlusion.³⁴ Topical tea tree oil has also been reported as successful in some cases, evidence class 2C.³⁵

Topical Agents for Home Use by Prescription

Immunomodulators stimulate the release of key factors that regulate the immune system.¹⁹ Imiquimod (Aldara) 5% cream is an immunomodulator that is FDA approved for use for genital and perianal warts in patients 12 years or older. It induces secretion of interferon alpha and other cytokines. While it has not received FDA approval for treatment of nongenital warts, off-label use reportedly indicates successful treatment of nongenital warts in some cases.³⁶ It is dosed topically in adults and children older than 12 at bedtime, three times a week with or without duct tape or adhesive tape occlusion. More frequent use up to twice daily has been reported, but irritation may be increased with use that is more frequent. There are no reported interactions with other drugs. Contraindications are documented hypersensitivity. Precautions include pregnancy category C with fetal risk revealed in studies in animals, but not established or not studied in humans. It may be used if benefits outweigh the risk to the fetus. Local irritation may occur at application sites including redness, itching, and burning. It is evidence category 1C.

5-Fluorouracil (Efudex) is a topical antineoplastic chemotherapeutic agent that inhibits cell growth and proliferation and is primarily used to treat actinic keratoses and superficial basal cell carcinomas. It has been reported to be effective as an off-label use in treating warts, when used under occlusion and has been more successful in treating flat warts than plantar and common nongenital warts. Dosing in adults is application of the 5% solution or cream daily for up to 1 month. It may be used under occlusion,

but risk of irritation increases. Pediatric usage is not established. There has been no reported drug interactions used topically. Contraindications include documented hypersensitivity and breastfeeding. Precautions include pregnancy category X, contraindicated, and benefit does not outweigh risk. Moderate to severe skin irritation may occur locally. It is category 2B.

Podophyllotoxin (Podofilox) is a purified ingredient of podophyllin and is less irritating than podophyllum resin (see below). Podophyllin is a cytotoxic compound that tends to work better on mucosal surfaces and is used more commonly in the treatment of genital warts (see Chapter 21). Podophyllotoxin is available by prescription and can be applied by the patient at home. Dosing in adults and children of the 0.5% purified solution is that it may be applied topically bid for 3 consecutive days, repeat weekly, not to exceed 4 weeks. Little information is available regarding using it to treat nongenital warts. There are no reported drug interactions. Contraindications are documented hypersensitivity and prolonged use in diabetics and those with impaired circulation. Do not use on nevi or birthmark, do not use on irritated skin or infected skin. It is pregnancy category X, contraindicated and benefit does not outweigh risk. There is insufficient information for rating in an evidence class at this time.

Tretinoin (Retin-A) is a topical retinoic acid that primarily is used to treat acne. It has been successful in off-label use in treating flat warts. It is applied topically daily. Contraindications include documented hypersensitivity and breastfeeding. Precautions include pregnancy category X, contraindicated, and benefit does not outweigh risk. Mild to moderate skin irritation may occur locally. There is insufficient information for rating in an evidence class at this time.

Cidofovir (Vistide) is an antiviral agent used for the treatment of cytomegalovirus infection in HIV patients. It is a nucleotide analog that inhibits viral DNA polymerase and induces apoptosis. Currently it is only available for IV administration to HIV patients for treatment of cytomegalovirus infection. A topical gel has been evaluated in clinical trials for use in treatment of HPV infection. In two patients with recurrent persistent nongenital warts in whom multiple standard therapies were not responsive, the warts resolved using topical cidofovir gel applied 1-2 times per day.³⁷ This remains an investigational drug for warts.³⁸ Dosages in adults and children are not established. Interactions and contraindications other than documented hypersensitivity with topical use have not been established. Precautions include pregnancy category C with fetal risk revealed in studies in animals but not established or not studied in humans. Other precautions for topical use have not been determined. Intralesional injection used to treat nongenital warts has also been proposed. There is insufficient information for rating in an evidence class at this time.

Topical Agents for In-Office Use

Contact sensitizers that induce allergic contact dermatitis, causing a localized inflammation and immune response, may induce wart resolution. Dibutyl squaric acid, also known as squaric acid dibutyl ester (SADBE), and diphen-cyclopropenone (DCP) are contact sensitizers that are not mutagenic/carcinogenic. Dinitrochlorobenzene (DNCB) is a contact sensitizer that is mutagenic according to the Ames test and possibly carcinogenic and should be avoided as when dealing with a potential oncogenic type of wart virus. Older RCT studies with DNCB showed DNCB to be more than twice as effective as placebo.¹⁵ None of these contact sensitizers are FDA approved for medical use and are considered experimental. Apply topical solution to adult or child older than 12 in a light-shielded accessible location such as the inner upper arm to achieve initial sensitization, then apply to warts every 1 to 4 weeks as needed until wart resolves. For SADBE typically a 4% solution is used for sensitization and a 4% or 1% solution is applied topically to the wart. There are no reported drug interactions. Contraindication is documented hypersensitivity. Precautions include pregnancy category C with fetal risk revealed in studies in animals but not established or not studied in humans. It may be used if benefits outweigh the risk to the fetus. Erythema and pruritus occur at treated sites, and occasionally allergic contact dermatitis may be severe (blistering) or rarely become disseminated. Recall dermatitis may occur commonly at the initial sensitization site. Regional lymphadenopathy may occur. DNCB is evidence category 1B, and SADBE and DCP are evidence category 1C.

Podophyllum resin (Podocan-25) is a resin extract derived from *Podophyllum peltatum*, the mayapple plant that contains several cytotoxic compounds. It has a powerful irritant effect and must be used with caution. It works better on mucosal surfaces than keratinized surfaces and is therefore, more commonly used for treatment of genital warts (See Chapter 21). Trained personnel must apply it topically in adults and children because of adverse effects and oral toxicity. It may be left on skin for 1-6 hours before washing off. There are no reported drug interactions. Contraindications are documented hypersensitivity, prolonged use in diabetics and those with impaired circulation, do not use on nevi or birthmarks, do not use on irritated skin or infected skin. It is pregnancy category X, contraindicated, and the benefit does not outweigh the risk. Other precautions include, that podophyllin may cause significant irritation, local erosion, ulceration, and scarring. Systemic side effects of excessive absorption may include fever, nausea, vomiting, confusion, coma, ileus, renal failure, paresthesias, polyneuritis, and leucopenia. Avoid extensive application because of risk of systemic absorption. It is category 1C, with no RCT supporting its effectiveness for nongenital skin.

Cantharidin (Canthacur) is a dried extract of blister beetle (Spanish fly) 0.7% solution in flexible collodion. Dosing in adults and children is to apply sparingly with the wood end of a cotton-tipped applicator in the physician's office, and allow area to be completely dry. Tape occlusion after application can enhance penetration in large or plantar warts, but should be used with caution. Cantharidin causes epidermal necrosis and blistering. Repeat applications at 3 to 4 week intervals may be required. There are no reported drug interactions. Contraindications include documented hypersensitivity. It should not be used near the eyes. Precautions include pregnancy category C with fetal risk revealed in animal studies but not established or not studied in humans. It is a strong vesicant and should be used with caution in intertriginous areas because of possible smearing or occlusion. Adverse effects include blistering, epidermal necrosis at sites of application, and possible "ring wart phenomenon" in which virus is spread circumferentially in adjacent tissue damaged by the treatment process. It is evidence class 2B.

Aminolevulinic acid (Levulan Kerastick) is a photosensitizer that is approved for actinic keratoses and has been successfully used topically off-label in combination with blue light to treat flat warts.³⁹ Several RCT studies on other nongenital warts have produced conflicting results.¹⁵ The main adverse events have been burning pain during and mild discomfort following the treatments. There are no reported drug interactions. Precautions include pregnancy category C with no animal or human data. Photosensitivity occurs after application and before blue light treatment. It is evidence category 2B.

Trichloroacetic acid (Tri-Chlor) is a caustic compound that causes immediate superficial tissue necrosis. It is available as 80% solution that for adults is painted onto lesions in the office after excess keratotic debris is pared. Repeat therapy is performed weekly as needed until the wart resolves. Pediatric use is not established. There are no reported drug interactions. Contraindications include documented hypersensitivity and prolonged use in diabetic persons and those with impaired circulation. Do not use on nevi or birthmarks, face, or mucous membranes. Do not use on irritated skin or infected skin. Precautions include pregnancy category C with fetal risk revealed in studies in animals but not established or not studied in humans. It may be used if benefits outweigh the risk to the fetus. Application may cause pain, burning, and ulceration. If not applied carefully, destruction with resultant scarring of normal surrounding skin may occur. There is insufficient information for rating in an evidence class at this time.

Intralesional Injections

Intralesional immunotherapy off-label using injections of *Candida*, mumps, or *Trichophyton* skin test antigens has been shown to be effective in the treatment of warts,

with reports of success in up to 74% of patients.⁴⁰ A small amount of the antigen is injected intralesionally at the base of the wart every 2-4 weeks until resolution. It is variably effective, evidence class 2C.

Bleomycin (Blenoxane) is an antineoplastic cytotoxic polypeptide chemotherapeutic agent that inhibits DNA synthesis in cells and viruses. It has affinity for HPV-infected tissue and induces vascular changes that result in epidermal necrosis. Bleomycin has been beneficial in treating resistant warts. It is recommended to be held in reserve as a third-line treatment when standard therapies have failed. Wart resolution rates have ranged from 33-92%.^{41,42} In adults the treatment involves injecting 0.5-1 U/mL of the solution directly into the wart, not to exceed 1.5 U/treatment. This treatment is usually painful. Less painful administration involves placing 1 mg/mL drop onto the wart and pricking it into wart with a needle. Pediatric usage is not established. Interactions are unlikely when small amounts are injected intralesionally. Contraindications include documented hypersensitivity and breastfeeding. Precautions include pregnancy category D with fetal risk shown in humans, not recommended in pregnancy. It may cause pain with injection, local urticaria, vaso-occlusive phenomenon (Raynaud phenomenon) with possible distal necrosis of the digit. Permanent damage to nail matrix may occur when used periungually. It may cause mutagenesis and pulmonary toxicity (10%). Idiosyncratic reactions similar to anaphylaxis (1%) may occur, so it is important to monitor for adverse effects during and after treatment. Bleomycin is evidence class 2A.

Interferons alfa-2a and alfa-2b (Roferon and Intron A) are naturally occurring cytokines with antiviral, antibacterial, antitumor, and immunomodulatory actions; intralesional administration is more effective than systemic administration and associated only with mild flulike symptoms. Treatments may be required for several weeks to months before beneficial results are seen. Consider this treatment as third line, and reserve it for warts resistant to standard treatments. Cure rates of 36-63% have been reported. In adults it is injected directly into warts up to 3 times a week for 3-6 weeks. Pediatric dosing is not established. Interactions are minimal with the small amounts injected. Contraindications include documented hypersensitivity. It is to be used with caution in patients with brain metastases, severe hepatic or renal insufficiencies, seizure disorders, multiple sclerosis, or compromised CNS. Precautions include pregnancy category C with fetal risk revealed in studies in animals but not established or not studied in humans. It may be used if benefits outweigh the risk to the fetus. Transient flulike symptoms may occur after initial injections, although tolerance usually develops. Pain at injection sites may occur. Interferon alfa is evidence class 2B.

Systemic Agents

Cimetidine is a type-2 histamine receptor antagonist commonly used to treat peptic ulcer disease. Because of its

immunomodulatory effects at higher doses, cimetidine was considered a possible treatment for warts. However, study results have varied. Double-blind placebo-controlled studies have shown no benefit.⁴³ Dosing in adults and children is 20-40 mg/kg orally per day in divided doses every 6 hours, not to exceed 2400 mg/day. Drug interactions include that it can increase blood levels of theophylline, warfarin, tricyclic antidepressants, triamterene, phenytoin, quinidine, propranolol, metronidazole, procainamide, and lidocaine. Multiple potential drug interactions exist (see full prescribing information for more details). Contraindication is documented hypersensitivity. Precautions include pregnancy category B with fetal risk not confirmed in studies in humans but shown in some studies in animals. Serious reactions may include neutropenia, thrombocytopenia, agranulocytosis, and anemia. Common reactions include headache, nausea, vomiting, diarrhea, and rash. Older patients may experience confusional states. It may cause impotence and gynecomastia in young males. It may increase levels of many drugs. The dose should be adjusted or discontinued if changes in renal function occur. It is evidence class 3B for warts.

Cidofovir (Vistide) is an antiviral agent used for the treatment of cytomegalovirus infection in HIV patients. It is a nucleotide analog that inhibits viral DNA polymerase and induces apoptosis. Currently, it is only available for IV administration to HIV patients for treatment of cytomegalovirus infection. Two reports have described off-label intravenous cidofovir used for the treatment of extensive, disfiguring, and refractory warts in immunocompromised patients. This should be used with caution because of the risk of nephrotoxicity.^{37,44} Contraindications include hypersensitivity and elevated creatinine levels. Warnings include nephrotoxicity as well as neutropenia. Precautions include pregnancy category C with fetal rat low weight and fetal rabbit malformations but fetal risk has not been confirmed in humans. It should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. It may cause decreased ocular pressure, anterior uveitis/iritis, or metabolic acidosis. There is insufficient information for rating in an evidence class at this time.

Isotretinoin (Accutane) is a synthetic 13-*cis* isomer of the naturally occurring tretinoin (*trans*-retinoic acid), structurally related to vitamin A. It is approved for severe nodular acne but has also been helpful off-label in certain keratinization disorders. It may help off-label with extensive disabling hyperkeratotic warts in immunocompromised patients. It may help alleviate the pain related to the hyperkeratosis and facilitate the use of other treatments. Retinoids also have helped reduce the number of wart lesions in immunosuppressed renal transplant patients. The limiting side effects include liver function abnormalities, increased serum lipid levels, and teratogenicity. A US Food and Drug Administration mandated registry called iPLEDGE is now in place for all individuals prescribing, dispensing, or taking isotretinoin. This registry aims to further decrease the risk of pregnancy and other unwanted

and potentially dangerous adverse effects during a course of isotretinoin therapy. Dosage for adults and children older than 12 is 0.5-2 mg/kg/day orally divided into two doses and taken with food. Drug interactions include toxicity that may occur with vitamin A or acitretin coadministration. Pseudotumor cerebri or papilledema may occur when coadministered with tetracyclines. Reduced plasma levels of carbamazepine may occur. Contraindications include documented hypersensitivity, pregnancy, breastfeeding, paraben sensitivity, or history of psychiatric disturbance. Precautions include pregnancy category X, contraindicated and benefit does not outweigh risk. Common reactions include dry skin, cheilitis, photosensitivity, hypertriglyceridemia, hair loss, and decreased night vision. Inflammatory bowel disease may occur. It may be associated with development of hepatitis. Diabetics may experience problems in controlling blood glucose while on therapy. It is to be discontinued if rectal bleeding, abdominal pain, or severe diarrhea occurs. Use with caution if there is a history of depression or other psychiatric disorder. It is associated with severe birth defects, so females must use two forms of birth control throughout therapy and pregnancy tests must be checked monthly. There is insufficient information for rating in an evidence class at this time.

Surgical Care

Cryosurgery⁴⁵ with liquid nitrogen (-196°C) is the most effective method of cryosurgery. Less cold cryosubstances generally do not achieve sufficient freezing of tissue. It is best to apply liquid nitrogen using a cotton bud applicator or cryospray including the recommended 1-2 mm rim of normal skin tissue around the wart. Repeat every 1-4 weeks for approximately 3 months, as needed. Warn patients about pain and possible blistering after treatment. Use with caution on the sides of fingers, since it can injure underlying structures and nerves. Other side effects may include scarring, ulceration, or hypopigmentation. Wart resolution rates of 50-80% have been reported. Paring the wart, in addition to two freeze-thaw cycles, has been a valuable adjunct to cryosurgery for plantar warts.⁴⁶ It is evidence category 2A.

Lasers are an expensive treatment and are reserved only for large or refractory warts. Multiple treatments may be required. Local or general anesthesia may be necessary. A potential risk of nosocomial infection also exists in health care workers, since HPV can be isolated in the smoke plume and can be inhaled.⁴⁷ Carbon dioxide lasers have successfully treated resistant warts, but the procedure can be painful and leave scarring. One retrospective study revealed a cure rate of 64% at 12 months with carbon dioxide lasers.⁴⁸ The flashlamp-pumped pulse dye laser has shown mixed results in treating warts, with decreased risk of scarring and transmission of HPV in the smoke plume.⁴⁹ The Nd:YAG laser may be used for deeper, larger warts. Laser treatments are evidence category 2B.

Electrodesiccation and curettage may be more effective than cryosurgery, but it is painful, more likely to scar, and HPV can be isolated from the plume. There is insufficient information for rating in an evidence class at this time.

Surgical excision should be avoided in most circumstances because of the risks of scarring and recurrence. There is insufficient information for rating in an evidence class at this time.

CONCLUSIONS

The methods and scientific quality of the reviewed trials are quite variable. There is good evidence that topical treatments containing salicylic acid have a therapeutic effect on nongenital warts. Weaker evidence supports the use of hypnosis for resolution of warts. Resolution rates with placebo preparations are variable but nevertheless considerable. For most other treatment modalities, there is a considerable lack of evidence on which to base rational treatment for nongenital warts. The efficacy of cryotherapy is roughly equivalent to the efficacy of simpler and safer treatments such as topical salicylic acid. The benefits and risks of most of the treatments remain to be determined by future research in the form of RCT. Adequate funding of such trials remains a chronic issue.

What We Know

- Treatment of warts can be difficult. Warn patients that multiple treatments often may be required. The patient must build a CMI response against the wart virus to obtain resolution.
- Salicylic acid topical treatment of nongenital warts is moderately efficacious. Warn patients that treatments may result in pain, irritation, blistering, ulceration, and even scarring. Cryosurgery can also be efficacious, but with associated pain and risk of scarring or hypopigmentation. Other methods are of lower proven efficacy. See Table 22-1.
- Perform surgical removal of warts with caution, because an increased risk of scarring exists, without an increased rate of wart resolution.
- If a wart is extremely large and resistant to conventional therapies, consider an incisional biopsy to rule out the diagnosis of verrucous carcinoma, a rare, slow growing, low-grade, well-differentiated carcinoma that most commonly occurs on the plantar surface and can become deeply invasive. Metastases are rare. Verrucous carcinoma can easily be misdiagnosed as a common wart, because the two share similar clinical and histologic characteristics.
- No vaccine is currently available for non-genital warts.

Treatment of Herpes Simplex

23

Tejas Patel, B.S., L. Katie Morrison, M.D., Natalia Mendoza, M.D.,
and Stephen Tyring, M.D., Ph.D.

INTRODUCTION

Herpes simplex viruses cause intermittently recurring mucocutaneous vesicular eruptions. These commonly encountered human DNA pathogens usually replicate in the skin and mucosa and then infect the nerve endings. The virus then ascends to ganglia, where it remains during latency until reactivation. Of the two types, HSV-1 is most commonly associated with orofacial lesions, while HSV-2 is mostly associated with genital pathology. However, both viruses can cause infections in either area. Herpes viruses can also infect noncutaneous organs including ocular tissue or the CNS. HSV is also an important risk factor for acquisition and transmission of HIV.

EPIDEMIOLOGY

Worldwide, genital herpes is the most common sexually transmitted disease. An estimated 40–60 million persons in the United States have a history of genital herpes infections, and new infections occur at a rate of approximately 500,000 to 1 million per year.¹ Because of lack of awareness and frequent recurrence, many transmissions occur by asymptomatic shedding. HSV-1 seropositivity is common amongst the adult population and infections are commonly acquired in childhood. HSV-2, however, is correlated with sexual behavior, and is therefore usually acquired in adolescence and adulthood.

SEARCH METHODOLOGY

Literature searches for randomized controlled trials, meta-analyses, and reviews were conducted. Final reviews included studies published through February 2010. Both Cochrane Central Register of Controlled Trials (key words: herpes labialis, herpes genitalis) and PUBMED (search terms: herpes labialis, herpes simplex, herpes genitalis, herpes suppression, herpes treatment) were used in searches. To be included, studies were evaluated for feasibility in treatment options, degree of efficacy, and reasonable evaluations of commonly accepted treatment options.

Background-Treatment of HSV

Acyclovir

The advent of acyclovir in herpes treatment is still considered one of the most important advances in antiviral therapy. While first developed as a possible anticancer drug, its use for inhibition of viral activity, specifically against herpesviridae, was evident early on. Extensive literature has been published confirming its high clinical efficacy.

Since its arrival three decades ago, its mechanism of action has been the prototype in antiviral drug development. Acyclovir is a synthetic acyclic purine nucleoside analogue; it is converted to its active compound by a viral encoded tyrosine kinase to a monophosphate derivative. This event makes it a selective inhibitor for HSV-infected cells. It is then phosphorylated by cellular kinases to the active compound. This molecule is concentrated up to 100 times higher in infected cells compared to those uninfected. Acyclovir triphosphate then competes with deoxyguanosine triphosphate for viral DNA synthesis. As the active compound lacks the 3' hydroxyl group needed for DNA elongation, the viral DNA polymerase is inactivated when the chain terminates with the addition of acyclovir triphosphate. Selective action for viral replication versus host DNA replication is conferred, as the viral DNA polymerase has a greater affinity for activated acyclovir over host DNA polymerase.²

Acyclovir was originally tested and marketed as a topical and IV medication for use in treatment of susceptible herpesviridae infections. Steady state peak levels of IV doses every 8 hours of 5 mg/kg is 9.9 pg/mL and of 10 mg/kg is 20 pg/mL. To enhance patient compliance and ease administration, an oral form was produced. Although bioavailability was compromised, increased oral dosing regimens of 200 mg and 800 mg produced acceptable steady state peak levels of 0.57 ug/mL and 1.57 ug/mL, respectively. Acyclovir is minimally metabolized and is excreted 85% in its original state by glomerular filtration and tubular secretion. Therefore, renal dosage adjustments may be necessary. In patients with normal renal function, acyclovir has a half-life of 2 to 3 hours.³

Within the herpesviridae family, acyclovir is an effective therapeutic regimen for a host of viruses because of its selective mechanism of action. Evaluating activity with average inhibitory concentration 50, acyclovir is most active against HSV-1 (at 0.04 ug/mL). HSV-2 requires 0.10 ug/mL, and VZV 0.50 ug/mL for effective antiviral activity.⁴ Because of its very high efficacy with herpes simplex viruses, acyclovir has been the most widely prescribed antiviral therapy for acute and recurrent episodes since its introduction.

What is the Role of Medications in Therapy for Primary Therapy in Herpes Labialis Infections?

Treatment in herpes labialis has historically been challenging because of the high rates of recurrence. Patients have been treated with a wide variety of topical and oral applications including zinc oxide/glycine cream, antiviral cream, anesthetic cream, heat therapy, and oral antivirals. Patients treated with topical acyclovir cream in a randomized double blind controlled study experienced a mean duration of episodes of 4.3 days compared to 4.8 days for those treated with the vehicle control (hazards ratio [HR] = 1.23; 95% confidence interval [CI], 1.06 to 1.44; P = 0.007). There was a statistically significant reduction in the duration of lesion pain and efficacy was evident whether therapy was initiated “early” (prodrome or erythema lesion stage) or “late” (papule or vesicle stage).⁵ Another earlier double-blind, placebo controlled, randomized studies found a significant reduction in the duration of vesiculation from 2.7 to 1.8 days (P = 0.016) and in the total healing time from 8.3 to 5.7 days (P = 0.022) on topical acyclovir.⁶ This may be explained by time of initiation of therapy and the degree of penetration of vehicle used.

Penciclovir, which has a similar mechanism of action to acyclovir, was used in another study in a cream-based application. The multicenter placebo-controlled study reported several clinical endpoints. Healing of classic lesions (vesicles, ulcers, and/or crusts) was 0.7 day faster for penciclovir-treated patients compared with those who received vehicle control cream (median, 4.8 days vs 5.5 days; hazard ratio [HR], 1.33; 95% confidence interval [CI], 1.18-1.49; P<.001). Pain (median, 3.5 days vs 4.1 days; HR, 1.22; 95%

CI, 1.09-1.36; P<.001) and lesion virus shedding (median, 3 days vs 3 days; HR, 1.35; 95% CI, 1.10-1.64; P=.003) also resolved more quickly for penciclovir-treated patients compared to patients who applied the vehicle control. The efficacy of penciclovir cream was apparent when therapy was initiated in early or late stages.⁷ However, acyclovir cream is usually more practical as penciclovir must be applied every 2 hours during the day. Another topical agent is docosanol, a compound with a unique mechanism of action involving viral fusion inhibition. In randomized, clinical trials, a 10% docosanol cream formulation, initiated within 12 hours of symptom onset, demonstrated efficacy in reduction of time-to-healing compared with a polyethylene glycol control.⁸ Because of its great safety profile and ease of use, it is the first topical antiviral approved for over-the-counter use in recurrent herpes labialis.

Because of the cumbersome use of topical medications, patients sometimes prefer oral therapy with antiviral medications. Early double-blind, randomized, patient-initiated clinical studies with oral acyclovir showed the mean duration of pain was reduced by 36% (P = .02) and the mean healing time to loss of crust by 27% (P = .03) in the treatment group.⁹ In one study, patients with herpes labialis were instructed to use study medications at the first symptom of an outbreak; findings indicated 1-day valacyclovir treatment regimen for oral HSV is safe and effective.¹⁰ It has also been shown that single-dose famciclovir reduced time to healing of herpes labialis lesions by approximately 2 days compared with placebo¹¹ (Table 23-1).

Research question and answers:

What Does the Data Indicate Regarding Preventative Treatments for Recurrent Oral Herpes Lesions?

Sun exposures, and most particularly UV rays, have been known to affect the cutaneous immune response. One double-blind, placebo-controlled crossover study found after placebo and UV exposure, herpes labialis developed in 27 (71%) of the 38 patients, in contrast, when sunscreen was applied before UV exposure, no lesions developed, but 1 of the 35 patients shed virus at the exposure site.¹² However, another study with skiers showed application of a sunscreen

with a sun protection factor (SPF) of 15 failed to influence the reactivation rate as compared with a placebo.¹³ More research may be needed to discern the benefits of sunscreen in preventing relapse of herpes outbreaks.

Topical acyclovir cream therapy was studied in skiers who had experienced more than three episodes of sun-induced herpes labialis during the previous year. The acyclovir group had significantly fewer lesions ($p <0.01$) than the placebo group (21% vs. 40%) during the 4-day follow-up period.¹⁴ Two other similar trials sought to study the long-term effects with application of prophylactic acyclovir cream, which was applied 2 or 4 times a day for 16 weeks.¹⁵ Only the 4 times a day application showed minor differences in number of days with lesions (acyclovir group: 9.5 days; placebo group: 12.4 days) and symptoms (acyclovir group: 12.2 days; placebo group: 17.4 days).¹⁶ Because of the small benefits, this therapy may not justify the impracticality of frequent applications through the day.

In one study, only 7% of patients treated prophylactically with oral acyclovir developed lesions compared to 26% with placebo during observation on their ski holidays.¹⁷ Additionally, double-blind, placebo-controlled studies with valacyclovir have also yielded encouraging results, 60% in a valacyclovir group compared to only 38% in a placebo group were recurrence-free throughout the

4-month treatment period ($P=.041$). The mean time to first recurrence was significantly longer with valacyclovir (13.1 weeks) compared with placebo (9.6 weeks) ($P=.016$). The total number of recurrences in patients using valacyclovir was 24 compared with 41 in patients using placebo¹⁸ (Tables 23-2 and 23-3).

What is the Role of Medications in Therapy for Primary Herpes Genitalis Infections?

Oral acyclovir therapy, being nearly as effective as IV, but with easier administration has been the drug of choice in primary and recurrent episodes of genital herpes. Despite its use, acyclovir seems to be much more effective on the primary infection compared to subsequent recurrences. In one of the first studies of the drug, subjects were randomized to receive either placebo or acyclovir (200 mg per dose) five times daily for 10 days. Compared to placebo, acyclovir treatment significantly reduced virus shedding, new lesion formation after 48 hours, and the duration of genital lesions in both men and women. The total duration and severity of clinical symptoms (such as pain, adenopathy, dysuria, and malaise) were significantly reduced by acyclovir in both men and women by the third and fourth

day, respectively ($P < 0.025$).¹⁹ Another double-blind, placebo-controlled study showed that primary genital herpes patients treated with acyclovir had shorter median duration of viral shedding (2 days), time to crusting of all lesions (7 days), time to healing of all lesions (12 days), and duration of local pain (5 days) and constitutional symptoms (3 days) were shorter than among placebo recipients (9, 10, 16, 7, and 6 days, respectively).²⁰ In efforts to try to find more efficacious treatment regimens, one study compared whether receiving higher (4 g) than standard (1 g) daily dose of oral acyclovir had a significant effect on clinical outcomes. There was no statistically significant difference in the duration of symptoms or viral shedding between the two dose groups, nor did the median time to first recurrence differ between the two groups. Also noteworthy was that adverse gastrointestinal effects developed in 8% of subjects receiving the higher dose, whereas no adverse reactions were observed among those receiving the standard dose ($P = 0.10$).²¹

Because of the frequent dosing regimen of acyclovir, many patients may not be completely compliant, and therefore may not maintain therapeutic drug levels. As such, valacyclovir is available for once daily dosing and even has shown higher absorption rates. In international, multicenter, double-blind, randomized clinical comparison trials, valacyclovir and acyclovir did not differ significantly in efficacy with respect to duration of viral shedding (HR, 1.00; 95% CI, 0.84-1.18), time to healing (HR, 1.08; 95% CI, 0.92-1.27), duration of pain (HR, 1.0; 95% CI, 0.85-1.18), and time to loss of all symptoms (HR, 1.02; 95% CI, 0.85-1.22).²² Valacyclovir has been approved for primary genital herpes therapy at a dosage of 1000 mg BID for 10 days.

Another oral medication with the similar mechanism of action, famciclovir, is metabolized to penciclovir, which is active against herpes virus. In the treatment of primary genital HSV, famciclovir has been shown to have equal efficacy to acyclovir at a dose of 250 mg 3 times a day for 5 to 10 days. Also the effects of famciclovir 125, 250 or 500 mg 3 times daily for 10 days were not significantly different from acyclovir 200 mg 5 times daily for 10 days.²³ No significant differences in times to cessation of viral shedding, complete healing, or loss of all symptoms was observed between the two groups in these studies. Again,

reduced administration frequency is a practical advantage over acyclovir (Table 23-4)

What Are the Evidence-Based Treatments for Recurrent Herpes Genitalis?

As stated before, acyclovir remains the prototypical drug for HSV genitalis infections. Topical 5% acyclovir in polyethylene glycol ointment decreased the duration of viral shedding but had no significant clinical benefits. However, although there is a statistically significant benefit to using oral acyclovir in genital herpes recurrence, it shortens the duration of viral shedding and time to healing (6 days down from 7 without therapy), when initiated within the first 24 hours of onset. Other symptoms, such as pain, itching, and time to next episode are not affected.²⁴ These results indicate that most patients have limited clinical improvement for episodic treatment of recurrent genital herpes.

Another study, which sought to compare valacyclovir and acyclovir episodic therapy in recurring herpes attacks showed better outcomes, though still marginal. Patients self-initiated oral therapy with 1000 mg of valacyclovir hydrochloride twice daily, 200 mg of acyclovir 5 times daily, or placebo for 5 days. Both drugs were significantly more effective than placebo in speeding resolution of herpetic episodes (median duration, 4.8, 4.8, and 5.9 days, respectively); the hazards ratios for valacyclovir and acyclovir vs. placebo were 1.66 (95% CI, 1.38-2.01) and 1.71 (95% CI, 1.41-2.06) (both $P < .001$) respectively. Similarly, valacyclovir and acyclovir significantly hastened lesion healing (HR vs. placebo 1.88 [95% CI, 1.53-2.32] and 1.90 [95% CI, 1.55-2.34], respectively; $P < .001$). Pain duration was shorter in valacyclovir and acyclovir-treated patients (median, 2 vs. 3 days). Viral shedding stopped faster in patients treated with valacyclovir or in patients treated with acyclovir (2.25, 2.24 times respectively) versus placebo. Aborted episodes, in which lesions did not progress beyond the macule or papule stage, were increased in patients treated with valacyclovir (25.9%) or acyclovir (24.8%) versus placebo (19.8%). Valacyclovir and acyclovir did not differ significantly with regard to their respective effects on any of the above parameters.²⁵

^aFor human immunodeficiency virus-positive patients, suggested regimens were derived from studies of patients with genital herpes. However, we expect these treatments to also be useful for patients with labial herpes.

*Reproduced with permission from *Archives of Internal Medicine*. June 9th, 2008. 168(11):1137–1144. ©2008 American Medical Association. All rights reserved.

Famciclovir has been shown to be significantly more effective than placebo in treatment of recurrent episodes of genital herpes when taken at 125, 250, or 500 mg doses BID for 7 days. When initiated within the first 6 hours of symptoms, famciclovir significantly reduced the time to healing, the time to cessation of viral shedding, and duration of lesion edema. This treatment also significantly reduced the symptoms of pain, burning, tenderness, and tingling.²⁶ Therefore, famciclovir is effective for acute episodic treatment of recurrent genital herpes and provides the convenience of twice-daily administration (Table 23-5).

What Are the Evidence-Based Treatments for Herpes Simplex II?

Suppressive therapy with oral acyclovir is very effective in reducing recurrences of genital herpes by up to 80%. Successful suppressive therapy may be achieved with lower levels of drug dosing and patients may need titration to discern the minimum dose required. Reassessment of need for suppression may be performed every 12 months.³

In one early trial, adults with six or more episodes of genital herpes in the previous year were enrolled in a 1-year, multicenter, double-blind trial, comparing placebo with 400 mg of acyclovir administered orally twice daily. Patients with episodes during the study were treated with 200 mg of acyclovir administered orally five times daily for 5 days; this allowed comparison of suppressive and episodic treatment. After 1 year, 44% versus 2% of patients (suppressing and placebo/episodic respectively) remained free of recurrences, and the mean numbers of recurrences per year were 1.8 and 11.4, respectively. There was no evidence of substantial adverse effects, and therefore successful suppression can be maintained for extended periods.²⁷ One study showed that resistance to acyclovir

of herpes simplex virus was not observed over 5 years of treatment. It also reported maintenance of efficacy and of good safety profiles, further expanding treatment longevity.²⁸ Similar trials with acyclovir suppression at various dosage regimens have shown the utility of antiviral therapy in avoiding recurrent outbreaks.

Valacyclovir also showed promising results in suppressive therapy with an easier regimen. In an international, randomized, double-blind, placebo-controlled suppression study, 500 mg daily of valacyclovir significantly prolonged the time to first recurrence of HSV-2 genital herpes in newly diagnosed subjects compared to placebo, with approximately 43% of subjects on placebo and 71% of subjects on valacyclovir recurrence-free at 24 weeks ($P < 0.001$). It also reduced the mean number of genital HSV-2 recurrences per month during the 24-week study period (0.11 for valacyclovir, 0.48 for placebo, $P < 0.001$).²⁹ In another study to discern dosing regimens, patients were randomized to receive valacyclovir (250 mg, 500 mg, or 1 g once daily, or 250 mg twice daily), acyclovir (400 mg twice daily), or placebo, for 1 year. There was a dose-response relationship ($P < .0001$) across the once-daily valacyclovir regimens, and twice-daily valacyclovir and acyclovir were similar in effectiveness. In patients with less than 10 recurrences per year, valacyclovir 500 mg once daily was sufficient for suppression. One gram of valacyclovir once daily, 250 mg of valacyclovir twice daily, or 400 mg of acyclovir twice daily were more effective in patients with 10 or more recurrences per year.³⁰

Famciclovir suppressive treatment for genital herpes recurrence was approved at a dose of 250 mg BID. The first of two multicenter, double-blind, placebo-controlled studies demonstrated the median time to first recurrence was 82 days versus 114 days in placebo compared to those receiving 125 mg of famciclovir once a day. The time to the first clinical recurrence was significantly prolonged in subjects

who received famciclovir, 125 mg twice daily (HR, 1.8; 95% CI, 1.0-3.0; P=.03), and in those who received famciclovir, 250 mg twice daily (HR, 3.6; 95% CI, 1.9-6.9; P<.001) when compared to placebo. Furthermore, famciclovir 250 mg twice daily, which was found to be the optimal dose, suppressed recurrences in 90% of the treatment group, compared with 48% in the placebo group.²³ The other study showed in an intent-to-treat analysis, famciclovir (125 mg or 250 mg 3 times daily or 250 mg BID) significantly delayed the time to the first recurrence of genital herpes at all dose regimens (HR, 2.9-3.3; P<.001); median time to recurrence for famciclovir recipients was 222 to 336 days compared with 47 days for placebo recipients. Encouragingly, the number of patients without recurrence was approximately 3 times higher in famciclovir recipients (79%-86%) than in placebo recipients (27%) at 6 months (relative risks, 2.9-3.1; P<.001); efficacy was maintained at 12 months.³¹ In both studies, famciclovir was well tolerated with an adverse experience profile comparable to placebo.

Comparative studies given above have shown similar efficacy of acyclovir and valacyclovir. Famciclovir 250 mg BID and valacyclovir 500 mg daily were compared in two randomized, double-blind, placebo-controlled studies. In study 1, first recurrence time was similar in famciclovir and valacyclovir recipients, HR 1.17 (95% CI, 0.78-1.76), but time to first molecularly confirmed recurrence was shorter among famciclovir recipients, HR = 2.15 (95% CI, 1.00-4.60). In study 2, HSV was detected on 3.2% of days among famciclovir recipients and 1.3% of days among valacyclovir recipients, relative risk 2.33 (95% CI, 1.18-4.89).³² Most recently, a meta-analysis was performed, evaluating 14 randomized clinical trials. In antiviral drug groups compared with the placebo, the global relative risk of developing at least one recurrence during the study was reduced by 47% (95% CI 45%-49%). The data also revealed the best regimens which had comparable efficacies; (ie., acyclovir) (400 mg twice daily), valacyclovir (250 mg twice daily), and

famciclovir (250 mg twice daily), or once daily valacyclovir (500 mg)³³ (Table 23-6).

How is Antiviral Therapy Used to Decrease Transmission Rates?

Acyclovir used in infected sexually active patients, can also be used to address concerns for spreading the infection to sexual partners. Earlier studies did not show a decrease in the rate of viral shedding during the asymptomatic phase. However, one study did find a 95% reduction in subclinical shedding while patients were on acyclovir therapy.³⁴ Another study found suppression with acyclovir regimens lead to decreased viral shedding, but not to undetectable levels.³⁵ In an investigation of daily genital secretions taken from infected women, patients were discovered to have 80% reduction in frequency of HSV-2 DNA detection while on acyclovir 400 mg BID; upon discontinuation, patients resumed original levels of shedding.³⁶ A recently published double-blind, three-period crossover trial examined viral shedding with the antivirals valacyclovir and acyclovir against placebo. HSV was detected at least once in 62 (90%) participants by culture and in 68 (98%) by PCR. During placebo, the total HSV shedding rate was 15.4% of days by culture (PCR, 40.2%); the subclinical shedding rate was 6.6% by culture (PCR, 27.1%). Both antivirals were associated with lower HSV shedding by culture (relative risk [RR], 0.03 [95% CI, 0.01–0.07] for valacyclovir and RR, 0.05 [95% CI, 0.03–0.10] for acyclovir) and PCR (RR, 0.18 [95% CI, 0.12–0.26] for valacyclovir and RR, 0.20 [95% CI, 0.15–0.28] for acyclovir), compared to placebo. No significant differences in frequency and quantity of HSV were detected by PCR between the valacyclovir and acyclovir arms.³⁷ These findings are encouraging since decreased viral shedding is a necessary component of a reduced transmission rate.

This may be the mechanism behind decreasing transmission rates in an investigation of discordant couples counseled on safe sex practices. This study found that once

TABLE 23-6—Chronic Suppressive Therapy for Genital Herpes

Antiviral Drug	Dosing Schedule	Level of Evidence	FDA Approved	CDC Recommended
Acyclovir	400 mg twice a day 400-800 mg twice to 3 times a day ^a	I ^{61,69,71,81} I ⁸⁹	Yes No	Yes Yes

daily suppressive therapy with valacyclovir reduced the risk of transmission of HSV-2 in heterosexual immunocompetent adult couples discordant for HSV-2 infection. In an 8-month double blind study, daily valacyclovir compared to placebo reduced the risk of acquisition of symptomatic genital HSV-2 infection by 75% (2.2% placebo vs. 0.5% valacyclovir; HR = 0.25; p = 0.008). The overall risk of acquisition of HSV-2 infection (defined via laboratory-confirmed symptoms or seroconversion) was reduced by 48% (3.6% placebo vs. 1.9% valacyclovir HR = 0.52; p = 0.04).³⁸ These results were reinforced with a double-blind randomized trial in which patients were assigned to a 500 mg valacyclovir arm or placebo for 8 months. Of the 743 valacyclovir patients, four developed clinically symptomatic HSV-2 infection, as compared to 16 of 741 who were given placebo (HR, 0.25; 95 percent CI, 0.08 to 0.75; P=0.008). Subclinical infection as detected in an additional 14 of the susceptible partners who received valacyclovir (1.9%), as compared with 27 (3.6%) who received placebo (HR, 0.52; 95 percent CI, 0.27 to 0.99; P=0.04). Seroconversion of genital secretion occurred at the rate of 2.9% of the days among the HSV-2-infected (source) partners who received valacyclovir, as compared with 10.8% of the days among those who received placebo (P<0.001). The mean rates of recurrence were 0.11 per month and 0.40 per month, respectively (P<0.001).³⁹ Based on these studies, another group devised a mathematical model of HSV-2 epidemiology, which included suppressive therapy with the efficacy observed in the clinical trial. The resulting data demonstrated that with coverage rates of 3.2%, the incidence of HSV-2 would be reduced by between 1.8% and 2.8%. Higher coverage rates were estimated to reduce the incidence of new cases up to 13%. It was found that suppressive therapy reduces incidence of HSV-2, and that starting suppression closer to the time of infection reduces the number of new cases.⁴⁰

How are Treatment Regimens Modified for Immunocompromised Patients?

Just as in most fields, many patients are not textbook cases and may present with a myriad of different comorbidities. There have been evident challenges in finding appropriate treatments for people with some degree of compromised immune systems. However, because of the significant reduction in quality of life in these patients, much effort has been placed towards alleviating possible stressors.

For oral herpes, a recent systematic review of 17 trials analyzed preventative interventions. It was found that in placebo controlled trials for the prevention of HSV manifestations, acyclovir was effective when measured by oral lesions or viral isolates (RR = 0.16, 95% CI 0.08 to 0.31 nine trials; RR = 0.17, 95% CI 0.07 to 0.37 nine trials). There was no evidence that higher doses of valacyclovir are more efficacious than lower doses, or that valacyclovir is more effective than acyclovir. Interestingly, in one trial placebo

was found to be more effective than prostaglandin E for prevention of viral isolates (RR = 1.87, 95% CI 1.12 to 3.14). Acyclovir was also found to be effective for the treatment of HSV in terms of duration of viral shedding (median of 2.5 days versus 17.0 days, P = 0.0002; 2 days compared to more than 9, P = 0.0008), time to first decrease in pain (median 3 days compared to 16, P = 0.04), complete resolution of pain (9.9 days compared to 13.6 days, P = 0.01; median of 6 days compared to 16, P = 0.05), 50% healing (median of 6 days compared to 11, P = 0.01) and total healing (median 13.9 days compared to 20.7 days, P = 0.08; median of 8 days compared to 21, P = 0.0).⁴¹

Genital herpes in immunocompromised patients has been studied extensively as well. In one of the first studies, patients received acyclovir at 250 mg/m² intravenously over 1 hour every 8 hours for 7 days or placebo. It was found that acyclovir recipients had significantly shorter periods of virus shedding (p<0.0002) and lesional pain (p<0.01), and more rapid lesion scabbing (p<0.004) and time to healing (p <0.04).⁴² Another study delineated effective regimens of acyclovir 400 mg 5 times a day for 5 days or until the eruption clears and then 400 mg 3 times a day for 1 or 2 months followed by 400 mg twice a day thereafter.⁴³ A study on dosing and alternative treatments revealed that oral valacyclovir is comparable to IV acyclovir in achieving systemic exposure levels. Testing of blood levels showed acyclovir levels after oral valacyclovir 1000 mg and IV acyclovir 5 mg/kg with AUC0-8 (oral/IV ratio = 1.16; 90% CI 0.98-1.39). Oral valacyclovir appears to lead to similar treatment outcomes as IV acyclovir therapy, and offers a convenient, safer, and more cost effective alternative.⁴⁴ Further randomized trials are needed to test the equivalent efficacy of other antivirals to IV acyclovir.

For Severe Manifestations of HSV Infections, What Are the Evidence-Based Treatment Guidelines?

Though primary and recurrent episodes described above can both be treated with oral therapy, severe reactions to infection need regimens that are more aggressive. Intravenous antivirals are the most effective treatment for disseminated herpes outbreak usually leading to a large reduction in symptoms. Patients with serious HSV systemic disease burden, (i.e., disseminated infection, pneumonitis, or hepatitis) or CNS complications (i.e., meningitis or encephalitis) typically need hospitalization for IV treatment. The literature supporting concrete treatment regimens is limited, however, the CDC web site recommends: acyclovir 5–10 mg/kg body weight IV every 8 hours for 2–7 days or until clinical improvement is observed, followed by oral antiviral therapy to complete at least 10 days of total therapy.

Severe manifestations of herpes simplex infection, such as herpes gingivostomatitis and eczema herpeticum,

have sparse data analyzing efficacy of pharmacotherapy pertaining to individual disease states. One randomized-controlled study with herpes gingivostomatitis showed marginally better results in the acyclovir group compared to the placebo group in children <6 years of age in reducing the number of individuals with oral lesions (RR 0.10 (95% CI 0.02 to 0.38), new extra oral lesions (RR 0.04 (95% CI 0.00 to 0.65), difficulty in eating (RR 0.14 (95% CI 0.03 to 0.58), and drinking difficulties (RR 0.11 (95% CI 0.01 to 0.83), however the study design may have been subject to some bias. The other study with 20 patients showed no benefit in the antiviral group compared to placebo. The Cochrane database review on this subject concluded that there was weak evidence to support acyclovir treatment for decreasing some of the symptoms caused by primary herpetic gingivostomatitis.⁴⁵ As such, treatment guidelines supported by effective trials are limited. Most of these infections are treated intravenously with antivirals within dose safety limits based on therapy for primary oral or genital infection regimens.

What Are the Treatment Options for Acyclovir Resistant Herpes Infections?

For the most part, antiviral resistance in herpes simplex infections has not been a major issue in treating HSV infections in immunocompetent patients to date. However, the incidence of acyclovir resistance in immunocompromised patients has been greater (4-7%).⁴⁶ During worldwide clinical trials and surveillance programs for the last 20 years, thousands of HSV isolates have been collected to test for HSV susceptibility to acyclovir or penciclovir. Authors studying these isolates published two consistent findings: (1) The prevalence of acyclovir-resistant HSV is higher in severely immunocompromised patients than in immunocompetent patients; (2) there was no increase in the prevalence of resistant HSV in either immunocompromised or immunocompetent populations during the studied period. Furthermore, through clinical and laboratory experience, with very rare exceptions, acyclovir-resistant mutants do

not appear to be capable of initiating a latent infection that can subsequently be reactivated. Almost all resistant HSV mutants lack the ability to express functional TK and which may account for this phenomenon.⁴⁷

Nevertheless, in these exceptions, as well as severely immunocompromised patients, treatment options have been delineated to address the extent and severity of HSV infection. Foscarnet is a pyrophosphate antagonist that binds to viral DNA preventing pyrophosphate exchange. It does not require phosphorylation, and is therefore active against HSV strains that are resistant to HSV based upon TK variations. In one uncontrolled study, 81% of patients with resistant infection exhibited clinical response to treatment with foscarnet.⁴⁸ Another option is the alternative nucleoside analogs, such as cidofovir, an acyclic nucleoside phosphonate analogue of deoxycytosine monophosphate. Since cidofovir is a nucleotide, it bypasses the first HSV-dependent phosphorylation step required for nucleosides such as acyclovir. A randomized, double-blind, clinic-initiated, sequential dose-escalation pilot study was performed to compare the safety and efficacy of single applications of 1, 3, and 5% cidofovir gel with placebo in the treatment of early recurrent genital herpes. Cidofovir gel at all strengths significantly decreased the median time to negative virus culture in a dose-dependent fashion (3.0 days in the placebo group versus 2.2, 1.3, and 1.1 days in the 1, 3, and 5% cidofovir gel treatment groups, respectively; P = 0.02, 0.0001, and 0.0003, respectively). A trend toward a reduction in the median time to complete healing in association with treatment was present, but the differences were not statistically significant (5.0 days in the placebo group versus 4.3, 4.1, and 4.6 days in the 1, 3, and 5% cidofovir gel treatment groups, respectively).⁴⁹

Additional treatments are available or being tested for future use in HSV treatment, including trifluridine, interferon alpha and beta, lobucavir, cidofovir, edoxudine, and many vaccines aimed at prevention.⁵⁰ However, the risk of adverse events for all alternative therapies, most commonly compromise of kidney function, makes these medications challenging to use.

What We Know

Genital herpes is the most common sexually transmitted disease. 67 million people have genital herpes infection; the annual incidence is 1 million cases per year.

Acyclovir is the prototypical herpesviridae DNA polymerase inhibitor and has selectivity by being activated by viral tyrosine kinase.

Treatment for primary orofacial herpes infection:

- Acyclovir 15 mg/kg 5 times a day for 7 days
- Valacyclovir 1 g BID for 7 days
- Famciclovir 500 mg BID for 7 days

Treatment for episodic orofacial herpes recurrence:

- Acyclovir 400 mg 5 times a day for 5 days

Treatment for primary genital herpes infection:

- Acyclovir 400 mg 3 times a day or 200 mg 5 times a day for 7-10 days
- Valacyclovir 1 g BID for 7-10 days
- Famciclovir 250 mg 3 times a day for 5-10 days

Treatment for episodic genital herpes recurrence:

- Acyclovir 200 mg 5 times a day for 5-10 days

- Valacyclovir 2 g BID for 1 day
- Famciclovir 500 mg 3 tab as single dose
- Penciclovir topical 1% cream applied every 2 waking hours for 4 days
- Acyclovir topical 5% cream applied 5 times a day for 4 days

Suppressive therapy for orofacial HSV disease:

- Acyclovir 400 mg BID
- Valacyclovir 500 mg once a day, 1 g once a day, 500 mg BID (for immunocompromised)
- Famciclovir 500 mg BID

- Valacyclovir 500 mg BID for 3 days
- Famciclovir 125 mg BID for 5 days
- See table for alternative regimens

Suppressive therapy for genital HSV disease:

- Acyclovir 400 mg BID
- Valacyclovir 500 mg or 1 g once a day, 250 mg BID, 500 mg BID (for immunocompromised)
- Famciclovir 250 mg BID, 500 mg BID (for immunocompromised)

Although acyclovir resistance is rare, it does occur in select patients, most specifically those in an immunocompromised state. In these patients, intravenous and intralesional foscarnet or cidofovir have been used with varying success.

Treatment of Herpes Zoster

Nancy Anderson, M.D., Shawna McCarty, M.D., Michael Messina, M.D.,
Jeffrey R. Smith, M.P.H., and Tracy Leong, M.D.

INTRODUCTION

Varicella zoster virus is the causal agent of varicella and herpes zoster (HZ) in humans. HZ results from reactivation of latent varicella zoster virus (VZV) within the sensory ganglia.

Incidence and severity relate with age where >50% of all patients who develop HZ are greater than 60 years old.

A frequent and often very debilitating complication is postherpetic neuralgia, a pain syndrome that develops while or can persist after the dermatomal rash has healed and can be prolonged and greatly affect QOL (quality of life).

There are advantages, but limitations to current therapies for HZ and postherpetic neuralgia.

ETIOLOGY

Herpes zoster is caused by an infection from the varicella zoster virus, which is a member of the family herpesviridae and thus a double-stranded DNA virus with a lipid envelope surrounded by an icosahedral nucleocapsid.¹ The virus is commonly spread by several routes including: direct person-to-person contact, droplet or airborne transmission, respiratory secretions of patients with primary varicella infections, or from the vesicles of patients with herpes zoster. Herpes zoster is a local manifestation of reactivation of latent varicella zoster virus in the dorsal root ganglia or cranial nerve ganglia. Patients with herpes zoster should be considered infectious from the prodromal symptoms begin to 1 week after the appearance of vesiculopustular lesions.²

DIAGNOSIS

Herpes zoster is diagnosed clinically and typically presents as a vesicular rash with an erythematous base in a dermatomal distribution,³ the rash is typically unilateral and accompanied by neuralgic pain. Frequently the neuralgic pain can precede the vesicular lesions by several days. Herpes zoster most commonly affects the thoracic, cervical, and ophthalmic dermatomes. The vesiculopustular

rash typically lasts 7-10 days, and heals within a month. Up to 30% of patients develop complications from herpes zoster, most notably postherpetic neuralgia.²

In 2007, a study was conducted to look at the accuracy of diagnosing acute herpes zoster infections clinically. The study concluded that 91% of cases of clinically diagnosed acute herpes zoster were confirmed on serologic testing in cohort of 260 patients.⁴ Several laboratory tests are available to aide in the diagnosis of herpes zoster; however most are commonly used when the clinical diagnosis of herpes zoster is not obvious.

Other diagnostic testing includes tzanck smears, viral cultures, direct fluorescent antigen assays, and PCR analysis. Tzanck smears are scrapings from the base of the vesicular lesion that characteristically show eosinophilic intranuclear inclusions and multinucleated giant cells.¹ Traditionally this test has a low sensitivity and specificity, failing to differentiate herpes zoster from herpes simplex. Viral cultures provide a definitive diagnosis, but the results usually take 48 hours. Direct fluorescent antigen assays are more sensitive than viral cultures; additionally they have the ability to distinguish between herpes zoster and herpes simplex. PCR analysis is useful in complicated cases and is recommended in patients with suspected varicella virus myelitis, vasculopathy, or zoster sine herpete.³

EPIDEMIOLOGY

Herpes zoster (VZV) HHV-3 has worldwide distribution and 98% of the adult population is seropositive.

HZ is generally considered a disease in patients older than 50 and affects that group more severely, but is also common in younger persons who had primary varicella infection within the first year of life. Individuals with history of primary varicella have a 20% life chance of developing HZ. The severity and incidence of the infection increases significantly with age. The incidences of HZ in the U.S. and Europe are 2.5/1000 between the ages of 20-50, 5.1/1000 between ages of 51-79, and 10.1/1000 in those greater than 80 years of age. The incidence of varicella and

HZ has increased in the immune-compromised population, especially in those affected with HIV.⁵⁻⁶

What are risk factors for HZ especially in RA cohort?

In a national cohort of veterans with rheumatoid arthritis, HZ was 9.96/1000 patient years. Risk factors for HZ included older age, prednisone use, medications used to treat moderate and severe rheumatoid arthritis, malignancy, chronic lung disease, renal failure, and liver disease. Among patients receiving tumor factor α antagonist, etanercept (hazard ratio 0.63) and adalimumab (hazard ratio 0.53) were associated with lower risk of HZ.⁷

What are costs to health system for HZ and PHN?

In the data from the Australian population from 2000 to 2006, zoster and PHN incidence rates were estimated as 10/1000 and 1.45/1000 persons respectively with antiviral prescribed for 73.5% of zoster cases. Total costs to the health system were estimated at 32.8 million a year. The substantial burden of HZ and PHN highlights the benefit of zoster vaccination.⁸

What are effects of varicella vaccine on HZ?

In data from University of Michigan, regarding HZ before and after the introduction of the varicella virus vaccine in the U.S was observed; as the rates of varicella-related hospital discharges and costs have decreased, there has been a significant increase in herpes-zoster-related discharges and changes disproportionately among older adults. HZ vaccine may mitigate these trends for HZ hospitalizations.⁹

The CDC also has addressed speculation that a universal vaccine program might lead to increase in HZ. Incidents have been supported by modeling studies that assume that exposure to varicella boosts immunity and protects against reactivation of VZV as HZ. Such studies predict an increase in HZ incidence until the adult population becomes predominantly composed of individuals with vaccine-induced immunity that does not harbor wild-type VZV. In the United States, a varicella vaccination program was initiated in 1995. Since then, studies monitoring HZ incidence have shown inconsistent findings: two studies have shown no overall incidence, but one study has shown an increase. Studies from Canada and the U.K. have shown increased rates of HZ incidences in the absence of a varicella vaccination program. Data also suggests that unidentified risk factors for HZ are changing over time. Further review of the contribution of these different factors on HZ epidemiology will be challenging.¹⁰

Continued studies are looking at the vaccine and the effects on morbidity of HZ. CDC stated in 2006 a two-dose

varicella vaccine was recommended for the children. Data is inconclusive regarding the effect of the varicella vaccination program on HZ epidemiology.¹¹

The Shingles Prevention Study Group demonstrated that HZ vaccine significantly reduced the morbidity because of HZ and PHN in adults >60 years old.¹²

TREATMENT FOR ADULTS >18 YEARS

Currently there are three US Food and Drug Administration (FDA)-approved medications for the systemic treatment of herpes zoster: acyclovir, valacyclovir, and famciclovir. The intended use of antiviral medications in immunocompetent patients is to accelerate wound healing, minimize the severity of the disease, reduce pain, and reduce the risk and/or duration of post-herpetic neuralgia. The main goal for the use of these medications in immunocompromised patients, in addition to the above, is to halt viral replication and to treat or prevent more severe complications of herpes zoster reactivation, such as ophthalmic herpes zoster (*herpes ophthalmicus*). Bromovinyl deoxyuridine (marketed as brivudin) is another antiviral agent licensed for use in Europe and not in the USA and therefore will not be covered in this discussion.

Immunocompetent Patients

The efficacy of antiviral therapy has been well established by many randomized-controlled clinical trials. These medications are all dependent on viral thymidine kinase (TK). They are phosphorylated to the active form that by viral TK which can then be further phosphorylated to the bi- and triphosphate active forms, which will thus inhibit viral replication. Certain patients should be considered for systemic oral antiviral therapy.¹³ See Table 24-1 for a list of those who would fit the criteria for antiviral administration. Mild cases of zoster with minimal pain involving the trunk in immunocompetent young adults can be managed successfully symptomatically without the intervention of antiviral therapy.

Acyclovir was the first medication approved in the USA for the treatment of herpes zoster. The dosage and recommended use of acyclovir is 800 mg 5 times daily for 7-10 days.¹⁴⁻¹⁵ It has been shown through several randomized, placebo-controlled trials that if treatment is started within 72 hours of lesion onset, at a dose of 800 mg 5 times a day, there is accelerated wound healing and cessation of

TABLE 24-1—Administration Criteria for Antiviral Therapy in Adults (>18y)¹

>= 50 years of age
Moderate to severe pain
Moderate to severe rash
Nontruncal involvement

new lesion formation.¹⁶ It has also been shown through a meta-analysis by Wood et al. that acyclovir was superior to placebo in inducing resolution of moderate to severe zoster-associated pain. The patients experienced pain-free periods starting at 28 days compared to 32 days and were free of pain in 28 days compared to 67 days for acyclovir and placebo, respectively.¹⁷ In a reanalysis of a prior study, Huff et al. showed that acyclovir reduces the pain in patients with chronic zoster, the median time was 20 days versus 62 days with placebo in 187 immunocompetent patients ($P=0.02$).¹⁵

Because of its bioavailability, acyclovir needs to be administered multiple times throughout the day to maintain a therapeutic serum level. Valacyclovir is the pro-drug of acyclovir and has a much better bioavailability, 3-5 times as great. It is metabolized to the active metabolite acyclovir by viral enzymes. When administered as 1g orally 3 times daily, the measured serum levels of valacyclovir are significantly higher. Beutner et al. have shown that acyclovir and valacyclovir share the same time of wound healing when either are initiated within 72 hours of lesion onset, and that valacyclovir is superior to acyclovir in accelerating the resolution of zoster-related pain (median duration of pain, 38 days vs. 51 days; $P=0.001$). They also compared two different dosages of valacyclovir compared to acyclovir in patients greater than 50 years, and confirmed that the proper dosage of valacyclovir should be 1g 3 times daily for 7 days.¹⁸

Famciclovir is dosed at 500 mg 3 times daily for 7 days. Two clinical trials were conducted that compared famciclovir (at several dosages) to either acyclovir or placebo.¹⁹⁻²⁰ In one; a multicenter study was done on 419 immunocompetent adults with uncomplicated herpes zoster. Famciclovir was well tolerated with a safety profile similar to that of placebo. Lesion healing was accelerated and duration of viral shedding was reduced. Patients also experience a two-fold decrease in the duration of post-herpetic neuralgia when compared to placebo recipients. Famciclovir was given in both 500 mg and 750 mg TID for 7 days.²⁰

Tyring et al. compared valacyclovir to famciclovir in a head-to-head randomized-controlled trial. The two proved to be equally effective in accelerating cutaneous wound healing and initiating pain resolution. These two newer antiviral medications are advantageous to the patient over acyclovir because of their ease of administration (being 3 times a day compared to 5 times a day).²¹ See Table 24-2 for dosage schedules for the antiviral medications FDA-approved for herpes zoster.

Three meta-analyses^{17,22-23} and several randomized-controlled trials^{15,18-20,24-26} have demonstrated the effectiveness that antiviral therapy has in reducing the duration and incidence of prolonged pain in patients with herpes zoster.

Orally administered acyclovir, famciclovir, and valacyclovir have been shown to be well tolerated and safe. The most commonly experienced side effects include nausea

TABLE 24-2—Systemic Oral Antiviral Medications for the Treatment of Herpes Zoster in Adults (>18y)

Medication	Recommended Dosage	Duration of treatment, days
Acyclovir	800 mg 5x daily	7
Valacyclovir	1000 mg 3x daily	7
Famciclovir	500 mg 3x daily	7

and headaches (10-20% of patients), but at a rate comparable to placebo.^{18,20,25}

Several studies have also been done to see whether extending the treatment period beyond the recommended 7 days would be beneficial in the treatment of herpes zoster. These studies showed that there may be minimal benefit from the added treatment time, but not significant enough to recommend any further extension of treatment duration. Certain circumstances may lead the clinician to consider extending the treatment beyond 7 days. These may include (but not limited to) persistent vesicle formation, persistent pain, or involvement of the skin, muscles, and eyes that persists beyond the 7 days.^{18,27}

These studies have all shown that when any of the above-mentioned antiviral medications are administered orally within 72 hours of a herpes zoster outbreak, there is a significant reduction in the duration of viral shedding, new lesion formation, and an acceleration of rash healing. They also reduce the duration and severity of the associated pain if administered acutely.

Supplementation with analgesic pain medications is often desired by patients because of their desire to be free of pain. The selection of pain medications may vary on a case by case basis, but the goal should be to maintain a constant level of analgesia rather than a treat as needed situation. See Table 24-3 for a summary of the recommended corticosteroid and analgesic supplementation for the treatment of herpes zoster.

TABLE 24-3—Examples of Oral Corticosteroid and Analgesic Medications Used in the Treatment of Herpes Zoster (>18y)

Medication	Recommended dosage
Oxycodone*	5-30 mg PO q4 hr PRN or 10-160 mg PO q12 hr ER tab (for opioid tolerant patients)
Gabapentin*	300-1200 mg PO TID; Max 3600 mg/day
Prednisone*	60 mg PO daily with slow taper over 21 days

*See entire monograph for each medication for full prescribing information.

Immunocompromised Patients

Patients considered to be immunocompromised are those with disorders of cell-mediated immunity, often because of systemic disease or medical intervention. These patients are at higher risk of developing herpes zoster, and if profoundly immunocompromised can develop disseminated herpes zoster and visceral organ involvement. Those who are at greatest risk of developing herpes zoster are summarized in Table 24-4.

Immunocompromised patients often experience a more dramatic and more serious herpes zoster outbreak, often being more complicated and more common when compared to immunocompetent patients. Initiation of antiviral therapy should begin within 1 week of onset and anytime before full crusting of lesions has occurred. Oral therapy with acyclovir, valacyclovir, or famciclovir can be used in most patients with localized disease and with close clinical observation. Intravenous acyclovir therapy is reserved for those with disseminated disease, those with ophthalmic involvement, severe immunosuppression, and those who are unable to take oral medications. Foscarnet is the drug of choice for the treatment of acyclovir-resistant herpes zoster.²⁸

The recommended dose for intravenous acyclovir in patients with suspected visceral dissemination is 10 mg/kg (or 500 mg/m²) every 8 hours. Once the infection improves and is under control, intravenous therapy can be discontinued and oral therapy initiated.²⁹

For patients who are not as severely immunocompromised, it has been recommended that oral antiviral therapy be initiated with close clinical observation at the same dosages of acyclovir, famciclovir and valacyclovir that are recommended for immunocompetent patients. Famciclovir and valacyclovir may prove more advantageous for this patient population for their bioavailability and ease of administration. It is also recommended that any patient with ocular involvement be evaluated by an ophthalmologist as well as receive intravenous acyclovir, even if it is greater than 72 hours after rash onset.³⁰⁻³¹

Valacyclovir was studied in a randomized, double-blind, controlled trial comparing two dosage regimens and their outcomes in immunocompromised patients: 1g TID versus

2g TID. The results showed no distinct difference in the time to full crusting of the rash, and both dosing schedules were well tolerated, and safe.³² HIV-infected patients have a higher risk of relapsing infection, therefore they should be treated until all lesions have healed, which is often longer than the standard 7-10 day course.¹³ The use of adjunctive corticosteroids in HIV-infected patients has not been studied and thus not recommended until future studies are performed and prove their usefulness.¹³

Atypical presentations or nonresponsive therapies in immunocompromised patients should raise the suspicion of acyclovir-resistant VZV. This resistant virus has a mutation in the gene encoding the viral thymidine kinase, and as a result, the medications used are not activated and therefore are ineffective. Foscarnet or cidofovir may be needed in these patients.¹³

TREATMENT FOR CHILDREN 0-18 YEARS

Primary infection with the VZV virus results in varicella, commonly known as chickenpox. After the primary infection, the virus establishes a latency period in which it will reside in the dorsal sensory ganglia or the cranial nerve ganglia. Reactivation of the virus results in what is commonly known as shingles or zoster. For every 1000 children who present to the pediatrician, one may present with herpes zoster thus making this condition fairly uncommon in children.

Immunocompetent

A prospective cohort study followed 118 immunocompetent pediatric patients with herpes zoster for a period of 6 years to evaluate the long-term sequelae of childhood zoster. After the initial outbreak, patients were evaluated at 1, 3, 6 and 12 months for any residual pain, and again at 3 and 6 years for evaluation of general health. None of the study participants were treated with systemic antiviral therapy. At 3 months, none of the patients reported post-herpetic pain and all continued to be asymptomatic throughout the remainder of the study. From this article, it can be concluded that the likelihood of a healthy pediatric patient developing postherpetic neuralgia is negligible; suggesting that treatment for immunocompetent children with herpes zoster is possibly unnecessary.³³

Feder et al. presented five cases in which immunocompetent children between the ages of 3 and 8 years developed herpes zoster. Based on the presentation and outcome of each patient, the authors concluded that herpes zoster is a rare occurrence in healthy children and is usually a self-limiting condition that does not require treatment. However, ophthalmic involvement of herpes zoster or considerable pain and rash upon presentation are two exceptions in which antiviral therapy of zoster is indicated. Antiviral drugs commonly used against herpes zoster are acyclovir, valacyclovir, and famciclovir.³⁴

TABLE 24-4—At Risk Populations for Developing Herpes Zoster¹

Patients with:	
Lymphoproliferative disorders	
Organ transplant recipients	
AIDS	
Patients receiving:	
Systemic corticosteroid therapy	
Other immunosuppressive medications	

Since all antiviral medications have been shown to be more or less equal in terms of efficacy, the selection of an antiviral agent is often dictated by other factors. For example, acyclovir has relatively poor bioavailability, necessitating frequent dosing and making it less ideal for a patient with poor compliance. Since valacyclovir and famciclovir have excellent absorption and bioavailability, these drugs can be conveniently dosed at less frequent intervals. However, both drugs are only available in oral form, while acyclovir can be administered both orally and intravenously. Thus, a young child or infant who cannot swallow pills is not a candidate for treatment with valacyclovir or famciclovir, and intravenous administration of acyclovir would be preferred in this situation. Cost is also another factor that may influence drug selection; generic acyclovir remains the least expensive treatment among the antiviral medications.³⁵

Immunocompromised

In immunocompromised children, intravenous acyclovir has remained a mainstay of treatment. Small case series have shown effectiveness of oral acyclovir and valacyclovir in immunosuppressed patients; however no official dosing regimen has been established.²⁴

Bomgaars et al. looked at the safety of valacyclovir in immunocompromised children with concurrent herpes zoster infections. Results showed that oral valacyclovir was a safe drug with minimal side effects and authors suggest the use of valacyclovir in the treatment of immunosuppressed pediatric patients with zoster.³⁶

Tyring et al, in a randomized, double-blind, multicenter, acyclovir-controlled study, evaluated the efficacy and safety of famciclovir in immunocompromised patients over the age of 12. Oral famciclovir was dosed at 500 mg 3 times daily, and acyclovir was dosed at 800 mg 5 times daily, each for 10 days following bone marrow solid organ transplantation or chemotherapy. The results of this study revealed that acyclovir and famciclovir were equivocal in terms of pain and length of disease.³⁷

POSTHERPETIC NEURALGIA (PHN)

Post herpetic neuralgia has been defined as persistent pain after an episode of herpes zoster. It is the most frequent complication of herpes zoster. The specific time frame warranting a diagnosis of PHN has been arbitrary ranging from 30-120 days after the resolution of the rash of herpes zoster.³⁸

What are the risk factors for developing PHN?

Older age has long been established as a risk factor for developing PHN. More recent studies have established

additional risk factors including: severe acute pain, severe rash, prodrome preceding the rash. Female sex has been shown to be a risk factor in some studies, but inconsistently reported as a risk factor in others.³⁸

Do corticosteroids have a role in prevention of PHN?

Corticosteroids have historically been advocated in treatment of herpes zoster and prevention of PHN. The adoption of glucocorticoids as being a standard modality for the prevention of PHN was largely based on studies done in the 1950-1980s. These studies were done on small sample sizes (4-40 pts), had inadequate use of controls, and often arbitrary definitions of PHN.⁵⁷⁻⁶⁰

More recent studies, done on larger sample sizes, have demonstrated that corticosteroids do not reduce the incidence of PHN. A randomized double blind, placebo-controlled study evaluated 208 immunocompetent patients 50 years and older. The patients were divided into four groups: acyclovir (800 mg daily 5x/day x 21 days) + prednisone (60 mg/d x 7 days, 30 mg/d x 7 days, 15 mg/d x 7 days); acyclovir + prednisone placebo; prednisone + acyclovir placebo; and acyclovir placebo + prednisone placebo. The group receiving acyclovir + prednisone showed accelerated time to: crusting/healing of the rash, resolution of acute neuritis, return to uninterrupted sleep, return to ADLs, and cessation of analgesic medications. The acyclovir + prednisone group failed to show statistical difference in rates of persistent pain in a 6 month follow-up period. It was concluded that corticosteroids, when used in treatment of herpes zoster, have a role in improving quality of life, but no role in prevention of PHN.³⁹ Another large double blind, controlled trial of 349 patients, confirmed the lack of efficacy of glucocorticoids in the prevention and severity of PHN.⁴⁰ The results of these two studies have been supported by other smaller scale trials.⁶¹⁻⁶⁴

In conclusion, the majority of these studies support the idea that glucocorticoids do not decrease the incidence or severity of PHN. Treatment with glucocorticoids does lead to faster time to rash healing and greater pain reduction during the acute phase of herpes zoster. GC should not be considered standard of care in the treatment of herpes zoster. The risk to benefit ratio must be weighed before using glucocorticoids in the treatment of herpes zoster.

Is gabapentin effective as a first line agent in treatment of PHN?

The mechanism of gabapentin in the treatment of neuropathic pain is unclear, but potentially related to modulation of calcium channels. Chronic neuropathic pain is in part mediated by calcium channels in the spinal cord. Gabapentin modulates these channels. A multicenter, randomized, double-blind, placebo-controlled 8-week

trial showed that gabapentin is effective in treating pain and sleep disturbance associated with PHN. Two hundred and twenty-nine patients were randomized to placebo and gabapentin-treated groups. In the gabapentin group, a 300 mg/d starting dose was initiated. Over a 4 week period, this dose was titrated up to a maximum dose of 3600 mg/d (divided over three doses). The maximum dose was then maintained for another 4 week period. Subjects in the gabapentin group had a statistically significant reduction in daily pain scores from 6.3 to 4.2 points. The placebo group showed only a 6.5 to 6 point reduction. There were no major adverse side effects of gabapentin. Minor side effects included somnolence, dizziness, ataxia, peripheral edema, and infection. Somnolence and dizziness were the most frequently reported side effects, 27.4% and 23.9% respectively. There was no difference in the frequency of side effects reported in the elderly subjects compared with the younger ones. This study concluded that gabapentin should be included as a first line agent for treatment of PHN, because of its statistically significant pain reduction and minor side effect profile.⁴¹

Regarding effective dosing of gabapentin, a large multicenter, randomized, double-blind, 7 week clinical trial compared gabapentin 1,800 mg/day, 2,400 mg/day, and placebo. Doses were tapered up then maintained for 4 weeks. In the gabapentin group, 74/223 reported at least 50% reduction in pain compared to 16/111 in the placebo. No difference in pain reduction was found between the two doses of Gabapentin.⁴²

Pregabalin has also been shown to be effective in the treatment of PHN. In a randomized, placebo-controlled trial, 173 patients were evaluated over 8 weeks. Pregabalin was dosed at 50 mg TID x 3 days, then 100 mg TID x 3 days, and then 200 mg TID for the remainder of the trial. In the group treated with pregabalin, a 30% or more reduction in pain was reported by 63% compared to 25% in placebo ($p=.001$). A 50% or greater pain reduction was reported in 50% of pregabalin subjects versus 20% of placebo ($p=.001$). Overall sleep interference scores were also improved in the pregabalin group ($p=.0001$). Side effect profile was similar to gabapentin, with dizziness and somnolence occurring most frequently.⁴³

Does antiviral treatment prevent post herpetic neuralgia?

A randomized, double blind, multicenter study compared valacyclovir 1,000 mg tid for 7 or 14 days and acyclovir 800 mg 5x/day for 7 days. Total number of patients enrolled was 1,141. The patients were evaluated over a 6 month period. Valacyclovir treatment for 7 and 14 days was shown to have a shorter duration of PHN-associated pain ($p=.001$ and $p=.03$ respectively) when compared to the acyclovir group. The median time to resolution of pain in the valacyclovir 7- and 14-day groups was 38 and 44 days

respectively, compared to 51 days in the acyclovir group. Results showed that valacyclovir demonstrates a 34% faster resolution in pain when compared to acyclovir. The study concluded that valacyclovir accelerates the cessation of PHN-associated pain, decreases the proportion of patients with pain lasting at least 6 months, and had a similar safety profile compared to acyclovir. There was no statistical significance in incidence of PHN between the valacyclovir and acyclovir groups.⁴⁴

Another randomized, double blind, placebo-controlled trial evaluated the effects of famciclovir on PHN. A total of 419 patients were randomized to three groups: famciclovir, 500 mg tid, famciclovir 750 mg tid, or placebo for 7 days. Both famciclovir 500 mg and 750 mg were shown to have more rapid resolution of pain that was statistically significant, when compared to placebo ($p=.02$ and $p=.01$ respectively). There was an approximately 2 month reduction in the duration of PHN. It was concluded that famciclovir was effective in reducing the duration of PHN, but showed no statistical difference in the incidence of PHN.²⁰

Other placebo-controlled, randomized-controlled trials have also been unable to provide convincing evidence that antivirals have a significant effect on the incidence of PHN.⁶⁵⁻⁶⁶

A Cochrane Database Systemic Review investigated the efficacy of antivirals in the prevention of PHN. Five different databases were searched, years ranging from 1966 to 2009. Selection criteria included all randomized and quasi-randomized controlled trials in which antivirals were given within 72 hours of the onset of rash associated with herpes zoster. Six trials with a total of 1211 subjects were evaluated. One trial evaluated famciclovir and the other five acyclovir. Results showed no statistically significant difference in the incidence of PHN occurring in placebo and acyclovir treated patients at 4 months or 6 months after rash onset ($p=.15$ and $p=.62$ respectively). They did show some reduction in the duration of PHN-associated pain. The famciclovir group also did not show decreased incidence of PHN that was statistically significant. The review concluded that acyclovir does not significantly reduce the incidence of PHN and that there are insufficient trials to determine if the other antivirals have a role in prevention of PHN.⁴⁵

Are TCAs or opioids more effective in the treatment of PHN?

Tricyclic antidepressants and opioid analgesics have been widely used as a first line treatment for postherpetic neuralgia.⁴⁶ A double-blind placebo-controlled, crossover trial evaluated opioids, TCA, and placebo in 76 patients with postherpetic neuralgia. The patient population was older than 18 years of age and neuropathic pain had been persistent for at least three months after healing of the rash of herpes zoster. Each patient underwent three different treatment periods, each a total of 8 weeks duration. The three

treatment periods included controlled release morphine sulfate (mean daily maintenance dose 91 mg), nortriptyline (89 mg), and placebo. If the patients could not tolerate either the morphine or nortriptyline, methadone 15 mg and/or desipramine 63 mg were substituted respectively. There was a 1 week wash-out period between each set of treatments. Each study drug was started at low doses and titrated up biw until the patients experienced dose-limiting side effects or maximal relief of their pain.

The study concluded that both opioids and TCAs had statistically significant pain relief when compared to placebo. On a scale of 1-10, mean decrease in pain with TCAs and opioids were 1.4 and 1.9 respectively. Placebo demonstrated only a .2 reduction in pain. The increased pain reduction in the opioids compared to TCAs was not statistically significant ($p=.06$). Despite the higher incidence of side effects including nausea, constipation, drowsiness and dizziness, 53% of the patients preferred opioids over TCAs (30%; $p=.02$). The study concluded that although opioids had more favorable pain control trends when compared to TCAs, it is premature to say that opioids should be first line in place of TCAs in the treatment of PHN. It was suggested that tolerance could be a factor in determining long-term clinical usefulness of opioids in the treatment of PHN. The observation period in this study was only 8 weeks and the authors concluded that further long-term studies are needed to more adequately address the issue of tolerance with chronic treatment.⁴⁷

Is nortriptyline superior to amitriptyline in the treatment of PHN?

Amitriptyline (AT) has been widely used a standard therapy in treatment of PHN. Many trials have shown amitriptyline to have significant effect in pain relief of PHN when compared to placebo.⁶⁷⁻⁶⁸ The downside of treatment with amitriptyline is dose-limiting side effects such as dry eyes, dry mouth, constipation, dizziness, and drowsiness.⁴⁸ Nortriptyline (NT) is a metabolite of amitriptyline that has a much more favorable side effect profile. In a randomized, double-blind, crossover trial of amitriptyline compared to nortriptyline, it was hypothesized that NT may be more effective than AT in treatment of PHN. The study enrolled 33 patients who had moderate to severe pain of more than 3 months (with a median of 13 months) after an outbreak of herpes zoster. A total of 31 patients completed the trial. Each patient was treated by a 5 week course of AT followed by 5 weeks of NT with a 2 week wash-out period in between. Dosing was started at 10 mg for patients >65 years and 20 mg for those <65 years. Doses were titrated up by 10 mg every 3-5 days as tolerated, based on adverse side effects. A steady maintenance dose was achieved for the last 2 weeks of treatment. There was no statistically significant difference in pain reduction between AT and NT. AT was shown to have an increased number of intolerable side

effects when compared to NT ($p=.05$). Dry mouth, constipation, and drowsiness were the most common side effects. The study concluded that NT did not demonstrate statistically significant pain reduction when compared to AT in the treatment of PHN. Based on this study, NT would be superior to AT in regards to its side-effect profile, but not in pain reduction.⁴⁹

What role do topical medications have in the treatment of PHN?

Topical lidocaine and capsaicin have been among the most commonly used and well studied topical treatments for PHN. There have been multiple studies demonstrating efficacy of capsaicin cream (025%-075%) in the treatment of PHN.⁶⁹⁻⁷⁰ The cream must be applied multiple times per day for weeks at a time to achieve significant pain relief. Adverse effects such as burning, stinging, and erythema at application site can be unbearable in many patients limiting their use.⁶⁹⁻⁷⁰ A recent randomized, double-blind study evaluated the efficacy of a one-time application of high concentration capsaicin patch (8%), called NGX-4010. The goal of the study was to evaluate efficacy, tolerability and safety of high concentration capsaicin as a treatment for PHN. Four hundred and two patients, experiencing post herpetic pain for at least 6 months, were randomized to either the NGX-4010 group (8% capsaicin), or the control group receiving low-dose capsaicin patch (.04%). The capsaicin patches were applied once for 60 minutes duration. The patients were followed for an 8-12 week period, after the single patch application, to evaluate pain response. Change in the NPRS score (0-10 scale of pain scoring) from baseline was evaluated. Patients in the NGX-4010 group had statistically greater decrease in pain, at weeks 2 and 8, when compared to the control group. For the NGX-4010 group, the mean change in NPRS score was 29.6% compared to 19.9% in the placebo group ($p=.001$). Side effects in the NGX-4010 group such as erythema and pain at application site were common, but mild and self limited. The study concluded that one 60-minute application of high concentration 8% capsaicin patch, NGX-4010, can significantly reduce the pain of PHN for up to 12 weeks after the single application. Side effects are mild and self limited at the site of application. There are no adverse systemic side effects related to treatment with the patch.⁵⁰

Topical lidocaine 5% patch was approved by the FDA in 1999 as the first medically indicated treatment for PHN. There have been many studies reporting its efficacy in PHN-associated pain reduction.⁷¹⁻⁷² A randomized, double-blind, vehicle controlled study evaluated efficacy of lidocaine 5% patch in reduction of neuropathic pain. Ninety-six patients reported to have moderate to severe PHN-associated pain were evaluated. Pain was evaluated using the neuropathic pain scale (NPS) which includes ten different pain descriptors. Pain was evaluated at baseline

then re-evaluated after daily lidocaine 5% patch use for 3 weeks. Those in the lidocaine patch group were shown to have a decrease in NPS from baseline of 51.7 to a score of 36.4 at 3 weeks. Those in the vehicle group had an initial NPS score of 53.8 dropping to 46.1 at 3 weeks. Lidocaine patch was shown to have a statistically significant overall pain reduction when compared to the vehicle ($p=.043$).⁵¹

Is there a future for botox in the treatment of PHN?

Botulinum A toxin has been used in the treatment of many neurologic diseases including tics, migraines, and cervical dystonia. There have recently been many case reports documenting its efficacy in treatment of neuropathic pain, but is not yet a well studied treatment option and therefore not a standard of care.⁷³⁻⁷⁴ One case reported efficacy of botox in an 80-year-old male with PHN. The patient had been treated with TCAs, gabapentin, and carbamazepine without improvement of his pain. Pain reduction was finally achieved with increased doses of TCAs, gabapentin, and addition of morphine. The patient subsequently developed severe delirium and had to stop all oral medications. The patient was then treated with a thoracic epidural of 1 ug/mL of fentanyl in .25% bupivacaine infused at 5 mL/hr. The patient still experienced severe and persistent pain. A trial of BTX-A was used for the recalcitrant PHN associated pain. A total of 100 units of BTX-A were injected in a fanning pattern in the subcutaneous plane. A 23-gauge needle was used at four different sites in the area of pain. At each of the four sites, 20 routes of injection were done in a fanning pattern. Five units of BTX-A per route were injected at each of the four sites. Two days after the injection, pain was reduced from a 10 down to a 1 on the VAS (visual analog score). The pain relief lasted for a total of 52 days. The pain returned after this 52-day period.⁵²

In conclusion, BTX-A may be an emerging therapeutic option in treatment of PHN, but controlled studies will be necessary to further evaluate BTX-A in treatment of PHN.

ZOSTER VACCINE LIVE (ZOSTAVAX)

In 2006, US Food and Drug Administration approved Zoster Vaccine Alive (Zostavax) for the prevention of HZ in immunocompetent adults age 60 and over. The approval was based on the results of multicenter clinical trial, the Shingles Prevention Study. This study showed the vaccine significantly decreased incidence of shingles, burden of illness because of disease, and the development of as well as severity of, postherpetic neuralgia.⁵³

In a randomized, double blind, placebo-controlled trial with 38,546 patients greater than 60 years of age, the vaccine decreased number of illness because of HZ by 61.1% ($p < .001$), decreased the incidence of postherpetic

neuralgia by 66.5% ($p < .001$) and decreased incidence of HZ by 51.3% ($p < .001$).⁵⁴

The study had 95% of subjects continued to completion, with a median of 3.12 years of surveillance for HZ. A total of 957 cases of HZ (315 among vaccine recipients and 642 among placebo recipients) and 107 cases of PHN (27 among vaccine recipients and 80 among placebo recipients) were included in the efficacy analysis. The conclusion was the zoster vaccine markedly reduced morbidity from HZ and PHN among older adults.⁵⁵

RISK OF HZ IN PATIENTS ON ANTI-TNF ALPHA AGENTS (ANTI-TNF A)

These new agents are approved for rheumatoid arthritis, JIA (juvenile idiopathic arthritis), psoriatic arthritis, ankylosing spondylitis, and Crohn's CUC and little is known about the reactivation of latent viral infections.

Are Patients undergoing treatment with anti-TNF α agents at increase risk for developing herpes zoster?

Patients undergoing treatment with anti-TNF α inhibitors have been well known to be at increased risk for bacterial and opportunistic infections. Not much is known about the risk of viral infections or reactivation of latent viral infections associated with anti-TNF therapy. A recent prospective cohort investigated this idea in a population of RA patients undergoing treatment either DMARDs or one of the anti-TNF α inhibitors, including the anti-TNF α antibodies (adalimumab, infliximab) and etanercept. A total of 5040 patients were followed prospectively from 2001 to 2006. There were 86 cases of zoster reported in 82 patients. Thirty-nine of the cases were in those treated with anti-TNF α monoclonal antibodies (adalimumab and infliximab), 23 in etanercept and 24 in those treated with DMARDs. For the monoclonal antibodies, the crude incidence rate per 1000 patient-years was 11.1 (95% confidence interval, 7.9-15.1), for etanercept 8.9 (95% CI, 5.6-13.3), and for the DMARDs 5.6 (95% CI, 3.6-8.3). After adjusting for variables such as RA severity, age, and glucocorticoid use, there was an increased risk of herpes zoster in the anti-TNF α anti-body group (HR, 1.82 [95% CI, 1.05-3.15]). However, this increased risk was not high enough to be clinically significant. There was no significant increase in the etanercept group (HR, 1.63 [95% CI, 0.73-2.55]) or for anti-TNF α therapy when considered as a class (HR, 1.63 [95% CI, 0.97-2.74]). This study concluded that there may be an increase risk of herpes zoster in patients treated with anti-TNF α antibodies such as adalimumab or infliximab, but the anti-TNF α drugs as a whole do not demonstrate statistically significant increased risk of herpes zoster.⁵⁶ There have been other RCTs that have documented an increase incidence of herpes zoster in patients treated with

What We Know

- Varicella zoster virus is the causal agent of varicella and herpes zoster in humans. HZ results from reactivation of latent varicella zoster virus within the sensory ganglia. It has worldwide distribution and greater than 98% of adult population is seropositive. A frequent and often very debilitating complication is PNH, a pain syndrome that develops while on, or can present after the dermatomal rash has healed and can be prolonged and greatly affect the quality of life.
- The zoster vaccine live (Zostavax) markedly reduces morbidity from HZ and PHN among adults greater than 60 years of age.
- Glucocorticoids do not decrease the incidence or severity of PHN. Acyclovir does not significantly reduce the incidence of PHN. Nortriptyline is superior to amitriptyline in regards to its side effect profile, but it does not show increased pain reduction in the treatment of post-herpetic neuralgia.

infliximab or adalimumab⁷⁵), but further RCT must be done to further evaluate the clinical significance of these findings.

Treatment of Impetigo

25

Brian B. Adams, M.D., M.P.H.

INTRODUCTION

Impetigo contagiosum, spread by skin-to-skin contact, as well as through fomites, represents a superficial cutaneous bacterial infection. *Staphylococcus aureus* and much less commonly *Streptococcus pyogenes* cause impetigo.

EPIDEMIOLOGY

Impetigo commonly affects children and athletes with intense skin-to-skin contact or extensive exposure to colonized environments or fomites. Recent studies document the routine presence of *Staphylococcus aureus* on the surfaces of sports-related areas.^{1,2} For instance, in one study, investigators sampled for the presence of methicillin-resistant *Staphylococcus aureus* (MRSA) at nine Ohio high school wrestling and healthcare facilities.² All sites had MRSA; and nearly 90% of the tested surfaces of inner and outer circles of the wrestling mats demonstrated MRSA. Locker room benches (78%) also frequently possessed MRSA. Just over 50% of sampled treatment tables and locker room sinks had MRSA. Even the athletic training room doorknob demonstrated MRSA in 20% of the swabs.

A similar study, in the same area of the country, examining the environment of the athlete, discovered that 90% of athletic facilities possessed two or more positive MRSA surfaces.¹ In this study, the water coolers possessed the highest occurrence of MRSA (80%). Like the other study, locker room sinks and treatment tables demonstrated MRSA in 50-70% of the samples. These studies illustrate the prevalence of MRSA in the athletic environment and may explain, in part, the epidemics of impetigo observed in athletes.

ETIOLOGY AND DIAGNOSIS

Both methicillin resistant and methicillin sensitive variants of *Staphylococcus aureus* exist. This chapter extensively reviews the treatment of impetigo contagiosum and will only briefly discuss diagnostic aspects. Impetigo may occur as a primary infection, by affecting otherwise healthy skin, but also may complicate previously diseased skin. Dermatitis, such as atopic dermatitis and venous stasis dermatitis can commonly develop secondary impetiginization as these gram-positive organisms infect the perturbed epidermis.

Impetigo, in its mature presentation, appears as well defined, erythematous, and often honey-colored crusted, scaling papules and plaques. In athletes, these lesions especially occur in areas of skin-to-skin contact. The differential diagnosis of typical mature impetigo includes crusted and exudative dermatitis, lupus erythematosus, tinea corporis, and crusted herpes virus infection. The lack of characteristic findings of honey colored crust, in the early stages of disease, makes the diagnosis challenging. For instance, for reasons related to disqualification from competition, athletes present to the clinician soon after the development of nonspecific erythematous papules. Based solely on the clinical morphology of these very early lesions, the clinician will find it extremely difficult to distinguish acne, dermatitis, lupus erythematosus, and other infections such as tinea corporis and herpes simplex virus infection. As the lesions age, they acquire morphologic features that help the clinician differentiate among these cutaneous disorders.

Rarely, a bullous variety of impetigo occurs; the differential diagnosis of this variant includes bullous arthropod reaction and immunobullous disorders.

THERAPEUTIC APPROACH

Studies have not investigated the usefulness or optimal frequency and duration of nonpharmacologic approaches to impetigo. However, infected individuals should apply warm and moist compresses to the affected area several times per day for five to 10 minutes each time. Furthermore, individuals who develop impetigo should cover the area to prevent the spread to other individuals.

The main pharmacologic treatments for impetigo include topical and oral antibiotics. Many studies have studied the effectiveness of each against placebo and even against each other. A lack of information exists wherein studies compare a combination of topical and oral agents versus a single route of administration.

In the past decade, two large meta-analyses examined the treatment of impetigo. George and Rubin published a systematic review of the treatments for impetigo in 2003.³ Three hundred and fifty-nine studies fulfilled their criteria. They narrowed their search to include double-blind or observer-blind randomized control trials and to exclude non-English studies and those studies lacking in other specific data. Additionally, the authors also

wrote to pharmaceutical companies but did not detect any other relevant studies. Ultimately, only 16 studies from 1966–2002 satisfied their criteria for inclusion in their meta-analysis. The methodologies of these sixteen studies varied on several elements including subject age, comparative medications, duration of treatment, and time of assessment.

Seven studies treated infected individuals for 7 days,^{4–10} four studies treated infected subjects for 10 days,^{11–14} and three reports treated subjects for 14 days.^{15–17} One study treated subjects until clearance¹⁸ and one study only treated patients for 6 days.¹⁹

The four broad comparative groups among these studies included oral therapies compared to each other, topical antibiotics versus placebo, topical antibiotics against each other, and topical antibiotics compared to oral antibiotics. This meta-analysis only included two studies comparing only oral antibiotics in the treatment of impetigo. Demidovich et al.¹³ compared penicillin V, cephalexin, and erythromycin, while Jaffe et al.¹¹ compared amoxicillin and clavulanic acid with cefaclor. Three studies studied topical antibiotics versus placebo. Eells et al.⁵ Koning et al. 2002,¹⁷ and Zaynoun 1974⁴ studied topical 2% mupirocin, 2% fusidic acid cream, or gentamycin versus placebo, respectively.

Also in this meta-analysis, seven included studies evaluated head-to-head topical antibiotics; 2% mupirocin ointment versus 2% fusidic acid represented the most common comparison.^{6–8,10,15,16,18} The last comparative group investigated various oral antibiotics against various topical antibiotics. These investigators compared oral erythromycin (taken three to four times daily) or cephalexin to topical bacitracin or 2% mupirocin.^{9,12,14,19}

Overall, in this particular meta-analysis, topical antibiotics demonstrated a greater response in impetigo than placebo with an odds ratio of 2.69 and a 95% confidence interval of 1.49–4.86.³ No differences existed between topical 2% mupirocin ointment and 2% fusidic acid with an odds ratio of 1.76 and a confidence interval that included one [95% CI = 0.77–4.03]. While the pooled data

comparison between oral erythromycin and topical 2% mupirocin ointment or bacitracin revealed an odds ratio of 0.48, suggesting that topical antibiotics represented a superior therapy, the confidence interval included one [95% CI = 0.23–1.00]. The authors of this meta-analysis did not calculate a pooled odds-ratio for the two studies comparing oral antibiotics.³

This meta-analysis appropriately identified important limitations of their work. The outcome measures, specifically cure, varied among the studies. The duration also varied among the studies, though the authors suggest 7 days represents effective treatment duration. Last, most of the studies included in this meta-analysis involved very small numbers. The largest study of impetigo treatment involved 201 subjects; the median number of subjects in the 16 trials was only 60.

In summary, very few high-quality studies exist that critically compare topical antibiotics to other topical antibiotics or oral antibiotics. George and Rubin's meta-analysis nevertheless revealed that topical antibiotics clear impetigo significantly better than placebo and at least as well as oral erythromycin (Table 25-1).³

A larger meta-analysis searched several electronic databases as well as hand searched several references dating back to 1938.²⁰ The authors placed no restrictions on study language and they contacted pharmaceutical companies for data on unpublished or ongoing studies. The investigators included both bullous and nonbullous impetigo in their analysis. The authors identified fifty-seven trials that met their inclusion criteria that amounted to an overall total of 3533 subjects.

Interestingly the only study included in this systematic review, which compared oral antibiotics to placebo, found no statistical difference in the effect between oral penicillin and placebo in the treatment of impetigo.²¹ The pooled analyses of all studies comparing cephalosporins to other oral antibiotics revealed no statistical differences (odds-ratio = 1.67, 95% CI=0.93–3.00), while no cephalosporin performed better than another cephalosporin antibiotic in the treatment of impetigo (odds-ratio = 0.56,

TABLE 25-1—Summary of the Current Evidence for Impetigo

	Bacitracin	Mupirocin	Fusidic Acid	Rapamulin	Oral Antibiotics
Bacitracin					
Mupirocin	Mupirocin ++				
Fusidic Acid	Equivocal	Equivocal			
Rapamulin	No studies	No studies	Equivocal		
Oral Antibiotics	Unclear	Mupirocin ++	Fusidic Acid ++	No studies	
Placebo	Bacitracin +	Mupirocin +++	Fusidic Acid +++	Rapamulin +++	Unclear

+, weak evidence in favor of the medication

++, moderate evidence in favor of the medication

+++, strong evidence in favor of the medication

95% CI=0.24-1.31).²⁰ Furthermore, in their meta-analysis, no oral macrolides performed better than penicillin and its variants (odds-ratio = 1.99, 95% CI=0.92-4.34).²⁰ In summary, pooled analysis cast doubt on the superiority of any one oral antibiotic for treating impetigo.

Five studies examined topical antibiotics versus placebo in nonbullous impetigo; three additional reports, not included by George and Rubin³, studied specifically 2% mupirocin^{22,23} or bacitracin versus placebo.²¹ Unlike George and Rubin³, Koning et al.²⁰ did not include topical gentamycin compared to placebo in the analysis. Overall analysis revealed that topical antibiotics led to better improvement and cure rates than placebo with an odds-ratio of 6.49 (95% CI= 3.93-10.73).²⁰ Bacitracin failed to demonstrate superiority over placebo in one trial, although this study had limited enrollment and a large confidence interval.²¹

The authors included twelve studies examining the effect of topical antibiotics against each other. None of the individual studies demonstrated the success of one topical antibiotic over another. The overall analysis demonstrated an odds-ratio of 1.56 (95% CI= 1.09-2.24).²⁰ Many of the studies that did not show a significant difference between topical antibiotics had very small numbers eliciting a potential question of inadequate power to detect a difference.

The largest group of studies analyzed in this review involved topical antibiotics compared to oral antibiotics. Ten studies, comparing 2% mupirocin with erythromycin noted significantly better cure or improvement with 2% mupirocin (odds-ratio 1.76, 95% CI =1.05-2.97).²⁰ The authors also sub-pooled the three highest quality studies^{9,12,24} of these 10 reports and documented an odds-ratio of 3.73 (95% CI=1.35-10.34) strongly in favor of 2% mupirocin.²⁰ Other trials examined 2% mupirocin versus dicloxacillin,²⁵ cephalexin¹⁴, and ampicillin²⁶ and discovered no statistical difference between the groups. When the investigators included all studies that met their criteria, topical antibiotics (including bacitracin, fusidic acid, and 2% mupirocin), in general, possessed a slightly greater effect on impetigo than oral antibiotics with an odds-ratio of 1.6 (95% CI =1.12-2.29).²⁰ Many of the nonmupirocin topical antibiotics versus oral antibiotics studies yielded mixed results. For instance, no differences existed between bacitracin and erythromycin¹⁹ or penicillin,²¹ while oral cephalexin performed superiorly to bacitracin in another trial.¹⁴

Two studies examined the differences in effect between topical antibiotics and disinfecting treatments. One study found that hexachlorophene cleared impetigo no better than bacitracin (odds-ratio 3.97, 95% CI=0.15-104.18).²¹ Furthermore, another found no statistical difference between 2% fusidic acid and hydrogen peroxide;²⁷ however, a weighted summary of both studies discovered that topical antibiotics performed superiorly compared to hexachlorophene or hydrogen peroxide.²⁰

In summary, the extensive systematic review performed by Koning et al.²⁰ fails to identify a superior oral antibiotic for the treatment of impetigo. In addition, several well-designed studies note a significantly better clearance with 2% mupirocin over oral antibiotics. Mixed results exist regarding topical bacitracin as it performed as well compared to oral antibiotics in one study, and less well in another study. Likewise, topical bacitracin cleared impetigo as well as placebo in other contradictory trials (see Table 25-1).

Importantly, these two main meta-analyses did not include the first new topical antibiotic developed in many years. A recent novel FDA-approved topical antibiotic, 1% retapamulin, represents the first pleuromutilin antibacterial agent for the treatment of superficial skin infections. Two major studies have compared the effectiveness of 1% retapamulin to other topical agents in impetigo. No studies exist that compare 2% mupirocin and 1% retapamulin. Furthermore, in primary impetigo, no studies have compared the response rates of 1% retapamulin with that of oral antibiotics.

In a randomized, double-blind trial, topical 1% retapamulin achieved clinical success significantly more often than placebo and cleared both *Staphylococcus aureus* and *Streptococcus pyogenes*.²⁸ In this particular study, researchers compared 5 days of twice daily use of both agents. The investigators randomized 213 patients in a 2:1 ratio; 139 subjects applied 1% retapamulin and 71 subjects applied placebo. Eighty-six percent of the subjects treated with 1% retapamulin cleared, whereas 52% of those subjects treated with placebo cleared ($p<.0001$). The most common side effects in either treatment group were pruritus, paresthesias, and irritation.

Other investigators conducted a noninferiority study comparing 1% retapamulin to 2% sodium fusidate ointment.²⁹ This randomized, observer-blinded study found that in the intention-to-treat analysis, 1% retapamulin ointment applied twice daily for five daily had a ninety-five percent response rate, whereas 2% sodium fusidate ointment used three times daily for seven days demonstrated a 90% percent response rate. One percent retapamulin did not demonstrate superiority over 2% sodium fusidate ointment (see Table 25-1).

CONCLUSIONS

Despite the common occurrence of impetigo, few studies carefully examine the various treatment options. Meta-analysis, however, has shown that topical 2% mupirocin ointment clears impetigo at least as well as oral antibiotics. The topical application of this antibiotic also avoids the several potential side effects associated with systemic medications. The novel agent, topical 1% retapamulin, performs better than placebo; future studies need to compare this medication to topical 2% mupirocin and oral antibiotics. Furthermore, future work should also investigate the combination of topical and oral antibiotics compared to each individually.

What We Know

- Topical 2% mupirocin and 2% fusidic acid clear impetigo greater than placebo.
- No differences exist in effects between 2% mupirocin and fusidic acid.
- Topical antibiotics (2% fusidic acid or 2% mupirocin and perhaps bacitracin) clear impetigo as well as oral antibiotics and while not statistically significant, topical 2% fusidic acid and 2% mupirocin may perform better than oral agents.
- Topical 1% retapamulin performs greater than placebo, although 1% retapamulin demonstrates noninferiority to that of fusidic acid.

Treatment of Tinea Capitis

Hong-Liang Tey, M.D., and Yuin-Chew Chan, M.D.

INTRODUCTION

Tinea capitis is a dermatophytic infection of the scalp and hair. It is seen primarily in pre-adolescent children.

EPIDEMIOLOGY AND ETIOLOGY

Tinea capitis may be caused by any pathogenic dermatophyte from the genera *Trichophyton* and *Microsporum* except *T. concentricum*.¹ It has a worldwide distribution and the predominant species of dermatophyte responsible varies between different regions. In the United States, more than 95% of tinea capitis are caused by *T. tonsurans*.² In Europe, the most common pathogen is *T. tonsurans* in the United Kingdom, *Microsporum canis* in Central and Southern Europe, and *T. violaceum* in Greece and Belgium.³ *Microsporum canis* is a common organism in the developed countries worldwide and this has been attributed to tourism to endemic regions (such as the Mediterranean countries) and the close proximity between humans and companion animals.⁴ Several dermatophyte species, on the other hand, are geographically limited. *T. soudanense* is a common and endemic cause of tinea capitis in northwestern tropical Africa and West Asia.⁴

CLINICAL MANIFESTATION

Tinea capitis often presents with scaly patches on the scalp and a variable degree of inflammation. Clinical patterns include ectothrix, endothrix, favus, and kerion. Asymptomatic carriers have been found in families of up to 50% of children with tinea capitis.^{5,6}

Ectothrix

This presents as multiple circular patches of alopecia with broken-off hairs and scaling. The dermatophyte grows on the external surface of the hair, destroying the hair cuticle. Mycelium can be visualized on the external surface of the hair shaft under direct microscopy with potassium hydroxide preparation. Certain species fluorescence under Wood's light and this is because of the production of pteridine. These species include *Microsporum canis*, *M. audouinii*, *M. ferrugineum*, *M. distortum*, *M. gypseum* (sometimes), and *T. schoenleinii*. Ectothrix dermatophytes which do

not fluorescent under Wood's light include *Trichophyton rubrum*, *T. mentagrophytes*, *T. verrucosum*, *T. megninii*, *M. gypseum*, *M. nanum*. Therefore, if the infected hair of patient fluorescence under Wood's light, the infecting dermatophyte likely belongs to the *Microsporum* species.

Endothrix

The dermatophyte infects the interior of the hair shaft and under microscopy with potassium hydroxide preparation, mycelium can be seen within the hair shaft. The cuticle of the hair shaft is intact. This pattern is sometimes known as 'black dot ringworm' because remnants of broken brittle hair appear as black dots on the surface of the scalp. The infecting species include *T. rubrum*, *T. tonsurans*, *T. violaceum*, *T. soudanense*, *T. gourvillii*, and *T. yaoundei*.

Favus

This is a chronic inflammatory form of tinea capitis, which can lead to scarring alopecia. It is characterized by yellowish cup-shaped crusts (known as scutula) surrounding infected hair follicles. These crusts consist of hyphae and keratinous debris. It is primarily due to *T. schoenleinii* infection and is occasionally due to *T. violaceum* and *M. gypseum*. Hyphae and airspaces are seen within the hair shaft under direct microscopy with potassium hydroxide preparation.

Kerion

A severe acute inflammatory reaction to dermatophytic elements may result in a painful boggy mass associated with formation of pustules and regional lymphadenopathy. This may result in scarring alopecia. The most frequent pathogens are *M. canis*, *T. mentagrophytes*, *T. tonsurans*, and *T. verrucosum*.

DIAGNOSIS

The diagnosis of tinea capitis can be confirmed by microscopic examination (with potassium hydroxide preparation) and/or culture of plucked infected hair, skin scrapings, or skin swabs. Specimens for culture can be obtained with

the cotton swab technique, using the sterile swab stick transport medium set that one normally uses to perform a bacterial swab culture.⁷ The swab stick is moistened with tap water, and suspicious areas of the scalp are vigorously swabbed. The swab stick is then replaced into its container and sent to the lab for mycologic culture.

Microscopic examination with 10 to 20% potassium hydroxide preparation can provide a rapid diagnosis of tinea capitis but accurate evaluation is difficult in inexperienced hands. Culture is a better method of diagnosis for most practitioners, is more sensitive than microscopy but results may take 4 to 6 weeks. There was a recent publication on a new polymerase chain reaction-based restriction fragment length polymorphism (PCR-RFLP) method, which targets the 18S ribosomal DNA and internal transcribed spacer (ITS) region of fungi, and this allows for rapid detection and identification of dermatophyte species within 24 hours.⁸

TREATMENT

The primary aim of treatment is to achieve complete cure, clinically, and mycologically, using an agent with minimal side effects. As tinea capitis mainly affects children, besides efficacy and safety, the ease of administering the course of antifungal drug is important. A preparation with a more pleasant taste requiring a shorter duration of treatment will enhance the compliance rate of the therapy in children.

Griseofulvin is the systemic antifungal agent with the longest clinical track record. It has proven to be safe, is relatively inexpensive, comes in both tablet and suspension preparations, and is widely available. However, it has a bitter taste, has to be taken with meals, and needs to be taken for a rather long duration (usually 8 weeks).

Newer antifungal agents, such as terbinafine, itraconazole, and fluconazole, are increasingly being used because of their shorter duration of treatment, more consistent absorption rates, and longer periods of retention in infected tissues. They have also been shown to be safe in previous meta-analyses.^{9,10}

COMPARISON OF NEWER ANTI-FUNGAL AGENTS IN EFFICACY AND SAFETY TO GRISEOFULVIN IN THE TREATMENT OF TINEA CAPITIS

Methods

Inclusion Criteria and Outcome

Only randomized controlled trials (RCTs) comparing different systemic antifungal drugs for the treatment of tinea capitis were included. The subjects were children and adults with normal immunity with the diagnosis of tinea capitis confirmed by the presence of dermatophytes under microscopy and/or culture.

The primary outcome measure was the complete cure rate. Complete cure was defined as achieving both clinical and mycologic cure. The secondary outcome measures were:

- Mycologic cure rate (mycologic cure referred to negative results on microscopy and culture).
- Clinical cure rate (clinical cure referred to the resolution of clinical symptoms and signs)
- Severity and frequency of adverse effects.

Search methodology

A search of the MEDLINE, EMBASE, Cochrane Central Register of Clinical Trials, and the Cochrane Skin Group Ongoing Skin Trials Register was performed in October 2009 using the terms 'tinea capitis', 'griseofulvin', 'terbinafine', 'itraconazole', 'fluconazole', and 'ketoconazole'.

Data Collection

The titles and abstracts of all retrieved articles were screened with the inclusion criteria by two reviewers (Tey and Chan). For abstracts in which the study design was unclear, the full texts were reviewed. Subsequently, the full texts of all the articles selected were reviewed and data was extracted using a predesigned form.

Data Analysis

All analyses were performed using STATA Release 10 (STATA Corp, College Station, Texas). Pooling of treatment effect was accomplished using a random-effects model (DerSimonian and Laird method¹¹). Odds ratio (OR) were calculated such that values less than 1 favors griseofulvin and values more than 1 favors terbinafine. The I² test is used to check for heterogeneity of effect measures among the studies.

A study that included only *Microsporum* species found that the cure rate of griseofulvin tended to be higher than terbinafine.¹² Another study found that terbinafine was significantly better than griseofulvin in mycologic, clinical, and complete cure rates among patients with *T. tonsurans* infection. The study also found that griseofulvin was significantly better than terbinafine in mycologic and clinical cure rates among patients with *M. canis* infection.¹³ A subgroup analysis based on different dermatophyte species (*Microsporum* and *Trichophyton*), was therefore performed in this review. Adverse effects are described qualitatively.

Results

Included Studies

Seventeen trials involving 3635 subjects comparing different systemic antifungal treatments for tinea capitis were identified (Table 26-1). They were conducted between 1985 and 2008.

TABLE 26-1—RCTs Comparing Different Systemic Anti-Fungal Treatments for Tinea Capitis

Study	Year	Location	N	Comparative drugs		Outcome	Assessment (wk)
Caceres-Rios ¹⁴	2000	Peru (Lima)	50	Griseofulvin	Terbinafine	Complete cure	12
Dastghaib ¹⁵	2005	Iran	40	Griseofulvin	Fluconazole	Complete cure	8
Elewski ¹³	2008	Multiple centers around the world	1549	Griseofulvin	Terbinafine (oral granules)	Complete cure	10
Foster ¹⁶	2005	USA, Guatemala, Chile, Costa Rica, India	880	Griseofulvin	Fluconazole	Complete cure	10
Fuller ¹⁷	2001	UK	210	Griseofulvin	Terbinafine	Complete cure	24
Gan ¹⁸	1987	USA (Dallas)	80	Griseofulvin	Ketoconazole	Complete cure	8
Gupta ¹⁹	2001	Canada & South Africa	200	Griseofulvin	Terbinafine Itraconazole Fluconazole	Complete cure	12
Haroon ²⁰	1995	Pakistan	105	Griseofulvin	Terbinafine	Complete cure	12
Jahangir ²¹	1998	Pakistan	55	Terbinafine	Itraconazole	Complete cure	12
Lipozencic ¹²	2002	Europe and South America (22 centers)	165	Griseofulvin	Terbinafine (of different durations)	Complete cure	16
Lopez-Gomez ²²	1994	Spain (Madrid)	35	Griseofulvin	Itraconazole	Complete cure	12
Martinez-Roig ²³	1988	Spain (Barcelona)	13	Griseofulvin	Ketoconazole	Clinical cure	6
Memisoglu ²⁴	1999	Turkey	78	Griseofulvin	Terbinafine	Complete cure	12
Rademaker ²⁵	1998	New Zealand	24	Griseofulvin	Terbinafine	Clinical cure	12
Tanz ²⁶	1985	USA (Chicago)	22	Griseofulvin	Ketoconazole	Mycological cure	12
Tanz ²⁷	1988	USA (Chicago)	79	Griseofulvin	Ketoconazole	Complete cure	12
Wahab ²⁸	2007	Bangladesh	50	Griseofulvin	Fluconazole	Clinical and mycological cure	8

All the trials compared efficacy between different drugs. There were no trials comparing active treatment to placebo. Griseofulvin has been used as the standard for comparison in all studies, except for one which compared terbinafine to itraconazole.²¹ Griseofulvin was compared with terbinafine in eight studies (seven used terbinafine tablets and one used oral granules), with itraconazole in three studies, with fluconazole in four studies, and with ketoconazole in four studies.

The studies included subjects from most parts of the world. The assessment period was usually 12 weeks but ranged from 6 to 24 weeks. All studies reported complete cure except for four, of which two reported clinical cure as the outcome^{23,25}, one reported mycologic cure²⁶, and one reported both clinical and mycologic cure²⁸. All but one study¹⁸ reported adverse events.

Griseofulvin

Comparative Efficacy

Griseofulvin has been considered the gold standard for treatment of tinea capitis and it has been used to compare against newer antifungal agents.

With regard to *Trichophyton* species, a study involving 200 participants demonstrated no significant difference in

efficacy between 6 weeks of griseofulvin and 2 to 3 weeks of itraconazole, terbinafine, and fluconazole, although griseofulvin tended to be more effective.¹⁹

There is only one RCT in which *Microsporum* species accounted for the majority of the pathogens.¹² In this study, *M. canis* constitutes 98.5% of the *Microsporum* species. This study was not powered adequately for a statistical comparison between terbinafine and griseofulvin, but the cure rates tended to be lower in the terbinafine groups than in the griseofulvin group.

Adverse Effects

Griseofulvin was associated with a small number of adverse effects in the studies reviewed. These include gastrointestinal symptoms (vomiting, abdominal pain, diarrhea), headache, upper respiratory tract symptoms (nasopharyngitis, cough, infection), and rashes. No severe adverse effects have been noted.

Terbinafine

Comparative Efficacy

Seven studies comparing griseofulvin and terbinafine in 2163 subjects were analyzed and their characteristics are

TABLE 26-2—Characteristic of Studies Comparing Griseofulvin and Terbinafine

Study	Year	Location	N	Age	% of <i>Trichophyton</i> species	% of <i>Microsporum</i> species	Griseofulvin dosing	Griseofulvin duration (wks)	Terbinafine dosing	Terbinafine duration (wks)
Haroon ²⁰	1995	Pakistan	105	2 to 65	99%	1%	Gc	8	Ta	4
Memisoglu ²⁴	1999	Turkey	78	2 to 13	49%	48%	Gc	8	Ta	4
Caceres-Rios ¹⁴	2000	Peru (Lima)	50	1 to 14	74%	26%	Gc	8	Ta	4
Fuller ¹⁷	2001	UK	147	2 to 16	84%	14%	Gb	8	Ta	4
Gupta ¹⁹	2001	Canada & South Africa	100	5.8 (mean)	100%	0%	Ga	6	Ta	2 to 3

Elewski ¹³	2008	Multiple centers around the world	1549	4 to 12	65%	34%	Gd	6	Tb	6

Ga: 20 mg/kg per day; Gb: 10 mg/kg per day; Gc: 125 mg/day (<20 kg), 250 mg/day (20–40 kg), 500 mg/day (>40 kg); Gd: 125 mg/day (<14 kg), 250 mg/day (14–23 kg), 500 mg/day (>23 kg). Ta: 62.5 mg/day in participants weighing from 10 to 20 kg, 125 mg/day from 20 to 40 kg, and 250 mg/day over 40 kg. Tb: 125 mg/day in subjects weighing less than 25kg, 187.5 mg/day from 25 to 35kg, and 250 mg/day over 35 kg.

listed in Table 26-2. One open study was excluded because no data on the cure rates from each type treatment was provided.²⁵

In most of the studies, the majority of the pathogens belong to the *Trichophyton* species. One of the studies comprises entirely of *Microsporum* species¹² and another had similar portions of *Trichophyton* and *Microsporum* species²⁴. All the studies reported complete cure rate except for one¹⁴ which reported mycologic cure rate. The duration of griseofulvin was 6 or 8 weeks except for one study (12 weeks)¹². The duration of terbinafine in the majority of studies was 4 weeks; one other used 2 to 3 weeks,¹⁹ another used 6 weeks,¹³ and another used 6 to 12 weeks.¹² The mean durations of griseofulvin and terbinafine treatment are 8 and 4 weeks respectively. The dosing of griseofulvin and terbinafine used in the various studies are detailed in the legend of Table 26-2.

The results from the studies are summarized in Table 26-3. In the study by Lipozencic et al.¹² subjects treated with terbinafine were sub-grouped into treatment durations from 6 to 12 weeks. The cure rate at 16 weeks tended to decrease with increased duration of terbinafine treatment paradoxically, although it was not statistically significant. Only the group treated with 6 weeks of terbinafine, which is similar in duration to other studies, was included in the pooled analysis to compare with griseofulvin. The total number of subjects was 2094. The average duration of duration of griseofulvin treatment among the seven studies was 8 weeks and that for terbinafine was 4 weeks (rounded to the nearest week). The time of assessment of cure was 12 weeks for five studies, 16 weeks for one study¹² and 10 for another study.¹³ The cure rates for griseofulvin and terbinafine varied widely, from 39 to 92% and from 45 to 94% respectively.

TABLE 26-3—Results of Studies Comparing Griseofulvin and Terbinafine

Study	Year	N	Assess-ment (week)	Number cured with Griseofulvin	Number not cured with Griseofulvin	Number cured with Terbinafine	Number not cured with Terbinafine	% cure rate of griseofulvin	% cure rate of terbinafine

7	Elewski ¹³	1.274	1.007	1.612	30.57
	Pooled	1.227	0.785	1.919	100

Table 26-4 and Figure 26-1 show the pooled data analysis of the studies and the pooled OR does not significantly favor griseofulvin or terbinafine (1.22 favoring terbinafine; 95% CI=0.785-1.919; p=0.37). The test for heterogeneity is marginally insignificant (p=0.060), suggesting that the effect measures of the studies may not be homogenous.

A further analysis was performed only on the studies with *Trichophyton* species being the predominant

pathogen, (i.e., two studies were excluded).^{12,24} The total number of subjects was 1951 and the results are shown in Table 26-5 and Figure 26-2. The pooled OR favors terbinafine, although the difference did not reach statistical significance (1.49; 95% CI=0.975-2.277; p=0.065). The test for heterogeneity is insignificant (p=0.183), indicating homogeneity of effect measures.

A subgroup analysis was performed to compare the complete cure rates of griseofulvin and terbinafine in *Trichophyton* species (Table 26-6). In the study by Elewski et al.¹³ only data for *T. tonsurans* and *T. violaceum*, which together constitutes 98.4% to 99.4% of all *Trichophyton* species, is available. The total number of subjects was 1388 from four studies and Table 26-6 and Figure 26-3 show the pooled data analysis. The pooled OR significantly favors terbinafine (1.616; 95% CI=1.274-2.051; p<0.001) and the test for heterogeneity is insignificant (p=0.658).

Another subgroup analysis was performed to compare the complete cure rates of griseofulvin and terbinafine in *Microsporum* species (Table 26-3-26-7). In the study by Lipozencic et al.¹² all patients treated with terbinafine (which varies from 6 to 12 weeks) are included. In the study by Elewski et al.¹³ only data for *M. canis*, which constitute 85.4% to 88.6% of all *Microsporum* species, is available.

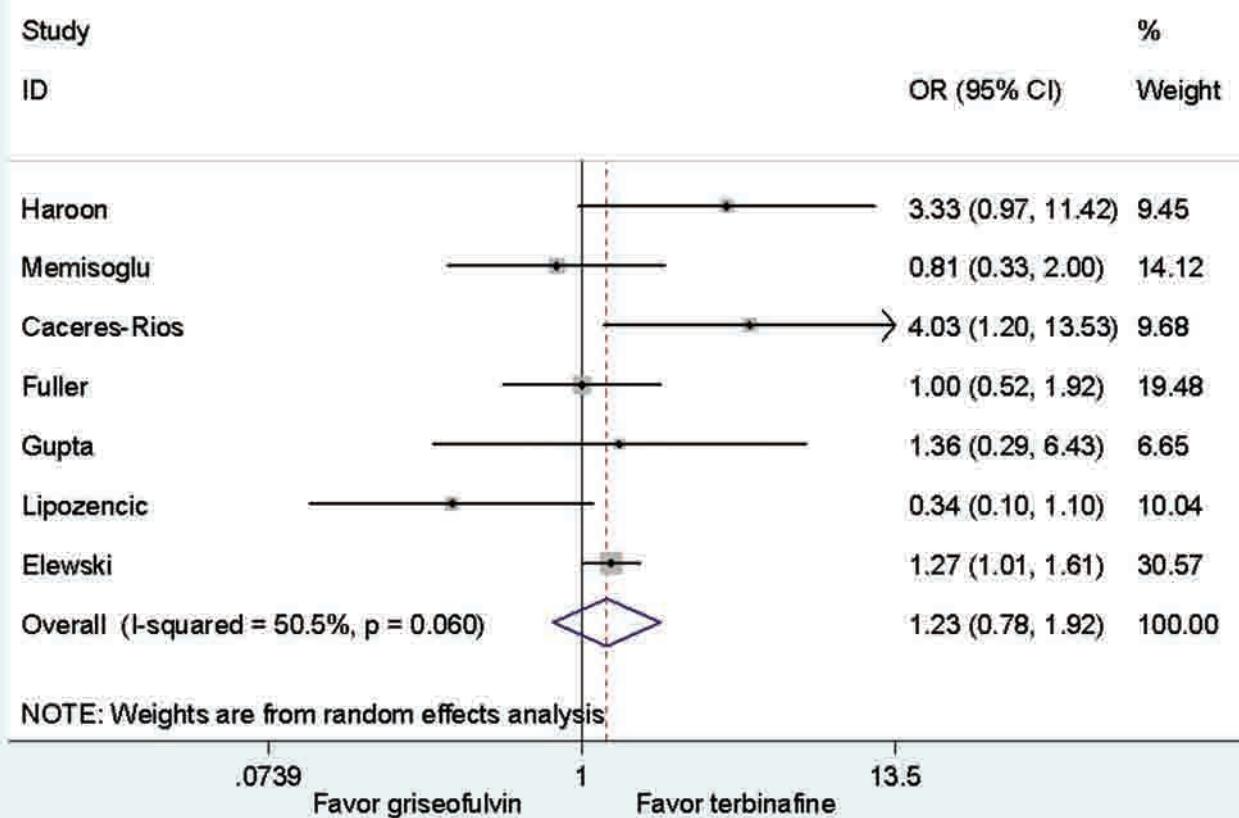

**FIGURE 26-1** Forest plot of studies comparing griseofulvin and terbinafine.

TABLE 26-5—Pooled Analysis of Studies with Predominant ($\geq 65\%$) *Trichophyton* Species Comparing Griseofulvin and Terbinafine

	Study	Odds-ratio	95% Confidence Interval	% Weight
1	Haroon ²⁰	3.333	0.973	11.423

3	Fuller ¹⁷	1	0.52	1.923
4	Gupta ¹⁹	1.362	0.289	6.426
5	Elewski ¹³	1.274	1.007	1.612
	Pooled	1.49	0.975	2.277
				100

The total number of subjects was 426 from three studies and Table 26-7 and Figure 26-4 show the pooled data analysis. The pooled OR significantly favors griseofulvin (0.408; 95% CI=0.254–0.656; $p<0.001$) and the test for heterogeneity is insignificant ($p=0.444$).

Adverse Effects

In these studies, the most frequent adverse events caused by terbinafine were gastrointestinal symptoms (such as vomiting, nausea, abdominal pain, and diarrhea) and upper

respiratory tract symptoms (such as infection, nasopharyngitis, cough, and rhinorrhea). Because of concerns about possible leucopenia and hepatotoxicity with the use of terbinafine, serum laboratory analyses were performed in four of the seven studies. No cases of abnormal hematologic indices or liver transaminitis caused by terbinafine were found.

Itraconazole

Comparative Efficacy

Three studies involving 140 subjects comparing itraconazole to griseofulvin and terbinafine were identified.^{19,21,22}

With regards to *Trichophyton* species, a trial which compared the efficacy of griseofulvin to itraconazole, terbinafine, and fluconazole, with 50 subjects in each group, did not demonstrate any significant difference in efficacy between 6 weeks of griseofulvin at 20 mg/kg/day and 2 to 3 weeks of itraconazole at 5 mg/kg/day.¹⁹

Another study involving 60 participants compared 2 weeks of itraconazole (50 to 200 mg/day based on weight) to 2 weeks of terbinafine, did not demonstrate any significant difference in the complete cure rates.²¹

With regards to *Microsporum* species, in a study in which *M. canis* comprised 91.4% of the pathogens, the

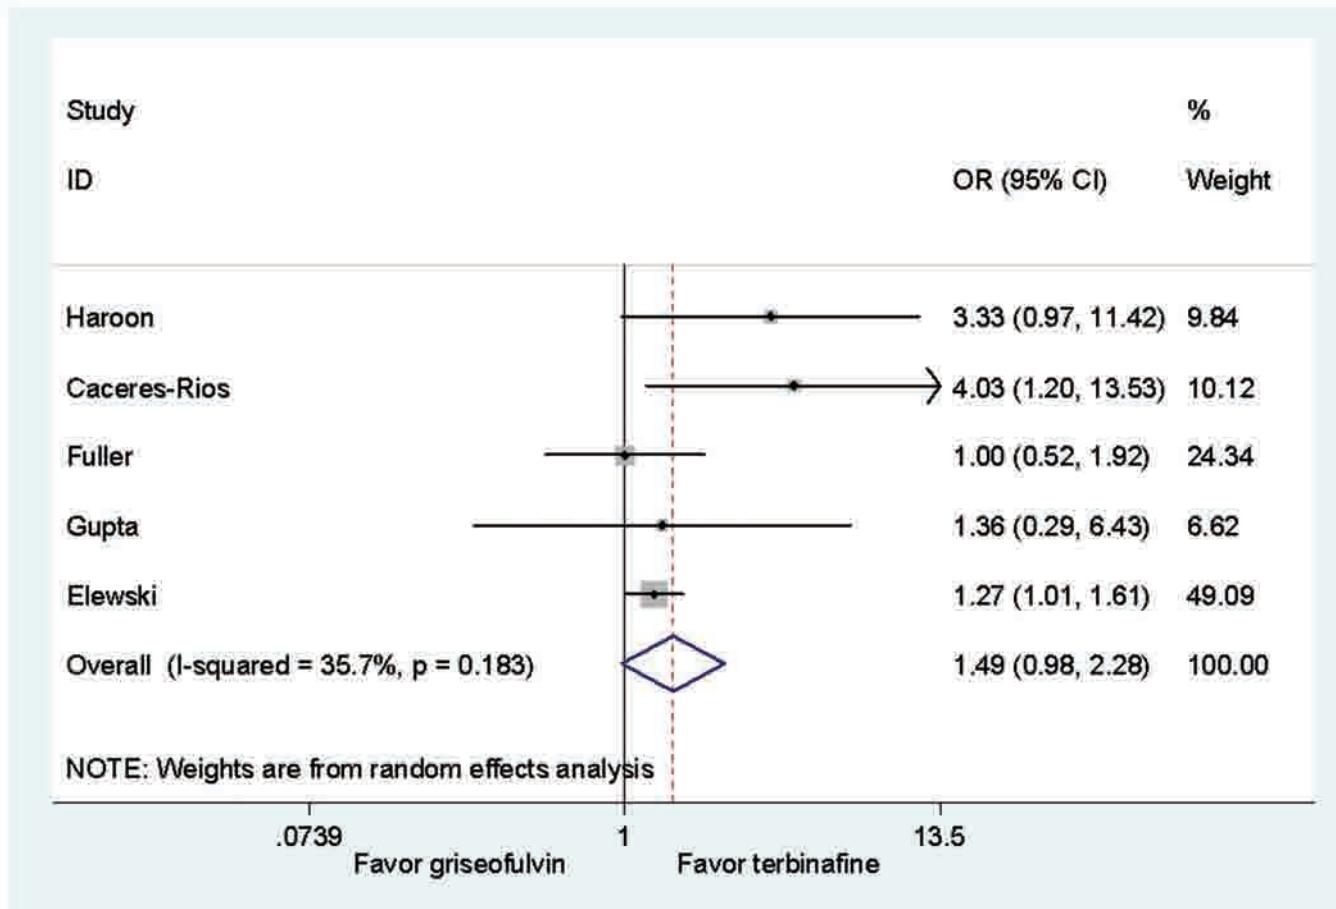

FIGURE 26-2 Forest plot of studies with predominant ($\geq 65\%$) *Trichophyton* species comparing griseofulvin and terbinafine.

complete cure rates of griseofulvin (ultra-microsized, 500 mg/day) and itraconazole (100 mg/day), each given for 6 weeks, were the same at 88% (15/17 and 15/17).²²

Adverse Effects

The most common adverse effects of itraconazole were gastrointestinal symptoms like nausea and abdominal discomfort. There were no severe adverse effects.

Fluconazole

Comparative Efficacy

Four studies involving 1020 subjects comparing fluconazole to griseofulvin were identified.^{15,16,19,28}

In three of the studies, *Trichophyton* species were the predominant (80% and more) pathogens, and there was no significant difference in the efficacy between fluconazole and griseofulvin.^{15,16,19} The first is a trial with 880 participants comparing fluconazole 6 mg/kg per day for 3 weeks, fluconazole 6 mg/kg per day for 6 weeks, and griseofulvin 11 mg/kg per day for 6 weeks.¹⁶ Another trial compared the efficacy of 6 weeks of griseofulvin to 2 to 3 weeks of itraconazole, terbinafine and fluconazole (6 mg/kg/day), with 50 subjects in each subgroup.¹⁹ The third trial involved 40 participants and the efficacy of 4 weeks of fluconazole at 5 mg/kg per day was comparable to 6 weeks of griseofulvin at 15 mg/kg per day.¹⁵

In one study, the pathogens were not reported.²⁸ Griseofulvin at 15 mg/kg/day was compared to fluconazole

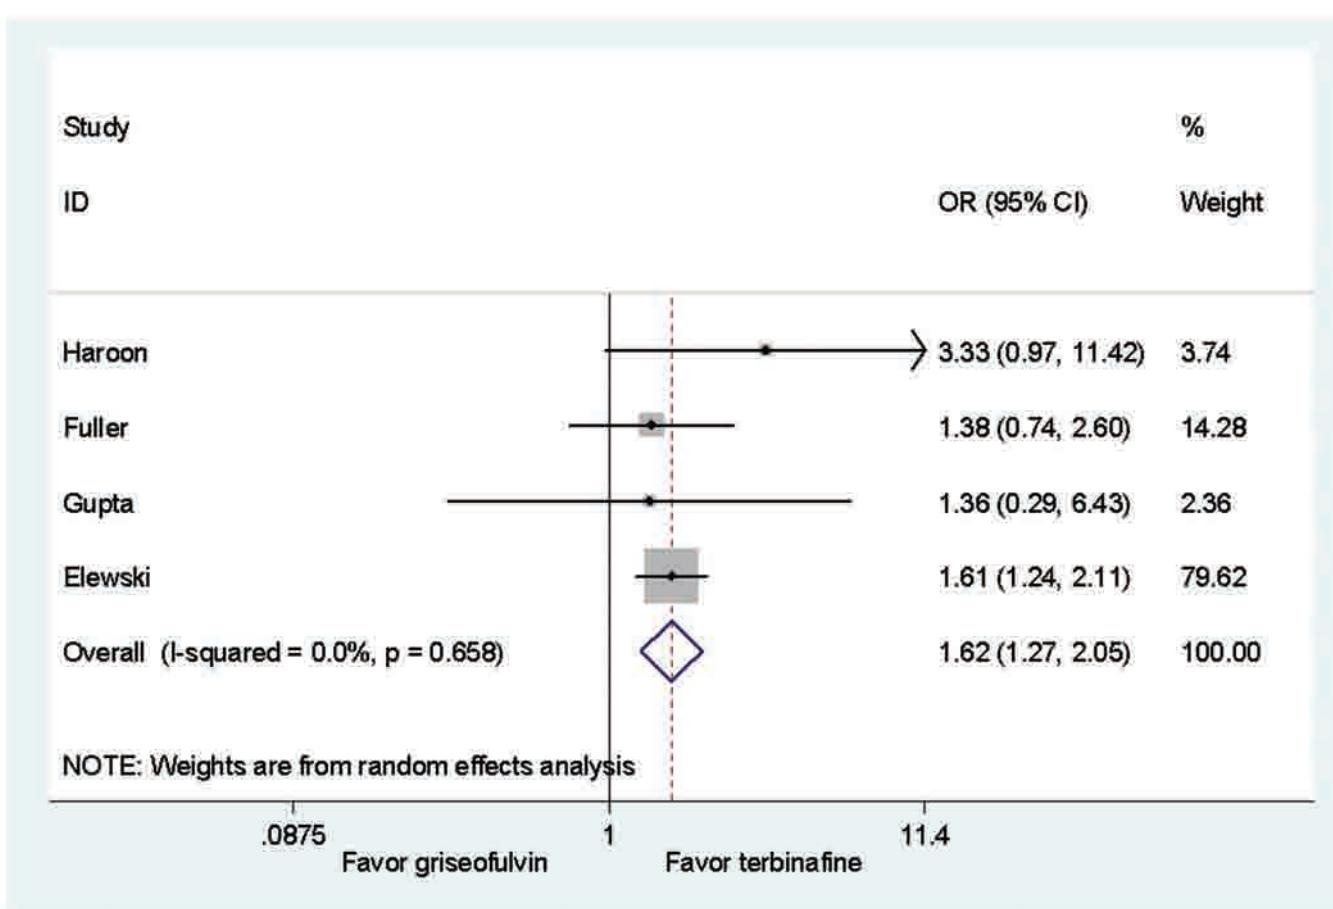

FIGURE 26-3 Forest plot of studies including only subjects infected by *Trichophyton* species.

TABLE 26-7—Subgroup Analysis of *Microsporum* Species in Studies Comparing Griseofulvin and Terbinafine

*Only figures for *M. canis* are available and included here.

at 6 mg/kg/day, each given to 25 subjects for 2 months. Griseofulvin demonstrated significantly higher clinical cure rate (84% vs 68%) and mycologic cure rate (68% vs 56%).

Adverse Effects

The most common adverse effects were gastrointestinal symptoms (such as abdominal pain and diarrhea), headache, rashes, and liver function test abnormalities. Most of these adverse effects were mild and reversible.

Ketoconazole

Comparative Efficacy

Four studies involving 194 subjects comparing ketoconazole to griseofulvin were found.^{18,23,26,27}

Ketoconazole at doses of 3.3 to 6.6 mg/kg/day for 6 weeks was compared with griseofulvin at 10 to 20 mg/kg/day for 6 weeks in a study consisting 79 subjects.²⁷ The complete cure rate was 48% (16/33) in the ketoconazole group and 54% (25/46) in the griseofulvin group at 12 weeks. Ketoconazole at 200 mg/day was compared to griseofulvin at 250 to 500 mg/day in an earlier trial involving 22 subjects by the same author.²⁶ There were no statistically significant differences between the mycologic cure rates.

Ketoconazole 5 mg/kg/day was compared to griseofulvin 15 mg/kg/day in an open study involving 80 subjects with *Trichophyton* species as the predominant pathogen.¹⁸ 59% (23/40) in the ketoconazole group, and 92% (37/40) in the griseofulvin group had complete cure after 8 weeks of therapy.

Ketoconazole 100 mg/day for 6 weeks was compared to griseofulvin 350 mg/day for 6 weeks in a small study with

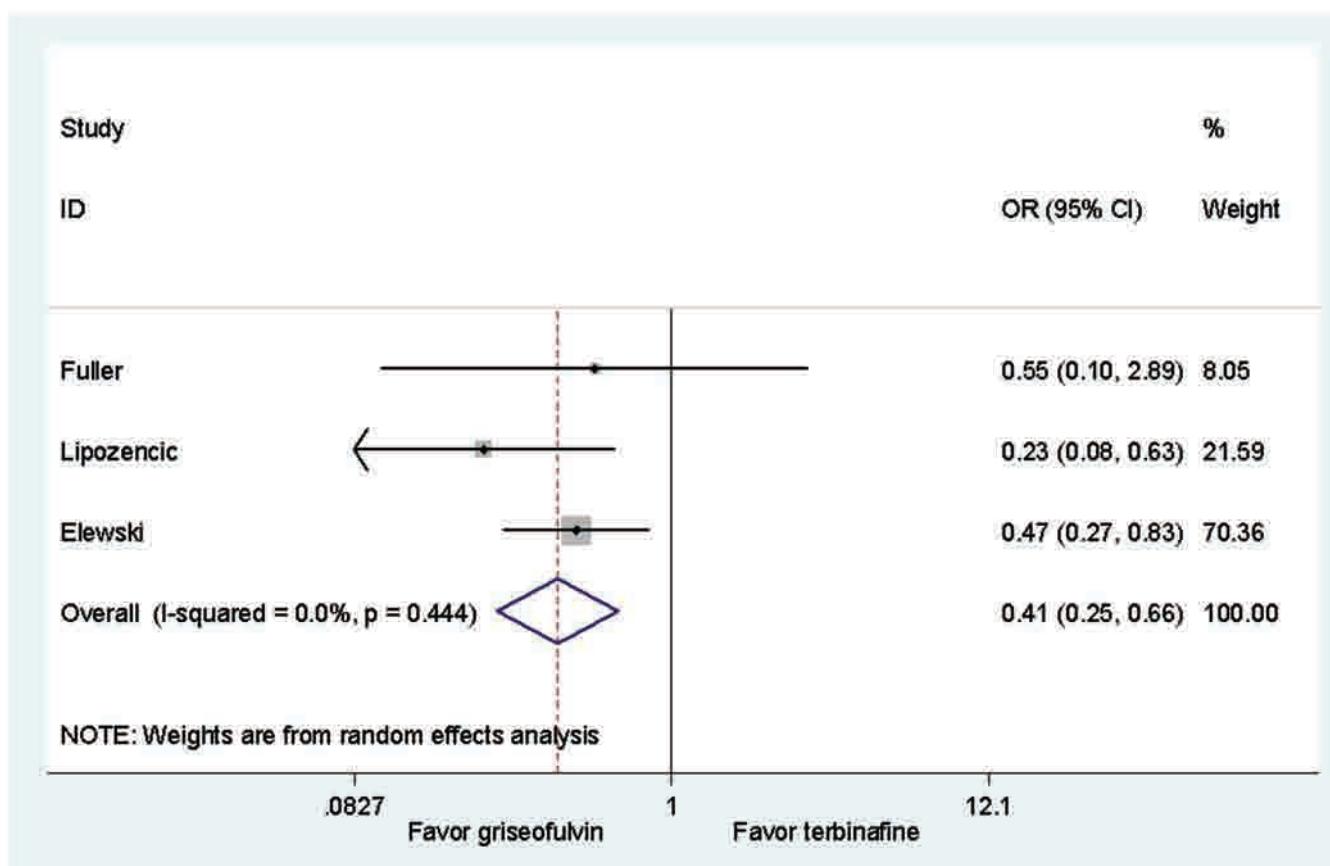

FIGURE 26-4 Forest plot of studies including only subjects infected by *Microsporum* species.

13 subjects.²³ All (8/8) the children in the ketoconazole group, and 80% (4/5) in the griseofulvin group, had clinical improvement and there was no mention of mycologic or complete cure rates.

Adverse Effects

There were no reports of severe adverse effects. Ketoconazole is known for its risk of severe liver toxicity, but there were no reported liver abnormalities among the subjects in these studies. Adverse effects included abdominal pain, nausea, and urticaria.

DISCUSSION

Griseofulvin

Griseofulvin is derived from a species of *Penicillium*, which is a fungus. It exerts its fungistatic effect by arresting mitosis at the metaphase stage of microtubule spindle formation, and thereby stopping cellular division and fungal cell wall synthesis in actively growing fungi. Because of its poor water solubility, it has to be taken with food, and a fatty meal will enhance its absorption. Microsized griseofulvin has a smaller particle size and is better absorbed in the upper gastrointestinal tract. A further increase in absorption is achieved by ultra-microsizing griseofulvin and this allows a reduction in dose by 33 to 50%. The efficacy and safety profile of both formulations microsized and ultra-microsized forms are similar,²⁹ but the latter is not available as a solution.

Griseofulvin is metabolized in the liver and is excreted both in the urine and feces. As it induces cytochrome P450 enzymes in the liver, the metabolism of certain drugs taken concurrently, such as ciclosporin, oral contraceptive pills, and warfarin, can be increased. Griseofulvin is classified in FDA Category C for use in pregnancy and its safety in lactation is undetermined.

Griseofulvin has a narrow spectrum of action, being only effective against the *Trichophyton*, *Microsporum*, and *Epidermophyton* species of dermatophytes. Griseofulvin is licensed for the treatment of tinea capitis in most countries and it has been used as the standard of care to compare with the newer antifungal agents. The advantages of griseofulvin are that it is inexpensive and the suspension formulation enables accurate dosing in children.

Efficacy

The reported efficacy rates of griseofulvin have been highly variable. A meta-analysis published in 2008 involving seven studies (n=438), demonstrated an overall mean mycologic cure rate of 73.4% (+/- 7%) with 4 to 6 weeks of griseofulvin.³⁰ Higher efficacy rates were reported with the use of higher dosages of griseofulvin (more than 18 mg/kg/d). The mean efficacy for *Trichophyton* and *Microsporum* were

67.6% (+/- 9%) in 5 studies (n=396) and 88.1% (+/- 5%) in 2 studies (n=42), respectively.

Dosing

The microsized formulation is administered at a dose of 10 to 25 mg/kg/day and the duration of therapy has generally been 6 to 8 weeks. An unpublished study involving 64 children in a region with high prevalence of *T. violaceum* compared using griseofulvin 10 mg/kg daily for 6 weeks, two doses of 50 mg/kg 1 month apart, and weekly doses of 50 mg/kg for 6 weeks.³¹ The mycologic cure rates between these regimens at 6 weeks and 6 months were not significantly different. In another study involving 35 children in Kenya, the response rate for a single 2 to 3 g dose was 57% and the cumulative response rate after three doses was 91%.³² These studies suggest that intermittent dosing, which enhances compliance, is also effective. These studies did not demonstrate an increased risk of adverse effects at higher dosages of griseofulvin.

Terbinafine

Terbinafine is a tertiary allylamine that inhibits the production of ergosterol, an essential constituent of the fungal cell membrane. It also inhibits squalene epoxidase, causing a toxic accumulation of squalene in the fungal cytoplasm and thereby kills the fungus. In contrast to griseofulvin, its absorption is not altered by food intake. It is very lipophilic and high concentrations are found in hair, stratum corneum, and sebum.³³ Terbinafine also persists in the tissues at fungicidal concentrations after treatment has ceased and cure rates continue to rise for several weeks after termination of therapy.

Eighty percent of the drug is metabolized by cytochrome P450 enzyme in the liver and 20% is excreted in the urine and faeces. The manufacturer does not recommend the use of terbinafine in patients with renal impairment (i.e., creatinine clearance of 50 mL/minute or less) or in those with preexisting liver disease as clearance of the drug may be decreased substantially. The level of terbinafine is decreased by rifampicin, a strong inducer of cytochrome P450 enzyme. Terbinafine in turn increases the levels of paroxetine, venlafaxine, and tricyclic antidepressants when they are used concurrently. Terbinafine is classified in FDA Category B for use in pregnancy and its use in lactation is contraindicated.

Terbinafine has demonstrated a good safety profile, and therefore, represents a good alternative to griseofulvin for treatment of tinea capitis in children. Its advantage is its shorter duration of treatment of about 4 weeks, in contrast to 6 to 8 weeks for griseofulvin. On the other hand, it is more costly and is not available in suspension or liquid formulation. Terbinafine hydrochloride oral granules have recently been developed as a new pediatric formulation consisting of miniature granules that can be sprinkled over food and swallowed easily.¹³ The granules are approximately 2.1 mm

in diameter and are film coated for masking the taste, facilitating its administration to children. This formulation is currently not widely available.

Meta-analysis of seven RCTs did not reveal any significant difference in efficacy between griseofulvin and terbinafine in the treatment of tinea capitis. In the pooled analysis of five studies in which *Trichophyton* species were the predominant (65% and more) pathogenic dermatophyte, terbinafine appeared to be more efficacious than griseofulvin. Subgroup analysis revealed that terbinafine was more efficacious than griseofulvin in treating tinea capitis caused by *Trichophyton* species. On the other hand, the analysis suggests that griseofulvin was more efficacious than terbinafine in treating tinea capitis caused by *Microsporum* species.

Several clinical applications can be derived from the above results. If clinical findings suggesting *Microsporum* species is the infecting dermatophyte, such as the presence of fluorescence under Wood's lamp, and having a pet which may have transmitted *M. canis*, empirical use of griseofulvin is recommended. In the absence of these features and in populations which *Trichophyton* species are the predominant pathogens causing tinea capitis, empirical use of terbinafine is recommended if cost is not an issue. When faster PCR-based diagnostic tests become commercially available,⁸ the identification of infecting species will enable a more targeted and effective use of anti-fungal agents.

Itraconazole

Itraconazole, a synthetic triazole derivative, is an azole antifungal agent and it is available in tablet and solution form. Its fungistatic activity is caused by the inhibition of the cytochrome P450-dependent synthesis of ergosterol, which is a vital component of fungal cell membranes. It is metabolized predominantly by the cytochrome P450 enzyme and the half-life of the drug is increased in liver impairment. Although approximately 40% of the drug is excreted in the urine as inactive metabolites, adjustment in dosage is not necessary in renal impairment.

Azoles are substrates and inhibitors of cytochrome P450 3A4 isoenzyme and P-glycoprotein (a plasma membrane transporter responsible for metabolism in intestinal enteroctyes) and they decrease the metabolism of multiple drugs.³⁴ Itraconazole is classified in FDA Category C for use in pregnancy and its use in breast-feeding mothers is contraindicated.

Some RCT evidence suggests that oral itraconazole is effective and safe when used for 2 to 6 weeks in the treatment of tinea capitis. The few studies available show that itraconazole is as effective as griseofulvin when used for 2 weeks against *Trichophyton* species and when used for 6 weeks against *M. canis*. The availability in both tablet and liquid formulation enables accurate and convenient dosing in children.

Fluconazole

Fluconazole is the first of the new subclass of synthetic triazole antifungal agents and it is available as tablet and suspension forms. Fluconazole is a highly selective inhibitor of the fungal cytochrome P450-dependent enzyme lanosterol 14- α -demethylase which converts lanosterol to ergosterol. The drug is cleared primarily by renal excretion and dose adjustment may be required in patients with renal impairment. Like other azoles, it decreases the metabolism of many drugs and increases their plasma concentration.³² Fluconazole is classified as FDA category C for use in pregnancy and as it is secreted in human milk at concentrations similar to plasma, its use in breast-feeding mothers is not recommended.

In studies with predominance of *trichophyton* species (80% and more), fluconazole used for 3 to 6 weeks is as effective as griseofulvin and is safe for the treatment of tinea capitis. The availability in both tablet and liquid formulation enables accurate and convenient dosing in children.

Ketoconazole

An occasional but serious adverse effect of ketoconazole is idiosyncratic hepatic toxicity (primarily hepatocellular type) and there have been rare fatalities from severe hepatic necrosis. The limited evidence available suggests that griseofulvin may be better than ketoconazole in the treatment of tinea capitis. Due to these reasons, ketoconazole is seldom used for tinea capitis, especially when safer azole compounds such as itraconazole and fluconazole are currently available.

Adjunctive Therapy

Topical Anti-Fungal Agents

Selenium sulfide shampoo was shown to be an effective adjunctive therapy to griseofulvin for the treatment of tinea capitis in a randomized controlled trial (Allen 1982). Ninety four percent of children with *T. tonsurans* infections treated with daily oral griseofulvin and selenium sulfide shampoo twice weekly demonstrated mycologic cure at 4 weeks compared to 75% of children who were treated with griseofulvin alone, or in combination with either a bland shampoo or topical clotrimazole. Another RCT of 54 patients with *T. tonsurans* tinea capitis treated with griseofulvin showed that twice weekly selenium sulfide shampoo was superior to nonmedicated control shampoo in achieving a faster mycologic cure.³⁵ There was, however, no difference between 2.5% and 1% selenium sulfide preparations in the time required to produce a negative culture and the authors concluded that commercially available 1% selenium sulfide shampoo is equally effective and less expensive compared to the 2.5% preparation.

An open study evaluated daily ketoconazole 2% shampoo for 8 weeks as a monotherapy for the treatment of *T. tonsurans* tinea capitis.³⁶ Six of the 15 children (40%) had negative cultures after 2 weeks but one child relapsed at the fourth week. The rest of the five children (33%) remained culturally negative for 12 months post-treatment.

A RCT was performed in Zimbabwe that compared 6 weeks of Whitfield's ointment (6% benzoic acid and 3% salicylic acid) with miconazole cream in the treatment of tinea capitis. There was no significant difference in cure rates between Whitfield's ointment and miconazole cream and the combined mycologic cure rate of both medications was 67% (22/33).³⁷ Another RCT was performed in Tanzania to access the efficacy of two months of Triclosan bar soap in comparison with regular soap against superficial mycoses (tinea capitis, pityriasis versicolor, tinea corporis, and tinea pedis).³⁸ No significant benefit was found with the addition of Triclosan to bar soap and the average mycologic cure rate of tinea capitis for both the Triclosan and placebo groups were 21.8%.

With regards to the management of asymptomatic carriers, there were no RCTs found. A nonrandomized study comparing different shampoos in carriers found that the mycologic cure rates for povidone-iodine shampoo, econazole shampoo, 2.5% selenium sulphide shampoo, and control shampoo were 94%, 47%, 50%, and 50% respectively.³⁹

In summary, There is limited RCT evidence to support the use of selenium sulfide shampoo as an adjuvant topical therapy in the treatment of tinea capitis. The main purpose of topical antifungal therapy is to achieve a faster mycologic cure so as to reduce the transmission of the disease. Although there is only limited evidence to support the treatment of carriers, it is reasonable to use these topical agents, in particular povidone-iodine shampoo, to reduce the carrier rate and to prevent carriers from getting infected subsequently.

Corticosteroids for Kerions

There were two RCTs that found that the addition of oral prednisolone to griseofulvin did not confer additional benefits or result in improved cure rates.^{40,41} Another RCT also did not find adjuvant intralesional corticosteroid beneficial for patients with kerions treated with griseofulvin.⁴²

CONCLUSION

Terbinafine, itraconazole, and fluconazole demonstrated comparable efficacy to griseofulvin in the treatment of tinea capitis. Terbinafine is more efficacious against *Trichophyton* species compared to griseofulvin, while evidence suggests that the converse is true with regard to *Microsporum* species. Griseofulvin, terbinafine, itraconazole, and fluconazole demonstrated good safety profiles when used in the treatment of tinea capitis. Griseofulvin has the advantages of a long and excellent safety record, wide availability, and

low cost. The newer anti-fungal agents, on the other hand, provide the advantage of a shorter duration of treatment and thereby help improve compliance.

As an adjuvant therapy to griseofulvin, selenium sulphide shampoo may shorten the time to mycologic cure and thereby reduce transmission. In the treatment of kerions with griseofulvin, oral and intralesional corticosteroids do not provide additional benefit.

What We Know

- RCT evidence indicates that terbinafine is more efficacious than griseofulvin in treating tinea capitis caused by *Trichophyton* species.
- RCT evidence suggests that griseofulvin is more efficacious than terbinafine in treating tinea capitis caused by *Microsporum* species.
- Some RCT evidence suggests that itraconazole is as efficacious as griseofulvin in the treatment of tinea capitis.
- RCT evidence indicates that fluconazole is as effective as griseofulvin in the treatment of tinea capitis although this may only be applicable to *Trichophyton* species.
- Griseofulvin, terbinafine, itraconazole, and fluconazole demonstrated good safety profiles when used in the treatment of tinea capitis.
- Limited RCT evidence suggests that selenium sulphide shampoo shortens the time to mycologic cure in patients treated with griseofulvin.
- Oral and intralesional corticosteroids do not provide additional benefit to griseofulvin in the treatment of kerion.

Treatment of Tinea Versicolor

27

Craig N. Burkhart, M.S., M.D., Craig G. Burkhart, M.S.P.H., M.D.,
and Dean S. Morrell, M.D.

INTRODUCTION

Tinea versicolor (TV) is a superficial fungal skin infection caused by *Malassezia* spp. It most commonly affects the upper body, arms, neck, and face as round or oval hyperpigmented or hypopigmented macules with overlying flaky scale (Figure 27-1). Although some patients experience mild pruritus, most are asymptomatic. TV is responsive to a multitude of therapies including several oral antifungals, various formulations of topical antifungals, keratolytic agents, and nonspecific antimicrobial agents. As recurrence is common, prophylactic regimens are often required.

The optimal therapy has a high cure rate; minimal side effects; a very low or prolonged time to relapse, and is cosmetically acceptable to the patient. The questions and responses that follow attempt to provide the best evidence available supporting various treatment approaches to TV, relying on data from randomized-controlled trials (RCTs). Where RCTs are unavailable, data from longitudinal observational studies will be discussed, recognizing that conclusions from this type of evidence are more limited.

EPIDEMIOLOGY

TV is a disease of teenagers and young adults that affects men and women equally within all socioeconomic groups. When children and older adults are affected, it is usually within the setting of other endogenous and exogenous predisposing factors. Endogenous factors predisposing individuals to TV include malnutrition, use of oral contraceptives, use of systemic immunosuppressants including corticosteroids, immune deficiency disorders including acquired immune deficiency syndrome (AIDS), and hyperhidrosis.¹ Exogenous factors include tropical climates, occlusion by clothing, creams, or lotions, and hospitalization.¹ Hygiene is not an important contributor to the development of TV. The significant importance of climate is highlighted by the 1% prevalence of TV in Scandinavia versus 50% prevalence in many tropical countries.

ETIOLOGY/DIAGNOSIS

Yeasts of the genus *Malassezia* are the cause of TV. Of the various species, *Malassezia globosa*, *M. sympodialis*, and *M. furfur* are the most common species and likely cause of TV.² Ninety to 100% of individuals carry *Malassezia* species as part of their normal flora, however, TV only develops when the organism converts from a yeast to the mycelia form and infects the stratum corneum.² The cause of pigmentary changes is incompletely understood, but is hypothesized to be caused by some combination of inflammation, alteration of melanin production, melanocyte damage, and abnormal melanosome transfer to keratinocytes.³ Azelaic acid, lipoxygenase, and tryptophan metabolites produced by the fungus are currently under investigation as causative factors for the above changes.³

Tinea versicolor is diagnosed clinically by the appearance of round to oval macules in mostly seborrheic areas. The macules may be pink, tan, brown, black, or hypopigmented, and smooth or covered with fine scale. Wood's light (365 nm filtered ultraviolet light) will produce a bright yellow or gold fluorescence in approximately one-third of cases.¹ Skin scrapings or tape strippings from the

FIGURE 27-1 Tinea versicolor commonly affects the upper body, arms, neck, and face.

edge of scaly lesions will reveal the characteristic “spaghetti and meatballs” appearance of spores and hyphae under light microscopy, after incubation in potassium hydroxide (KOH). Skin biopsy is generally not necessary, but will reveal hyphae and budding yeast within the stratum corneum after staining with periodic acid-Schiff or methenamine silver.

SEARCH METHODOLOGY

In general, the approach used was to restrict searches in Medline to RCTs or randomized longitudinal series, as well as systematic reviews of tinea versicolor treatment in the English literature. Open-label, long-term follow-up from RCTs is provided where applicable. We also conducted hand searches of bibliographic references. Retrospective studies were not included.

Is one oral agent more effective than others for tinea versicolor?

Seven studies have directly compared the efficacy of oral therapies for TV. Kose compared fluconazole 300 mg twice daily to itraconazole 400 mg twice daily for 2 weeks in 64 patients.⁴ Patients with extensive or recurrent TV were randomly assigned one of the above regimens. Clinical cure was defined as resolution of scaling, pigmentary changes, and pruritus. Mycologic cure was defined as a negative KOH and Wood's lamp examination. At completion of the study, 80% of the patients treated with fluconazole, 74% of the patients treated with itraconazole were clinically cured, and 88% in the fluconazole group and 80% in the itraconazole group were cured. The difference was not considered clinically significant.

Single dose fluconazole (400 mg) versus single dose itraconazole (400 mg) was compared by Partap et al. in a RCT of 40 consecutive patients with over 15% skin surface involvement.⁵ Clinical cure was defined as resolution of pigmentary changes at 8 weeks. Mycologic cure was defined as negative cultures at weeks 2 and 8. Relapse was defined as reappearance of clinical signs or a positive culture after initial improvement. Pigmentary changes resolved in 20% of the fluconazole group versus 5% in the itraconazole group (not statistically significant). Cultures were negative in 10% at 2 weeks and 65% at 8 weeks in the fluconazole group versus 30% and 20% respectively in the itraconazole group. Thirty-five percent of the patients treated with fluconazole relapsed versus 60% in the itraconazole group, which was statistically significant ($p<0.05$).

Two regimens of fluconazole (450 mg single dose and 300 mg two doses given one week apart) were compared to itraconazole 200 mg daily for 7 days by Montero-Gei et al.⁶ Ninety patients were evaluated in a multicenter open label RCT. Clinical cure was defined as an absence of erythema, scaling, or pigmentary changes at day 60. Mycologic cure

was defined by negative skin scrapings on microscopy. Clinical cure was achieved in 52% of the fluconazole single dose group, 70% with two doses of fluconazole, and 74% with itraconazole. The difference between two doses of fluconazole and 1 week of itraconazole were not statistically significant. Mycologic cure between two doses of fluconazole and itraconazole were also not statistically significant (77% and 78%, respectively).

Itraconazole and ketoconazole were compared by Shermer et al. in a single center open label RCT.⁷ Itraconazole was given to 35 patients at 200 mg daily for 1 week and to 34 patients at 100 mg daily for 2 weeks. Thirty-six patients received ketoconazole at 400 mg per day 7 days apart. Mycologic cure at 4 weeks was assessed and cure was obtained in 85% of those receiving itraconazole 200 mg daily for 1 week, 81% of those receiving itraconazole 100 mg for 2 weeks; and 83% of those receiving 2 doses of ketoconazole 400 mg 7 days apart. The differences were not statistically significant. Clinical cure was not assessed.

Bhogal et al. compared four regimens of fluconazole and ketoconazole in 180 patients in an open RTC⁸: ketoconazole 400 mg once (group 1), ketoconazole 200 mg daily for 10 days (group 2), fluconazole 400 mg once (group 3), and fluconazole 150 mg weekly for 4 doses (group 4). Follow-up examinations were performed at 2 and 4 weeks and then at 3, 6, and 12 months after treatment. KOH and Wood's lamp examinations were performed at each visit. At 4 weeks post-treatment, 66%, 73.3%, 80%, and 59% of patients were clinically cured. However, at 12 months post-treatment, no patients in group 3 relapsed, whereas group 1 had more relapses than any other group. The authors concluded that fluconazole 400 mg in one dose was the most effective treatment for TV.

Ketoconazole (400 mg repeated in 1 week) was compared to fluconazole (300 mg repeated in 1 week) by Farschian et al. in an open RCT.⁹ 128 patients were recruited into the study with 100 completing it. Patients were assessed by clinical examination, potassium hydroxide smears, and Wood's lamp at the beginning of the study, immediately after completing therapy, and at 4, 8, and 12 weeks after initiating therapy. At week 8, 90% of those in the fluconazole group and 88% of those in the ketoconazole group were mycologically cured (negative KOH). At week 12, 82% of the fluconazole group, and 78% of the ketoconazole group were mycologically cured. These differences were not statistically significant.

Similarly, no statistically significant difference was found between fluconazole (300 mg in 2 doses, 2 weeks apart) and ketoconazole (400 mg as a single dose) by Yazdanpanah et al.¹⁰ Patients were evaluated for the extent of lesions, hyperhidrosis, and greasiness of the skin at the initial visit and at 1 month after completion of therapy. Mycologic examination (10% KOH preparation and Wood's lamp examination) was only performed if there was a question about the diagnosis at the initial visit or about the patient's cure at the final visit. In this open RCT, ninety patients were recruited

with 30 patients being eliminated from the study, as they were lost to follow-up or utilized topical agents in addition to the study drugs. Twenty-two of 27 (81.5%) patients in the fluconazole group and 29 of 33 (87.9%) patients in the ketoconazole group improved at the study's conclusion.

No studies were found evaluating the efficacy of systemic terbinafine or griseofulvin; however, they are stated to be ineffective in the treatment of TV.¹

CONCLUSION

Azole antifungals are effective against TV. There is insufficient evidence to recommend any one azole over others. There is no data to support or refute the efficacy of oral terbinafine or oral griseofulvin in the treatment of TV, but they are felt to be ineffective as oral agents.

Is one topical agent more effective than others for tinea versicolor?

Multiple topical agents are effective in the treatment of TV with diverse mechanisms of action. Nonspecific

antifungal agents that work by removing infected stratum corneum or altering cell turnover rates include selenium sulphide, propylene glycol, Whitfield's ointment (benzoic acid 12% and salicylic acid 6%), sulphur and salicylic acid, povidone-iodine, and benzoyl peroxide. Specific antifungal agents that directly act against the fungus include haloprogin, zinc pyrithione, tolccilate, ciclopirox olamine, griseofulvin, terbinafine, and the azole antifungals. None have been compared head-to-head, however, efficacy in RCTs compared to placebo are available (Table 27-1).

CONCLUSION

Many topical agents appear effective in treating TV. Although there is insufficient comparative evidence to recommend one topical agent over others, only a few agents (i.e., selenium sulfide 2.5% lotion, terbinafine 1% solution, ketoconazole 2% cream, ketoconazole 2% shampoo, econazole nitrate 1% cream, clotrimazole 1% cream and clotrimazole 1% solution) have established efficacy in randomized placebo-controlled trials. It is prudent to utilize these more established agents over the less studied alternatives.

TABLE 27-1—Randomized, Placebo-Controlled, Double-Blind Studies of Topical Agents for Tinea Versicolor

Reference	Regimen	Number of Patients	Clinical Cure (%)	Mycologic Cure (%)
11	Selenium sulfide 2.5% lotion once-daily for 1 week	48	NR*	39(81)
	Selenium sulfide 2.5% lotion + 0.2% colorants once daily for 1 week	38	NR	27(71)
	Vehicle + -.2% colorants once daily for 1 week	46	NR	7(15)
12	Terbinafine 1% solution twice daily for 1 week	76	55 (72)	62 (81)
	Placebo twice daily for 1 week	34	9 (26)	14 (41)
13	Econazole nitrate 1% cream once daily for 2-3 weeks	67	NR	53 (79)
	Placebo once daily for 2-3 weeks	59	NR	37 (63)
14	Clotrimazole 1% solution once daily for 2 weeks	116	96 (83)	96 (83)
	Vehicle once daily for 2 weeks	107	68 (64)	68 (64)
	Clotrimazole 1% cream once-daily for 2 weeks	10	8 (80)	8 (80)
15	Vehicle once-daily for 2 weeks	8	3 (38)	3 (38)

	Placebo daily	50	11 (22)	11 (22)
16	Ketoconazole 2% shampoo on day one and placebo once daily for next 2	103	71 (69)	79 (78)
	Ketoconazole 2% shampoo once-daily for 3 days	106	77 (73)	89 (84)
	Placebo once-daily for 3 days	103	5 (5)	11 (11)

*Not reported

Is systemic therapy more effective than topical therapy for tinea versicolor?

Systemic therapy is sometimes recommended above topical therapy when TV involves a large area of skin or when the disease is recurrent; however, only one study addresses the effectiveness of oral versus systemic therapy. In an open, randomized trial, del Palacio Hernanz et al. compared itraconazole 200 mg daily for 5 days (20 patients) with 2.5% selenium sulfide shampoo (20 patients) daily for 7 days.¹⁷ Three weeks after completion of therapy 20% of patients in the itraconazole arm achieved clinical and mycologic cure versus 45% of patients in the selenium sulfide arm. Interestingly, despite the lower cure rate, all 20 patients (100%) in the itraconazole group and 10 of 20 patients (50%) in the topical group stated they preferred oral over topical therapy.

CONCLUSION

In the only study directly comparing systemic and oral therapy for TV, topical selenium sulfide shampoo appears more effective than oral itraconazole. There is no evidence by comparative trials to recommend the use of systemic therapy over topical therapy based on the extent or recurrence of TV. Therefore, the choice of systemic versus topical therapy for TV should weigh more heavily on individual patient characteristics (patient preferences, ability to apply medication, cost, potential drug interactions, etc.) than the extent or persistence of the disease.

What are effective approaches to prevent recurrence of tinea versicolor?

As stated in the introduction, multiple intrinsic and extrinsic factors predispose individuals to TV, and therefore, patients often require prolonged or recurrent therapy to maintain improvement. Indeed, recurrence rates as high as 60% at 1 year and 80% at two years have been reported after treatment of TV.¹⁸ Despite the high recurrence rates, studies of TV therapies rarely extend beyond 4 weeks. Three studies address prophylactic treatment of TV.^{18–20}

In an open label study, Rausch and Jacobs treated 22 patients with ketoconazole 400 mg by mouth once.¹⁹ All patients achieved mycologic cure (negative Wood's lamp and KOH examination) at 1 month. Patients were then continued on ketoconazole 400 mg by mouth once monthly. Follow-up of 20 of these patients ranged from 4 to 15 months (mean 8.2 months), during which one had a recurrence. Faergemann and Djärv followed patients for 11 months on ketoconazole 200 mg/d for 3 consecutive days, once per month and had a similar low rate of recurrence.²⁰

Faergemann et al. evaluated itraconazole prophylaxis in a 6-month multicenter RCT.¹⁸ In the open, active

treatment phase itraconazole 200 mg was given daily to 238 patient followed by 4 weeks without active therapy. Ninety-two percent (205 patients) were clinically improved and mycologically cured (negative KOH preparation). In the double-blind prophylactic treatment phase, patients were randomized to itraconazole, 200 mg (102 patients), or placebo (99 patients) twice on 1 day per month for 6 consecutive months. At the trial's conclusion 88% of the patients receiving itraconazole remained mycologically negative versus 57% of those in the placebo arm ($P<0.001$).

Topical therapies and oral fluconazole have not been evaluated as prophylactic therapies in a RCT, however, one open-label study did evaluate relapses at 2 years following initial clinical and mycologic cure with selenium disulfide suspension.²¹ In this study, Hersle et al. achieved clinical and mycologic cure (negative KOH preparation) 4 weeks after one application of selenium disulfide suspension. Twenty-nine patients were then treated prophylactically one night every third month for 1 year and 30 patients received no further therapy. At 24 months, 53% of those who did not receive prophylaxis relapsed versus 14% in the prophylaxis group.

CONCLUSION

Prophylactic therapy with oral itraconazole (400 mg/d) or ketoconazole (400 mg/d or 200 mg/d for three consecutive days) once monthly appear to be effective prophylactic regimens. There is not enough evidence to support prophylaxis with any topical agents or oral fluconazole at this time.

What is the optimal dosing regimen for oral ketoconazole?

Ketoconazole was introduced at 200 mg daily for 4 weeks, however, subsequent studies have found shorter regimens to be effective. Four studies directly compare various regimens of oral ketoconazole, with dosing ranging from one 400 mg dose of ketoconazole to five weeks of daily therapy.^{22–25}

The first comparative trial was an open-label trial of 64 patients that compared ketoconazole 200 mg daily for 3 weeks (32 patients) versus 5 weeks (32 patients).²² Clinical and mycologic cure were assessed at 2 weeks after treatment. Eighty-one percent of those receiving 3 weeks versus 100% of those receiving 5 weeks of ketoconazole were clinically and mycologically cured. In contrast, a double-blind, randomized trial Hay et al. compared ketoconazole 200 mg daily for 5, 15, and 25 days and found no statistical significance in cure with length of therapy.²³ Thirty-six patients were enrolled in the study with 12 patients randomized to each dosing regimen. To maintain blinding in patients with regimens less than 25 days, placebo was provided to day 25 after completing the active treatment phase. At 28 days after therapy 83%, 75%, and 67% of those who received

5 days, 15 days, and 25 days of ketoconazole were clinically and mycologically cured. The differences were not statistically significant. An even shorter regimen was evaluated in a double-blind, randomized, placebo-controlled trial by Zaias.²⁴ Fifty-nine patients were randomized to receive ketoconazole 200 mg daily for 10 days, ketoconazole 200 mg daily for 5 days (followed by 5 days of placebo), or 10 days of placebo. Patients were assessed clinically and mycologically (KOH exam) 30 days after therapy. Ninety percent, 84%, and 17% of those receiving ketoconazole for 10 days, 5 days, or placebo, respectively, were clinically and mycologically cured. There was no significant difference between ketoconazole groups, but both were statistically better than placebo.

Most recently, Fernandez-Nava et al. compared ketoconazole 400 mg once (60 patients) with ketoconazole 200 mg daily for 10 consecutive days (60 patients).²⁵ The study was carried out in the Philippines where the relative humidity ranged from 74%-77% during the study period. All patient had 25-50% body surface area affected as determined by physical examination, KOH, and Wood's lamp examination. At 1 month after therapy, 42% of those receiving ketoconazole 400 mg once and 51% of those receiving ketoconazole 200 mg daily for 10 days were mycologically cured (defined as a negative KOH and Wood's lamp examination). The difference was not statistically significant.

CONCLUSION

Ketoconazole appears effective in various regimens ranging from 400 mg once to 200 mg daily for 5 to 35 days. There is insufficient evidence to recommend longer courses of ketoconazole over very short courses ketoconazole.

What is the optimal dosing regimen for oral itraconazole?

Dosing studies of itraconazole have looked at frequency of administration (once daily versus twice daily); the minimal effective cumulative dose; and the optimal length of therapy for cure of tinea versicolor. All comparative studies have been open-label and small, involving 50 or less total patients for comparison. The optimal minimum total cumulative dose of itraconazole is generally believed to be one gram based on data from clinical experience and placebo-based studies, but not comparative studies.²⁶

The daily frequency of itraconazole administration to reach one gram has been evaluated in three open-label, randomized trials comparing twice daily to once daily dosing. Panconesi et al. compared itraconazole 200 mg daily in a single dose for 5 days (15 patients) versus itraconazole 200 mg daily in a divided dose for 5 days (15 patients).²⁷ One hundred percent of patients were cured

in both groups. Simoni et al. had similar results.²⁸ Fifteen patients received itraconazole 200 mg daily in a single dose and 15 patients received itraconazole 200 mg daily in a divided dose for 5 days. Four weeks after treatment, 100% of the patients in both groups were clinically and mycologically cured. Again, divided versus once daily administration had no effect on efficacy in a study by Fioroni et al. comparing 13 patients on itraconazole 200 mg as a single daily dose versus 15 patients on itraconazole 200 mg daily as a divided dose.²⁹ Both groups were 100% clinically and mycologically at 4 weeks after the end of treatment.

Three studies have compared itraconazole's efficacy when one total gram is administered over 5 days versus 10 days.^{26,30,31} Del Palacio-Hernandez et al. compared itraconazole 200 mg daily for 5 days (15 patients) versus itraconazole 100 mg daily for 10 days (15 patients) in a randomized open-label study.³⁰ Patients were considered cured if they had no or mild residual lesions at 3 weeks post-treatment and a negative KOH examination. Ninety-three percent and 87% of the patients were cured in the 200 mg and 100 mg itraconazole daily groups respectively. The same dosing schedules were compared by Estrada.³¹ Twenty-two patients were prescribed itraconazole 200 mg daily for 5 days and 20 patients were prescribed itraconazole 100 mg daily for 10 days. Patients were assessed by Wood's lamp examination and KOH at the end of treatment. Seventy-five percent of those prescribed itraconazole 200 mg daily were mycologically cured versus 95% of those on 100 mg daily—the difference was not statistically significant. Clinical cure and long-term follow-up were not reported. Lastly, Massone et al. assessed patients for clinical and mycologic cure 4 weeks after beginning treatment.³² One hundred percent (10 of 10 patients) of those receiving 100 mg daily for 10 days were cured versus 80% (8 of 10 patients) receiving 200 mg daily for 5 days.

The one gram cumulative dose has been tested against both greater and lesser doses in four randomized, open-label studies—none of them showing clinically significant differences. Two studies evaluated greater cumulative doses.^{33,34} Cuce et al. compared itraconazole daily for 7 days (21 patients) with itraconazole 200 mg daily for 5 days (15 patients).³³ Patients were evaluated by clinical examination, Wood's lamp examination, and KOH at 35 days from the start of therapy. Ninety percent of those in the 5-day group and 95% of those in the 7-day group were clinically and mycologically cured. There was no statistically significant difference in cure rates. Galimberti et al. compared the same regimens: itraconazole 200 mg daily for 5 days (13 patients) or itraconazole 200 mg daily for 10 days (15 patients).³⁴ Cure was defined as the absence of clinical symptoms and a negative culture result. Twenty-eight days post-treatment, 86.7% of those in the 7-day group and 77% of those in the 5-day group were cured. The difference was not statistically significant. Lower cumulative doses have also been compared in two

studies.^{35,36} Morales-Doria compared itraconazole 100 mg twice daily (1 gram cumulative dose) to itraconazole 100 mg once daily (500 milligrams cumulative dose).³⁵ Twenty-four patients received 1 gram total dose and 23 received 500 milligrams total dose. Mycologic cure was assessed by tape-stripping and light microscopy, however, clinical cure was not assessed. Twenty-eight days after completion of therapy, 96%, and 100% of patients were mycologically cured in the 1-gram group and 500-milligram group, respectively. Kose et al. compared one 400 mg dose (24 patients) versus a 7-day 200 mg daily dose (26 patients) of itraconazole.³⁶ Patients were evaluated by clinical examination, KOH preparation, and Wood's lamp examination. Six weeks after starting therapy 75% and 83% of patients in the one-day group were clinically and mycologically cured, respectively.^{36,37} Eighty-one percent and 88% of patients in the 7-day group were clinically and mycologically cured, respectively.^{36,37} The differences were not statistically significant.

CONCLUSION

Itraconazole is highly effective at 1-gram total dose whether given over 5 days or 10 days once daily or as a divided daily dose. Higher total cumulative doses have not been shown to be superior. On the other hand, there is evidence that lower doses (i.e., 400 mg once or 500 mg total dose given over 5 days) may be as effective as the standard 1-gram cumulative dose.

What is the optimal dosing regimen for oral fluconazole?

As fluconazole is highly concentrated and persistent within the stratum corneum, once weekly dosing is typically prescribed for superficial fungal infections including TV.³⁸ Two studies have compared four dosing schedules for fluconazole.^{6,39} Amer et al. compared fluconazole 150 mg weekly for four doses, fluconazole 300 mg weekly for four doses, and a single dose of fluconazole 300 mg repeated at 2 weeks.³⁹ Six hundred and three patients were randomized to each schedule. A clinical and mycologic (KOH preparation) assessment was performed weekly during the treatment phase, wherein patients only received their scheduled dose if they showed clinical or mycologic evidence of residual TV. Patients were assessed for mycologic cure at 28 days after completing therapy. Clinical cure was not reported. At the final evaluation, 78% (161/207 patients) in the group receiving fluconazole 150 mg weekly, 93% (178/190 patients) in the group receiving fluconazole 300 mg weekly, and 87% (179/206 patients) in the group receiving fluconazole 300 mg repeated at 2 weeks were cured. Both groups receiving 300 mg per dose had a statistically significant higher cure rate than the group receiving 150 mg weekly.

There was no statistically significant difference between the groups receiving 300 mg per dose.

Montero-Gei et al. evaluated fluconazole 450 mg once (30 patients) versus two doses of fluconazole 300 mg given 1 week apart (30 patients) versus itraconazole 200 mg daily for 7 days (30 patients) in an open-label, randomized comparative trial.⁶ Patients were assessed by clinical examination and skin scrapings at 30 and 60 days after initiating therapy. At day 30, 60% of patients in the 1-dose fluconazole group were clinically cured versus 77% in the 2-dose fluconazole group—this was not statistically significant. However, 70% of patients in the 1-dose fluconazole group were mycologically cured versus 97% in the 2-dose fluconazole group—this was statistically significant ($p<0.012$, Fishers exact test). There appeared to be a trend for increased cure at 60 days in the 2-dose fluconazole group: the 1-dose fluconazole group had a 52% clinical cure and 55% mycologic cure at 60 days versus 70% clinical cure and 77% mycologic cure in the 2-dose fluconazole group. The differences at day 60, however, were not statistically significant.

CONCLUSION

Fluconazole is effective when dosed weekly. Dosing at 300 mg weekly for 4 weeks or single dose fluconazole 300 mg repeated in 2 weeks are more effective than fluconazole 150 mg weekly for 4 weeks. In addition, it appears multiple smaller doses (i.e., two or more 300 mg doses) of fluconazole may be more effective than a single large dose of fluconazole (i.e., 450 mg once). Hence, the optimal regimen for fluconazole appears to be a single 300 mg dose repeated two to four times, with each dose administered 1 to 2 weeks apart.

What We Know

- Oral azole antifungals (ketoconazole, itraconazole, and fluconazole) are highly effective against tinea versicolor.
- Selenium sulfide 2.5%, terbinafine 1%, and multiple azole antifungal agents are highly effective against tinea versicolor.
- Monthly oral azole antifungals reduce recurrences of tinea versicolor.
- Ketoconazole is highly effective in dosing regimens ranging from 400 mg once to 200 mg daily for one to several weeks.
- Itraconazole is highly effective at 1-gram cumulative dose, but lower cumulative doses appear to be just as effective.
- Fluconazole appears to be most effective as a single 300 mg dose, given 2 to 4 times at weekly intervals.

BACKGROUND

Leishmania genus is an obligate intracellular protozoan causing leishmaniasis in humans and other mammals and is related to trypanosomes. Its transmission takes place via bites of sandflies as vectors of the disease.^{1,2} The parasite has two forms in its life cycle called amastigote and promastigote. The amastigote is the non-flagellated form and the promastigote has flagellates. These forms convert into one another based on the parasite life cycle. The female sandfly takes the amastigotes from mammals' bodies. The amastigotes convert into the promastigotes in the midgut of sandfly. When sandflies feed once again, the promastigotes will be transferred into the host skin, which they bite. It has been reported that as low as 100 parasites can generate the number of promastigotes required for the development of acute cutaneous leishmaniasis (CL), and numbers less than that may produce a silent form of the disease which could generate a protective immune response in some infected individuals.^{2,3}

ETIOLOGY AND PATHOGENESIS

More than 20 species of *Leishmania* are human pathogens. Well-known species causing Old World CL (OWCL) are *L. major*, *L. tropica*, *L. aethiopica*, *L. donovani*, and *L. infantum*. The reservoirs for these *Leishmania* species are small rodents, humans, rock hyrax, human and canine family, respectively. Several species of the genus *Phlebotomus* are vectors involved in transmission of Old World parasites. *L. braziliensis*, *L. guyanensis*, *L. panamensis*, *L. mexicana*, *L. venezuelensis*, *L. amazonensis*, *L. chagasi*, and *L. peruviana* are the species causing New World CL (NWCL). The vectors of this group of parasites belong to the genus *Lutzomia*. Common reservoirs for causative agents of NWCL are: forest rodents, foxes, sloths, and dogs.^{1,4,5}

Phagocytic cells of monocyte lineage and dendritic cells engulf the parasites and a parasitophorous vacuole will be formed and after a short time of hours the promastigotes convert into amastigotes and start dividing within phagocytes.²

When the *Leishmania* promastigotes enter the host, they manage to evade hostile environment and innate and adaptive immune responses. C3b complement protein is involved

in opsonization of the parasites. Special surface glycoprotein of parasite called gp63 attaches to C3b and form into iC3b, which is an essential step for the parasite. Opsonization and engulfment by phagocytic cells assist parasites to survive. Upon internalization of the parasites, fusion of phagosome with lysosome occurs, *Leishmania* amastigotes survive and multiply within the phagolysosomes by various mechanisms. One of these mechanisms is protection by acid phosphatases, which prevents killing of *Leishmania* by oxidative burst. This mechanism is based on a proton pump, which maintains the intracellular pH close to normal. This will consequently inactivate macrophage acidic enzymes and inhibition of lysoso-mal enzymes by lipophosphoglycan (LPG) molecules.⁶ Multiplication of the amastigotes results in macrophage rupture and release of the amastigotes, which will infect other cells.^{7,8}

Clinical manifestations of *Leishmania* infection depends upon *Leishmania* species and host genetic background, which generate immune responses. The outcome of *L. major* infection in murine model depends upon the type of immune response generated. Most strains of mice are resistant to *L. major* infection and develop a lesion similar to human CL, which heals spontaneously. Recovered mice are resistant to further infection and generate a Th1 immune response with high level of IFN- γ and low level of IL-4. On the other hand, *L. major* infection in susceptible BALB/c mice induces a progressive and eventually fatal disease with generation of Th2 response with high level of IL-4 and low level of IFN- γ .⁹

Leishmania infection induces both humoral and cellular immune responses, protection depends on generation of cellular immune response, and antibody level is very low in CL.

EPIDEMIOLOGY AND BURDEN OF DISEASE

Leishmaniasis is a widespread disease, which occurs in tropical and subtropical regions all around the world except Australia continent.¹⁰ From the 1.5-2 million annual worldwide new cases of leishmaniasis, 1-1.5 million cases are CL. CL is the most common form of leishmaniasis.¹¹ In CL, the lesion(s) is(are) confined to the skin usually on the

exposed parts of the body like arms, legs and face.^{12,13} CL is endemic in more than 70 countries and in some of them, an increase in the number of diagnosed cases over the past few years has been reported, which can be explained by better diagnosis and case notification, inadequate control of vector or reservoir, increased CL detection accompanied with opportunistic infections such as HIV/AIDS, and the emergence of antileishmanial drug resistance.^{10,14} Ninety percent of CL occurs in Iran, Afghanistan, Algeria, Brazil, Peru, Saudi Arabia, and Sudan.^{15,16} CL is increasingly seen in immigrants, military personnel, humanitarian aid workers, tourists and travelers who travel to areas where leishmaniasis is endemic.¹² CL emergence in Europe as a result of climate and environmental changes has been reviewed.¹⁷

CLINICAL FEATURES

Although different clinical classifications have been suggested for CL, it may be simply categorized to three main groups: localized, diffuse, and mucocutaneous. While the first two forms can occur in either OWCL or NWCL, the latter is more frequently associated with NWCL. Another form of CL which is known as leishmaniasis recidivans also exists.^{18,19}

LOCAL CUTANEOUS LEISHMANIASIS (LCL)

OWCL

Based on clinical appearance of the lesion(s), OWCL is commonly classified to dry and wet forms. The dry form, known as the anthroponotic CL (ACL) (Figure 28-1), urban, or late ulcerative form is caused by *L. tropica*, whereas the wet form (Figure 28-2), which is synonymous to zoonotic CL (ZCL), rural or early ulcerative form is caused by *L. major*.²⁰ The sandfly-mediated transmission

FIGURE 28-1 ACL lesion caused by *L. tropica* on the nose of a young girl in a CL endemic area in Iran. An erythematous plaque with erosions and adherent crusts are typical for ACL lesions also known as dry type CL.

FIGURE 28-2 ZCL caused by *L. major* on the dorsal surface of the left foot of a young Iranian man in a CL endemic area in Iran. The ulcerated plaque with a violaceous border and moderate exudate is typical clinical presentation of a well-developed large ZCL lesion.

of parasites is from animals to humans in ZCL and from human to human in ACL. In most cases of ZCL, the lesion usually heals spontaneously in less than one year, but most cases of ACL undergo spontaneous healing after 6-15 months with significant scars. ACL and ZCL may rarely coexist in the same patient.¹

NWCL

New World CL most commonly appears as LCL. In this form, there are one or multiple ulcers.^{21,22} The first lesion is a papule or pimple, which appears at the parasite inoculation site. Like in OWCL, this lesion grows and converts into an ulcer, which is covered by dried exudates. The ulceration may not happen and papules turn into nodules instead.¹⁷ Healing usually occurs spontaneously. Lesions caused by *L. mexicana* usually heal spontaneously in months; however, in cases of *L. brasiliensis*, the healing takes much longer.²³ Spontaneous healing of the lesions is usually associated with scar formation.

DIFFUSE CUTANEOUS LEISHMANIASIS (DCL)

Diffuse cutaneous leishmaniasis is a form of CL, which manifests with multiple lesions in at least two non-contiguous areas of the body. The dissemination should be distinguished from multiple inoculations. The lesions are non-ulcerative cutaneous nodules. Mucosal lesions inmate appear in less than 1/3 of patients.²⁴

MUCOCUTANEOUS LEISHMANIASIS (MCL)

There is a small risk that CL evolves into mucocutaneous leishmaniasis (MCL), especially in certain parts of America where some *Leishmania* species, which are able to cause

FIGURE 28-3 Amputation of nose, upper and lower lips caused by MCL in a Bolivian patient (Courtesy of Dr. Philippe Desjeaux).

mucosal lesions (Figure 28-3) exist.²² In some cases, the skin and mucosal lesions exist simultaneously, however, in Amazonian Brazil and when the causative agent is *L. braziliensis*, mucosal involvement is the result of an untreated old skin lesion in approximately 60% of cases.²¹

LEISHMANIASIS RECIDIVANS (LR)

This rare form of CL, which is also called lupoid leishmaniasis or leishmaniasis recidiva cutis, occurs in 3-10% of OWCL caused by *L. tropica* and is characterized by slowly progressive persistent lupoid papules or nodules which are recrudescent and occur in or around healed lesions (Figure 28-4). LR lesions may be persistent for 2-8 years and some reports have described seasonal variations in lesions. A great majority of lesions occur on the face but they can also occur on other parts of the body. LR has been reported as a rare type of NWCL with the same clinical presentation of LR in OWCL. *L. amazonensis*, *L. braziliensis* and *L. panamensis* have been reported as the causative agents of the New World LR.^{1,25,26}

DIFFERENTIAL DIAGNOSIS

Differential diagnoses of CL include bacterial infections such as furuncles, methicillin-resistant *Staphylococcus aureus* infections, ecthyma, and anthrax; mycobacterial infections including cutaneous tuberculosis in particular lupus vulgaris, leprosy, *Mycobacterium marinum* or other atypical mycobacteria; spirochetal diseases such as syphilis and yaws; fungal infections like sporotrichosis, paracoccidioidomycosis, histoplasmosis and blastomycosis. CL may mimic clinical features of both granulomatous inflammatory skin diseases like sarcoidosis and non-granulomatous inflammatory skin diseases like psoriasis and eczema. Skin cancers including squamous cell carcinoma, basal cell carcinoma, and malignant melanoma may also resemble CL lesions. Other differential diagnoses are

FIGURE 28-4 Leishmaniasis recidivans caused by *L. tropica*. Flesh-colored papules surrounding an old scar caused by ACL on the right cheek of a young Iranian man.

pyoderma gangrenosum, insect bite and hyperkeratotic lesions such as warts.^{22,23,26,27}

DIAGNOSIS

The history of traveling to endemic areas is an important factor in the diagnosis of leishmaniasis in countries where the disease is not endemic.²⁴

A direct smear from the periphery of an active lesion is one of the most commonly performed diagnostic methods. Detection of parasites inside macrophages is not always easy; macrophages and amastigotes inside them have diameters of 20-30 and 2-5 micrometers, respectively. The parasites inside macrophages are called Leishman, Donovan or Leishman-Donovan bodies. Leishman-Donovan bodies have a plasma membrane, a large basophilic nucleus, and a small, rod-shaped kinetoplastid extranuclear DNA from the flagellum base. The Giemsa stain is the method of choice for smears obtained from patients since using this technique, the flagellum will become bright red.²⁶ Culture on Nicolle-Novy-MacNeal (NNN) culture medium may increase the chance for detection of *Leishmania*. Histopathology may also be helpful. Recently, polymerase chain reaction (PCR) has been shown as an accurate test for diagnosis of CL through detection of *Leishmania* DNA.¹³

TREATMENT

Five therapeutic systematic reviews have been published for various forms of CL in 2007 and 2008²⁸⁻³². Although because of the heterogeneity of the primary studies, the level of evidence of these systematic reviews may not be as high as the level of evidence provided by the systematic reviews of homogenous randomized-controlled trials (RCTs), the authors believe that they are the highest available evidence on the treatment of CL (Table 28-1).

TABLE 28-1—Characteristics of Published Systematic Reviews on Treatment of CL/MCL Up to the Beginning of May 2010

Study	Searched resources and time period	Number of included studies (total number of patients)	Inclusion criteria	Exclusion criteria
Gonzalez et al., 2009²⁹ (NWCL)	Cochrane Skin Group Specialized Register—January 2009, Cochrane Central Register of Controlled Trials, (CENTRAL) issue 1–2009, MEDLINE (OVID)—2003 to January 2009, EMBASE (OVID)—2005 to January 2009, CINAHL—1982–May 2007, LILACS from its inception to January 2009, American College of Physicians (ACP) journal club—1991 to May 2007, ongoing trials, references of published studies, unpublished studies Adverse effects – MEDLINE (Ovid) – 1950–2007	38 (2728)	RCTs assessing the treatment of American CL or MCL Immunocompetent people having clinical presentation of American CL or MCL confirmed by proper diagnostic methods	Trials which were not clearly a RCT on American CL or MCL
Gonzalez et al., 2008³⁰ (OWCL)	Cochrane Skin Group Specialized Register—April 2008, MEDLINE (OVID) and MEDLINE(R) In-Process—2003 to April 2008, EMBASE (OVID)—2005 to April 2008, CINAHL—1982 to August 29, 2007; LILACS –from inception to April 2008, American College of Physicians (ACP) journal club—1991 to May 2007, ongoing trials, references of published studies, unpublished studies Adverse effects –MEDLINE (Ovid)–1950–2007	49 (5559)	RCTs Immunocompetent patients having OWCL whose clinical diagnoses were confirmed by one of these methods: smear, histology, culture or polymerase chain reaction	Leishmaniasis forms other than MCL MCL cases outside Latin America
Tuon et al., 2008³¹ (NWCL)	MEDLINE, LILACS, EMBASE, Web of Science—January 1966 to August 2006, Cochrane Library to 2006, bibliographic references, from the included studies, reference sections of primary studies, narrative reviews, and systematic reviews	54 (2969)	RCTs Giving data which enables comparison between cure and failure Providing information about internal and external validity Demographic data on population under study such as location of the patients and common species At least 5 patients in case series of treatments	Papers on MCL treatment from Latin America Giving data which enables comparison between cure and failure Providing information about internal and external validity Demographic data on population under study At least 5 patients in therapeutic case series
Amato et al., 2007³² (NWMCL)	MEDLINE—1966 to January 2007, LILACS - 1982 to January 2007, EMBASE—1966 to January 2006, Web of Science—1965 to January 2007, Cochrane Library to 2006, bibliographical references, from the included studies, reference sections of primary studies, narrative reviews, and systematic reviews	22 (635)	Papers on MCL treatment from Latin America Giving data which enables comparison between cure and failure Providing information about internal and external validity Demographic data on population under study At least 5 patients in therapeutic case series	Cases of patients who traveled tropical areas
Khatami et al., 2007³³ (OWCL)	Cochrane Central, Register of Controlled Trials - 3rd quarter 2006, Ovid, MEDLINE—1966 to July 2006, EMBASE—1980 to July 2006, Early online and other electronic, formats of article, manual search on all available issues of medical journals published in Iran up to June 2006, references of relevant articles and reviews, bibliographies of retrieved publications	50 (5515)	RCTs Therapeutic trials Trials in areas of OWCL endemicity or the study stated that patient had OWCL Trials on acute OWCL	Trials on vaccines and any preventive measure

NWCL, new world cutaneous leishmaniasis; RCT, randomized-controlled trial; MCL, mucocutaneous leishmaniasis (MCL); OWCL, old world cutaneous leishmaniasis.

Randomized-controlled trials investigating systemic and local therapeutic interventions for OWCL have been demonstrated in Tables 28-2 and 28-3, and those trials, which are concerned on local and systemic treatments for NWCL, are presented in Tables 28-4 and 28-5, respectively. Tables 28-6 and Table 28-7 have demonstrated systemic and topical studies on treatment of MCL, respectively (Tables 28-2 to 28-7.)

TREATMENT OF OWCL

A wide array of RCTs on therapeutic interventions have been included, critically appraised, and summarized in the systematic reviews of Gonzalez et al. and Khatami et al.^{30,33} The quality of conduct and report of most of those RCTs were low, so the validity of their findings was questionable. In addition, because of heterogeneity of the included studies, comparing different studies was not possible in many instances, which made the resulted evidence less robust in terms of strength of evidence.^{30,33} Also, it worth to mention that studies on some of the treatment modalities not included in these reviews or in the analysis, could have been proved to be potentially beneficial if they had been designed and/or performed appropriately.

In the following lines, some facts are briefly pointed out that healthcare professionals should pay attention to while thinking of interpretation of the results of the above-mentioned systematic reviews and choosing a medication to treat patients are briefly pointed out:

- The information about the outcomes assessed is not provided completely in all studies and the outcomes are not accurately addressed in all of them.
- Only about 35% of studies reported randomization and only 14% of studies properly reported allocation concealment methods.
- The degree of functional and esthetic impairment as well as scar prevention, and quality of life has not been investigated in the studies.
- There is a lack of good quality evidence on treatment modalities such as, amphotericin B, healing promoting therapies and alternative therapy.
- There are only a few high-quality studies amongst the ones investigated. As Gonzalez et al. and Khatami et al. have only ranked three and five studies, respectively, as high-quality studies in terms of randomization, allocation concealment, blinding and intention-to-treat; two were on *L. major* infections and one was on *L. tropica*-infected patients.^{30,33}
- There is still no ideal treatment profile of one drug able to treat different species without serious adverse effect.
- Majority of studies reported their primary outcome results at the end of treatment or less than 3 months after the end of the treatment and did not consider/report cure rates around or after 3 months.

- A few studies reported the cure rates as lesion-based and majority reported it as patient-based.^{30,33}

The treatments will be categorized in four major groups including pentavalent antimonials including meglumine antimoniate and sodium stibogluconate, paromomycin, azole agents, and miscellaneous treatments.

PENTAVALENT ANTIMONIALS

The pre-assumption that different regimens of antimonials are more effective than placebo in treatment of OWCL lesions, could only be proved with properly designed and performed RCTs comparing them in terms of efficacy and adverse effects; the evidence which is currently lacking. Having said that, it should be mentioned that for decades, these drugs have been the first-line agents for the treatment of leishmaniasis.³⁴ To the best of the knowledge of the authors and up to the date of writing, this chapter there is no placebo-controlled RCT, which has properly assessed the effectiveness of pentavalent antimonials in the treatment of OWCL.

The intraleisional administration of sodium stibogluconate has been found to be more effective than its intramuscular injections.³⁵ Other studied regimens or routes of administration of antimonials have not been reported to be significantly different from their comparator.^{36,37}

Paromomycin

Twenty-eight days of topical 15% paromomycin + 12% methylbenzethonium chloride twice daily has been found to be significantly more efficient than placebo.³⁸ In a recent meta-analysis, it has been reported that paromomycin is only effective when combined with methylbenzethonium chloride. Paromomycin efficacy was reported not to be significantly different from intraleisional antimonials.³⁹

Azoles

Oral fluconazole with the dosage of 200 mg/day for 6 weeks is found to be better than placebo for *L. major* infections.⁴⁰ When the causative agent is *L. major*, oral itraconazole with the dosage of 200 mg once daily for 8 weeks has been shown to be marginally more effective than placebo.⁴¹ However, when the causative agent was *L. tropica*, oral itraconazole at 200 mg/day for 6 weeks provides significantly higher cure rates in comparison to the placebo.⁴² Other regimens of azole agents were not therapeutically more effective than their respective control interventions.⁴³⁻⁴⁸

MISCELLANEOUS

Four weeks of photodynamic therapy (PDT) have been reported to be more effective in treatment of the OWCL

TABLE 28-2—RCTs of Local and Topical Treatments for OWCL Based on the Khatami et al. and Gonzalez et al. Systematic Reviews^{30,33}

Study (Country)	Sample size (experimental group(s))	Intervention(s) in experimental group(s)	Intervention(s) in control group(s)	FUD (Days)	Primary outcome	ARR (95% CI)*
Sadeghian et al., 2007 (Iran)	117 (57, 60)	Controlled localized heating with an radiofrequency (RF) heat generator (4 MHz, maximum output 90 W) to a surface temperature of 50°C for 30 seconds	IL MA 0.1-4 mL	180	Cure [†]	RR (95% CI): 0.72 (0.50-1.04) PB: 1.46 (1.18-1.80) LB: 1.42 (1.10-1.84)

TABLE 28-3—RCTs of Systemic Treatments for OWCL Based on the Khatami et al. and Gonzalez et al. Systematic Reviews^{30,33} (Continued)

Study (Country)	Sample size (experimental, control(s))	Intervention(s) in experimental group(s)	Intervention(s) in control group(s)	FUD (Days)	Primary outcome	ARR (95% CI)
Dogra, 1991 (India)	120 (60, 60)	Oral dapsone 100 mg every 12 hours for 6 wks	Placebo	45	Complete disappearance of induration/redness in nodular form or complete healing in ulcerative form + 3 consecutive NSs at 10-day intervals after completion of therapy, the first immediately after end of therapy	45.0 (27.9-58.5)
Al-Fouzan et al., 1991 (Kuwait)	24 (15, 9)	Oral itraconazole 100 mg bid for 6-8 wks	Placebo	105-140	>80% reduction of lesion size up to complete clearance	73.3 (34.2 - 89.1)
Dogra et al., 1990 (India)	20 (15, 5)	Oral single daily itraconazole, 4 mg/kg up to 200 mg/d for 6 wks	No treatment	90	Complete disappearance of induration or redness in nodular form Complete healing in ulcerative form+3 consecutive NSs at monthly intervals after therapy	66.7 (16.6 - 84.8)
Dogra et al., 1986 (India)	65 (50, 15)	Oral dapsone 2 mg/kg/d for 21 days	No treatment	201	Complete disappearance of induration or redness in nodular form or complete healing in ulcerative form + PC	80.0 (55.8-88.8)

*Gonzalez et al, defined cure when all inflammatory signs disappeared and complete healing through either scar formation or complete re-epithelialization occurred.³⁰ FUD, follow-up duration; ARR, absolute risk reduction; CI, confidence interval; IM, intramuscular; MA, meglumine antimoniate; wk(s), week(s); CR: cure rate; zinc sulfate; IL, intralesional; RR, risk ratio; qod, every other day; PC, parasitologic cure; IV, intravenous; SSG, sodium stibogluconate; LB, lesion-based; bid, twice a day; NS, negative smear.

TABLE 28-4—Topical Treatments for NWCL Based on Gonzalez et al. and Tuon et al. Systematic Reviews^{29,31}

Study (Country)	Sample size (experiment(s), control(s))	Intervention(s) in experimental group(s)	Intervention(s) in control group(s)	FUD (Days)	Primary outcome*	CR (%) or RR (95% CI)
Lobo et al., 2006 (Brazil)	37 (17, 20)	Single session of heat therapy	IV MA 20 mg/kg/d for 20 consecutive days	28	Cure	59.0 (Experiment) 10.0 (Control)
Soto et al., 2002 (Colombia)	45 (33, 12)	Topical WR279396 with 0.0005 mL/mm ² bid for 20 days	Placebo	200	Cure (70 days)	51.5 (Experiment) 47.1 (Control)
Arana et al., 2001 (Guatemala)	76 (38, 38)	Topical 15% paromomycin + 12% MBCL bid for 20 days	Topical placebo (white soft paraffin) ointment	365	Cure	2.38 (1.50, 3.80)
Neva et al., 1997 (Honduras)	53 (23, 30)	Topical 15% paromomycin + 10% urea tds for 4 weeks	Placebo	105	Cure (75 days)	4.3 (Experiment) 3.3 (Control)

*Based on Gonzalez et al, "Cure" has been defined as when all inflammatory signs have disappeared (either skin edema or hardening, or both), and that scarring or epithelialization has occurred in ulcerative lesions.²⁹ The figures in the parenthesis indicate the time point at which cure is defined in the primary study. FUD, follow-up duration; CR, cure rate; RR, relative risk; CI, confidence interval; qod, every other day; IV, intravenous; MA, meglumine antimoniate; bid, twice a day; MBCL, methylbenzethonium chloride; tds, three times a day.

lesions compared to placebo when the causative agent was *L. major*. It was also more effective than topical application of 15% paromomycin+12% methylbenzethonium chloride cream twice daily for 28 days.⁴⁹

Oral pentoxifylline has been found to be an appropriate adjuvant to intramuscular meglumine antimoniate therapy.⁵⁰ When the infection is caused by *L. tropica*, the heat therapy provides significantly higher cure rates compared to the intramuscular sodium stibogluconate but not to intralesional sodium stibogluconate.³⁵

Compared to intramuscular meglumine antimoniate, once weekly heat therapy for 4 weeks has been reported to result in significantly higher cure rates.⁵¹

Other treatment options including oral miltefosine,⁵² topical 5% imiquimod,^{53,54} and usage of honey as adjuvant to intralesional meglumine antimoniate injections,⁵⁵ have not been found to provide clinically or statistically significant results. RCTs conducted on oral allopurinol alone or combined with antimonials,^{56,57} and topical antifungal medications,^{58,59} did not show significant advantage of the experiments in comparison with controls too. Results of RCTs for oral and intralesional zinc sulphate were conflicting,^{60–63} as well as those of oral rifampicin.^{64,65} However, adding oral omeprazole to oral rifampicin has been reported to be significantly more effective than placebo in the treatment of OWCL caused by *L. tropica*.⁶⁶

Oral dapsone,^{67,68} combined cryotherapy-intralesional injection of pentavalent antimonials as well as one CO₂ laser RCT^{69–72} showed significant beneficial effects. This is the same for RCTs on trichloroacetic acid (TCA), Zerehsaz herbal extract (Z-HE) and healing promoting

measures.^{73–75} Results of RCTs on garlic cream, intralesional hypertonic saline solution and intralesional INF-γ were generally poor.^{76–78}

TREATMENT OF NWCL

Before beginning to discuss treatment options for NWCL and/or MCL, the authors would like to mention some points about Amato et al. systematic review.³² Considering the fact that almost all of the included studies in the aforementioned review were nonrandomized and/or uncontrolled, only two studies from their reviews are provided in Table 28-6. Using the critical appraisal skills programme (CASP) tool⁷⁹ for systematic reviews screening questions, this review did not have the proper design to be categorized as a systematic review of RCTs on treatment of ML. Hence, this review was excluded from the major resources used to write this section. The authors imagine that the following points have to be reminded with regard to Amato et al. review³²: (1) all except two studies were nonrandomized; (2) no study was blinded; (3) only half of the studies had inclusion criteria; (4) only 3 studies had exclusion criteria; (5) only 3 studies have been ranked by the authors as high quality studies; and (6) often because of the insufficient number of participants, no statistical analysis has been performed.

The general agreement based on the reviews of Gonzalez et al.²⁹ Tuon et al.³¹ and Amato et al.³² is that several factors such as treatment cost, adverse effects, local experience of clinicians, and availability of the medications should be considered in developing countries. These should be

TABLE 28-5—Systemic Treatments for NWCI Based on Gonzalez et al. and Tuon et al. Systematic Reviews^{29,31}

*Based on Gonzalez et al "Cure" has been defined as when all inflammatory signs have disappeared (either skin edema or hardening, or both), and that scarring or epithelialization has occurred in ulcerative lesions.²⁹ The figures in the parenthesis indicate the time point at which cure is defined in the primary study. † Studies in which both topical and systemic interventions have been used. FUD, follow-up duration; CR, cure rate; RR, relative risk; CI, confidence interval; qod, every other day; Sb, antimony; IV, intravenous; MA, meglumine antimoniate; IM, intramuscular; MBCL, methylbenzethonium chloride; bid, twice a day; SSG, sodium stibogluconate; GM-CSF, granulocyte colony stimulating factor; tds, three times a day; IFN- γ , Interferon gamma; qid, four times a day; wks, weeks; qd, daily; BCG, Bacillus Calmette-Guérin.

TABLE 28-6—Systemic Treatments of Mucosal Leishmaniasis (ML) Based on Gonzalez et al. and Amato et al. Systematic Reviews^{29,32}

Study & country	Sample size (experiment(s), control(s))	Intervention(s) in experimental group(s)	Intervention(s) in control group(s)	FUD (Days)	Primary outcome	RR (95% CI)
Llanos-Cuentas et al., 2007 (Peru)	38 (21, 17)	IM aminosidine sulfate 14 mg/kg qd for 21 days	IV MA 20 mg/kg in 250 mL 5%dextrose in water infused over a 20-minute period qd for 28 days	365	Cure*	0.05 (0.00, 0.78)
Machado et al., 2007 (Brazil)	23 (11, 12)	Oral pentoxifylline 400 mg tds for 30 days + IV SSG 20 mg/kg/d	Oral placebo orally tds for 30 days + IV SSG 20 mg/kg/d	730	Cure* at 4 months post-treatment	1.66 (1.03, 2.69)
Llanos-Cuentas et al., 1997 (Peru)	81 (40, 41)	IV SSG (20 mg of Sb ⁵⁺ /kg/d) plus oral allopurinol (20 mg/kg/d in 4 divided doses) for 28 days	IV SSG (20 mg of Sb ⁵⁺ /kg/d) for 28 days	365	Complete cicatrisation of the mucosal lesion 1 year post-treatment	0.62 (0.38, 1.03)
Franke et al., 1994 (Peru)	40 (20, 20)	IV SSG 20 mg/kg/d for 28 days	IV SSG 20 mg/kg/d for 40 days	365	Complete cicatrisation of the mucosal lesion 1 year post-treatment	0.83 (0.47, 1.47)

*Gonzalez et al. defined cure when all inflammatory signs disappeared and complete healing through either scar formation or complete re-epithelialization occurred.²⁹ FUD, follow-up duration; RR, relative risk; CI, confidence interval; IM, intramuscular; qd, daily; IV, intravenous; MA, meglumine antimoniate; tds, three times a day; Sb⁵⁺, pentavalent antimony; SSG, sodium stibogluconate.

considered while trying to figure out the best individualized therapeutic choice and management plan for every patient presenting with NWCL and/or mucosal leishmaniasis (ML).

Different types of treatment have been investigated in the above-mentioned systematic reviews. The Tuon et al. study is not a real systematic review of RCTs because less than half of all studies they have included are real RCTs.³¹

TABLE 28-7—Topical Treatments for NWCL Based on the Systematic Reviews of Gonzalez et al. and Tuon et al.^{29,31}

Study (Country)	Sample size (experiment(s), control (s))	Intervention(s) in experimental group(s)	Intervention(s) in control group(s)	FUD (Days)	Primary outcome*	RR (95% CI) or CR (%)
Lobo et al., 2006 (Brazil)	37 (17, 20)	Single session of heat therapy	IVMA 20 mg/kg/d for 20 consecutive days	28	Cure	CR: 59.0 (Experiment) CR: 10.0 (Control)
Soto et al., 2002 (Colombia)	45 (33, 12)	Topical WR279396 with 0.0005 mL/mm ² bid for 20 days	Placebo	200	Cure (70 days)	CR: 51.5 (Experiment) CR: 47.1 (Control)
Arana et al., 2001 (Guatemala)	76 (38, 38)	Topical 15% paromomycin + 12% MBCL bid for 20 days	Topical placebo (white soft paraffin) ointment	365	Cure	CR: 2.38 (1.50, 3.80)
Neva et al., 1997 (Honduras)	53 (23, 30)	Topical 15% paromomycin + 10% urea tds for 4 wks	Placebo	105	Cure (75 days)	CR: 4.3 (Experiment) CR: 3.3 (Control)

*Gonzalez et al. defined cure when all inflammatory signs disappeared and complete healing through either scar formation or complete re-epithelialization occurred.²⁹ FUD, follow-up duration; RR, relative risk; CI, confidence interval; CR, cure rate; IV, intravenous; MA, meglumine antimoniate; bid, twice daily; MBCL, methylbenzethonium chloride; tds, three times a day; wks, weeks.

The majority of the included RCTs in these reviews have been found to have moderate or low qualities and are prone to different kinds of bias. Therefore, the strength of resultant evidence is questionable.

Different treatment types will be categorized into four groups: pentavalent antimonials (meglumine antimoniate and sodium stibogluconate), paromomycin, azole agents, and miscellaneous treatments. As the authors have mentioned before in the treatment of OWCL section, there are some points, which need to be acknowledged while considering therapeutic options. In addition to the suggested points in the aforementioned section, the following should be considered regarding treatment of NWCL:

- The evidence on the therapeutic interventions for ML is limited and not substantial.
- There is lack of good quality evidence on treatment modalities such as azoles, amphotericin B, healing promoting therapies, and alternative therapy.
- Only about 30% and 13% of studies investigated by Gonzalez et al. properly reported randomization and allocation concealment methods, respectively.²⁹
- There are few high-quality studies amongst those included in the systematic review. Gonzalez et al. have only ranked two studies as high-quality studies in terms of randomization, allocation concealment, blinding and intention-to-treat. These studies were on patients infected with *L. mexicana*, *L. chagasi*, and *L. panamensis*.²⁹

PENTAVALENT ANTIMONIALS

Antimonials are still more effective than other therapeutic choices except pentamidine. Choosing between pentamidine and antimonials should be based on the region and the responsible species. It has been proposed that perhaps in cases of CL recurrence, pentamidine would be preferred to repeating antimonials.³¹

There are differences regarding drugs efficacy in different regions and with different *Leishmania* species. Based on the evidence from Colombia and Panama, when the causative organism is *L. braziliensis* or *L. panamensis*, intramuscular meglumine antimoniate and intravenous meglumine antimoniate do not increase cure rates when compared to placebo or no treatment.^{80,81} Intramuscular meglumine antimoniate does not provide significantly higher cure rates than placebo.⁸² No advantage is reported for either the 10-day or the 20-day regimens of intravenous meglumine antimoniate or intramuscular meglumine antimoniate when the causative agent is *L. braziliensis*, *L. panamensis*, or *L. mexicana*.⁸³ Also, 40 days of intravenous meglumine antimoniate treatment has no benefit over the 28-day regimen when the species is *L. braziliensis*. Other different dosages and/or regimens do not usually differ among treatment and control groups. This means that increasing or

decreasing the routine dosage and/or duration of treatment often fails to provide a clinical benefit over the current methods.⁸⁴⁻⁹³ However, there have been some exceptions to this fact, such as having significantly higher cure rates in 20-day intravenous meglumine antimoniate regimen versus 7-day intravenous meglumine antimoniate regimen when the organism is either *L. braziliensis* or *L. panamensis*.⁹⁴ In addition, when the organism is either *L. braziliensis* or *L. panamensis*, some additional benefits (i.e., synergism), are found while combining antimonial therapies with some other treatment modalities, such as combination of oral allopurinol and either intravenous meglumine antimoniate or intravenous sodium stibogluconate for 15 days or combination of oral pentoxyfylline and intravenous sodium stibogluconate for 30 days (*L. braziliensis* only). Other combinations including INF-γ, paromomycin 15% + methylbenzethonium chloride 12%, and imiquimod (5% or 7.5%) provided no extra benefit.²⁹

L. braziliensis, *L. amazonensis*, and *L. guyanensis* do not differ in terms of responding to antimonials.²⁹ This is true for other species as well; though they have not undergone analysis.

The branded meglumine antimoniate and generic sodium stibogluconate have been compared in terms of efficacy and side effects in few RCTs from Brazil and Colombia. They have been found to be equally efficient, although the sodium stibogluconate had more side effects.³¹

Tuon et al.³¹ have found no differences in terms of response to antimonials amongst the species they have found in their investigated studies (*L. braziliensis*, *L. amazonensis*, and *L. guyanensis*). There are some possible explanations for the differences observed in the response to antimonials in different regions and in different studies. These include: differences in host immunology, discrepancies amongst different *Leishmania* subspecies or strains, current diagnostic methods which can not define differences between *Leishmania* species (such differences have been shown using PCR), possible changes implemented by the *Leishmania* organism infected with *leishmania* virus, parasite intrinsic factors including its sensitivity to drugs, and primary resistance which is found in 14% of cases.³¹

Paromomycin (aminosidine)

Topical paromomycin in methylbenzethonium chloride provides significantly higher cure rates for *L. braziliensis* and *L. mexicana* infections when compared to placebo.²⁰ Tuon et al.³¹ do not suggest the isolated usage of topical paromomycin as a first-line therapy. A negative point with this drug is that it does not prevent the progression of CL into ML. However, when considering the fact that less than 5% of CL cases evolve into ML, the usage of paromomycin can be negotiated. A meta-analysis on the efficacy of paromomycin in comparison antimonials reported the odds ratios (ORs) (95% confidence interval [95% CI]) of

TABLE 28-8—Adverse Effects Reported in RCTS Conducted for OWCL Treatment Based on the Systematic Review by Gonzalez et al.³⁰

Intervention	Adverse Events
Pentavalent Antimonials (MA and SSG)	Pain at injection site, undefined local reactions, skin eruption, allergic maculopapular rash, sensitivity, pruritus, redness and swelling after the injection, edema, scaling at the periphery of site of injection, generalized muscular pain and weakness, sporotrichoid dissemination as satellite lesions, severe itch around the lesions, bradycardia or tachycardia, palpitation, local chest pain, headache, diarrhea, liver abnormalities, cough
Azoles (oral)	Nausea and vomiting, headache, dizziness, abdominal pain, increased liver enzymes
Paromomycin (topical)	Local reaction (inflammation, vesiculation, pain and/or redness), contact dermatitis, discharge, edema, pruritus, erythematous reaction, urticaria, lymphadenitis
Miscellaneous	
Allopurinol (oral)	Local reaction (inflammation, vesiculation, pain and/or redness), contact dermatitis, discharge, edema, pruritus, erythematous reactions, urticaria, lymphadenitis
Antifungals (topical)	Mild pruritus
CO² laser	Hyperpigmentation, persistent redness, hypertrophic scarring
Cryotherapy	Post-inflammatory hyperpigmentation, erythema, edema
Dapsone (oral)	Nausea, anemia
Healing promoting treatments	Drying of ulcers and skin surrounding them, mild burning sensation
Hypertonic NaCl (IL)	Pain at the injection site, sporotrichoid dissemination
Imiquimod (topical)	Moderate pruritus and burning sensation
INF-γ	Pain at the injection site, headache
Miltefosine (oral)	Nausea and/or vomiting, abdominal pain, diarrhea, cough, headache, pruritis, fever
Rifampicin (oral)	Elevated liver enzymes
Thermotherapy	Second-degree superficial burns
Zinc sulphate (IL)	Pain or burning sensation at injection site which can result in vasovagal shock inflammation
Zinc sulphate (oral)	Nausea and/or vomiting, leishmanid reaction and edema

MA, Meglumine antimoniate; SSG, sodium stibogluconate; IL, intralesional.

TABLE 28-9—Adverse Effects Reported in RCTS Conducted for NWCL Treatment Based on the Systematic Review by Gonzalez et al.²⁹

Intervention	Adverse events
Pentavalent antimonials (MA and SSG)	Myalgia, arthralgia, anorexia, malaise, mild-to-moderate muscle and joint stiffness, nausea, abdominal pain, headache, shortness of breath, mild elevations in liver enzymes, elevated triglyceride level, elevated creatine phosphokinase (CPK) level, fever, flu-like symptoms, pain at injection site, phlebitis at injection site, asthenia, pruritus, allergy, macular erythematous rash, herpes zoster, ECG abnormalities such as augmentation of QT interval in ECG, mild leucopenia, eosinophilia, and metallic taste
Azoles	Mild elevation of liver transaminases, fever, abdominal pain, nausea, headache, malaise, rash, dizziness
Paromomycin	Local pruritus, burning sensation, local pain, local edema, inflammation, soreness, redness, heat, exudation, fever, weakness
Miscellaneous	
Allopurinol (oral)	Mucocutaneous disease development within three months, headache, epigastric pain, eosinophilia, macular erythematous rash, herpes zoster, arthralgia, myalgia, fever and/or chills, abdominal pain, anorexia, thrombocytopenia
Aminoglycoside WR279396	Local reactions, moderate erythema

(Continued)

TABLE 28-9—Adverse Effects Reported in RCTS Conducted for NWCL Treatment Based on the Systematic Review by Gonzalez et al.²⁹ (Continued)

Intervention	Adverse events
Aminosidine sulphate	Increases in aspartate aminotransferase, myalgia, arthralgia, asthenia, anorexia, fever and/or chitis, pain at injection site
Imiquimod (topical)	Localized pruritus, erythema, edema, elevated liver enzymes, burning, local pain
INF-γ	Mild malaise, fever and/or chills and headache
Miltefosine (oral)	Nausea and/or vomiting, diarrhea, motion sickness, headache, increase in creatinine level, increases in aspartate aminotransferase or alanine aminotransferase
Pentamidine isethionate	Gastrointestinal events, musculoskeletal events, lesion pain, headache, paresthesia, weakness, fever and/or chills, bad taste, cough
Pentoxifylline (oral)	Nausea, arthralgia, dizziness, abdominal pain, diarrhea
Thermotherapy	Moderately severe local cellulites, superficial second-degree burn, secondary bacterial infection after treatment
Vaccine	Shallow necrosis and ulcers at inoculation site, headache, fever, bone and muscle pain, hypotension, cardiac rhythm disturbances, paresthesia, severe colic, pain at injection site

MA, meglumine antimoniate; SSG, sodium stibogluconate; ECG, electrocardiogram

0.25(0.12-0.49) and 0.55 (0.31-0.99) for topical and intravenous paromomycin, respectively.³¹ Ten days of topical paromomycin plus methylbenzethonium chloride plus 3 or 7 days of intravenous meglumine antimoniate had significantly lower results compared to intravenous meglumine antimoniate for 20 days. Topical paromomycin plus methylbenzethonium chloride plus 7 days of intravenous meglumine antimoniate had significantly higher results compared to this regimen for three days.⁹⁵ Other regimens or combinations of paromomycin did not result in significant differences.^{96,97}

A recent meta-analysis on topical paromomycin in CL has reported that topical paromomycin was less effective in NWCL compared to pentavalent antimonials. In addition, there was no significant difference between parenteral paromomycin and antimonials in terms of their effectiveness in NWCL.⁸⁰

Azoles

Although oral ketoconazole has been reported to be significantly more effective than placebo for treating NWCL caused by *L. panamensis* and *L. mexicana*, it provided no added benefit when compared to intramuscular meglumine antimoniate.⁸¹ Oral ketoconazole effectiveness was neither significantly higher than intramuscular meglumine antimoniate nor intravenous sodium stibogluconate.^{81,98} In a meta-analysis, the efficacy of azoles versus antimonials was investigated and an OR (95% CI) of 0.05 (0.01-0.09) was reported.³¹

MISCELLANEOUS

In infections by *L. braziliensis* and *L. panamensis*, there are controversial reports on the efficacy of oral allopurinol

when compared to antimonial therapy. One study reported that it was more efficient than intravenous meglumine antimoniate and than no-treatment, while it lost its effectiveness when combined with intravenous meglumine antimoniate. It had a synergistic effect when combined with intravenous meglumine antimoniate. Oral allopurinol plus intravenous meglumine antimoniate was reported to be significantly more effective than no treatment, while another study showed no significant difference in this regard. Also, allopurinol had significantly higher cure rates compared to no treatment.^{80,98,99} One study has reported that the aforementioned intervention even had lower efficacy in comparison with intramuscular meglumine antimoniate.⁸¹ It is a possibility that the route of prescribing antimonials is an important factor while assessing their efficacy versus allopurinol in a way that allopurinol has been more effective when antimonials are given intravenously and its efficiency decreases when antimonials are administered intramuscularly. In other regimens or combinations, there was no significant difference in primary outcome.^{87,100,101} In a meta-analysis the OR (95% CI) favoring allopurinol was 0.31 (0.18, 0.55).³²

There have been contradicting results about the efficacy of oral miltefosine in comparison with placebo. While one study showed significantly higher effectiveness, the other did not support this finding. This is possibly dependent upon the region and/or the species (*L. panamensis* vs. *L. braziliensis* and *L. mexicana*).¹⁰²

The suggested regimen for intramuscular aminosidine sulphate has been 18 mg/kg/d for 14 days since the 12 mg/kg/d regimen for 7 days has been shown to provide patients with lower cure rates. No other significant differences in terms of effectiveness or even lower cure rates has been reported for other intramuscular aminosidine sulfate regimens in other studies.¹⁰³⁻¹⁰⁵ The cure rate for intramuscular

aminosidine sulfate with the dosage of 14 mg/kg/d for 21 days was reported to be significantly lower than that of intravenous meglumine antimoniate with the dosage of 20 mg/kg/d for 28 days.¹⁰⁶

Intravenous pentamidine isethionate has been studied in cases of infection with *L. braziliensis* and there has been significantly lower cure rates for it when compared to intravenous meglumine antimoniate. Intramuscular pentamidine isethionate does not provide significantly higher cure rates compared to intramuscular meglumine antimoniate.^{105,107}

Topical aminoglycoside WR279396 did not show significantly higher cure rates compared to placebo.¹⁰⁸

Thermotherapy alone or in combination with antimoniais has not been proved to provide significantly higher cure rates than placebo or antimoniais.^{82,109}

Immunotherapy with vaccine and intradermal BCG have been found to have similar or significantly lower cure rates when compared to intramuscular antimoniais.¹¹⁰⁻¹¹²

Topical imiquimod 5% and 7.5% alone or combined with antimoniais, have been reported to have no significantly higher cure rates when compared to intravenous meglumine antimoniate in different species.^{113,114}

Subcutaneous INF- γ combined with intramuscular meglumine antimoniate has been reported to provide no higher cure rates compared to either 10-day or 20-day intravenous meglumine antimoniate.¹¹⁵

In the studies on the efficacy of topical or intralesional granulocyte macrophage colony stimulating factor (GM-CSF), combined with antimoniais compared to either placebo or intravenous antimoniais, no statistically significant difference has been reported.^{116,117}

A synergistic effect has been reported for oral pentoxifylline combined with intravenous sodium stibogluconate 20 mg/kg/d both for 30 days.¹¹⁸

ADVERSE EFFECTS

Gonzalez et al. have reported the adverse effects of therapeutic interventions, which was reported in the RCTs and included in their systematic reviews.^{29,30} These adverse effects are summarized in Tables 28-8 and 28-9 for the treatment of OWCL and NWCL.

SUMMARY

Despite existence of a large number of RCTs and publication of five systematic reviews, the bottom line of an evidence-based approach to the treatment of different types of CL can be summarized in the following sentence: "No high level evidence is available for the treatment of OWCL and NWCL." As Khatami et al. and Gonzalez et al. have mentioned in their systematic reviews, most of the conducted trials are of poor quality.^{29,30,33} Pentavalent antimoniais, which have been even considered as first-line treatment by some sources,¹¹⁹ can only be administered parentally, are associated with several adverse effects and not affordable for the majority of developing countries in which the disease is prevalent. Drug resistance to pentavalent antimoniai has also been reported and is an important issue for future research.^{120,121}

In order to combine the current best research evidence with some important practical issues regarding treatment of CL, an evidence-based clinical practice guideline has been developed in Iran, where it is endemic for CL because of *L. tropica* and *L. major*.¹²² In spite of its potential benefit for the country for which it has been developed, clinical practice guidelines should always be meticulously tailored for use in other countries.

Acknowledging the fact that still no effective and safe preventive intervention exists for CL, the need for

What We Know: Therapeutic Modalities for OWCL

Therapeutic modality*

Pentavalents antimoniais (either intralesional or systemic)

Topical paromomycin

Cryotherapy + intralesional meglumine antimoniate

Oral fluconazole

Oral itraconazole

Photodynamic therapy (PDT)

Thermotherapy

Oral pentoxifylline (as an adjuvant to intramuscular meglumine antimoniate)

Topical clotrimazole

Intralesional zinc sulfate

Other interventions

Strength of recommendation†

A

B

B

B

B

B

B

C

D

I

*All interventions are pertinent only for infection because of *L. major* with the exception of intralesional or systemic administration of pentavalent antimoniais, which may be used for infections attributed to either *L. major* or *L. tropica*.

† The strength of recommendations was addressed based on the U.S. Preventing Services Task Force (USPSTF) standards.¹²⁵

What We Know: Therapeutic Modalities for NWCL/MCL/ML

Therapeutic modality*	Strength of recommendation†
Systemic pentavalent antimonials	A
Topical paromomycin	B
Oral ketoconazole	B
Oral allopurinol (as an adjuvant to either intravenous meglumine antimonate or sodium stibogluconate)	C
Oral pentoxifylline (as an adjuvant to intravenous sodium stibogluconate)	C
Other interventions	I

*All interventions are pertinent for infections due to *L. braziliensis*, *L. panamensis*, or *L. mexicana* except oral pentoxifylline which is only pertinent to infections caused by *L. braziliensis*. Often modalities have been studied on other species as well including *L. guyanensis*, *L. peruviana*, and *L. chagasi*; however, these species have been investigated in fewer studies.

† The strength of recommendations was addressed based on the U.S. Preventing Services Task Force (USPSTF) standards.¹²⁵

properly designed, conducted, and reported RCTs with large sample size and clinically meaningful outcome measures is obvious. Performing such RCTs and consequently conclusive systematic reviews through updating current ones and or conducting new ones cannot be overemphasized for providing reliable strong evidence for treatment of this neglected but important disease.^{8,33,123,124}

Treatment of Head Lice

29

Terri Lynn Meinking, M.D., Ph.D.

INTRODUCTION

Head lice, are bloodsucking, wingless insects belonging to the order Anopura.¹ Pediculosis, the infestation of humans by lice, has been documented for thousands of years.² They are host specific so, *Pediculus humanus capitis*, the head louse, cannot be transmitted to or from pets or other animals.

Infestation with head lice is on the rise in the United States and worldwide. Well over a decade ago it was estimated that \$367 million was spent annually on the eradication of 12 million infestations in the U.S. alone.³ However today, because of the accelerating rate of resistance to most over-the-counter (OTC) pediculicides and the fact that patients use these remedies an average of five times before seeking treatment from a healthcare professional, no one can be sure how large that Infestation rate has grown.⁴

EPIDEMIOLOGY

School-aged children between 3 and 11 years, as well as their immediate contacts (such as day care providers, playmates, and family members) remain the most likely targets for infestation. The relatively high incidence of head lice in this group is probably related to head-to-head contact during play and the sharing of objects to which lice cling (e.g., naptime, combs, brushes, hats, barrettes, helmets, head phones, and other head gear). Mumcuoglu et al. found that children with longer and medium hair length were more often infested than children with short hair.⁵ In contrast to body and crab lice, which have given head lice a bad reputation, they are not linked to poverty, poor living conditions or refugee status, and are most commonly found in individuals in good health, with good hygiene and grooming habits.⁶

In the United States, head lice infest all levels of society and most ethnic groups. They can be found among Caucasians, Asians, Hispanics, and North, Central, and South American Indians. In the past the notable exception was the African-American population, where prevalence was so low that it was recommended that this ethnic group be excluded from prevalence estimates. In a 1977 study, Juranek found pediculosis capitis in only 0.3% (6/1853) of African-American children compared with 10.4% (573/5513) of other races.⁷ It is believed that the head louse indigenous

to this part of the world is not well adapted to grip the oval-shaped hair shaft characteristic of the hair found in the African-American population.⁸ In Africa, where the head lice have claws adapted to tightly curled, oval-shaped hair, pediculosis capitis is a serious problem among blacks.⁹

However, we have seen an increase in cases in this population in recent years. In our experience, in the Miami area more African-American children are infested with lice than in the past, and anecdotal evidence suggests that this may be an emerging trend nationwide. This may be attributed to the adaptation of the louse, changes to the hair structure caused by the blending ethnicities of the host as well as the increased global travel of mankind. Although the prevalence among African-Americans seems to be increasing, infestation in this population is still well below that in other races in the United States.

ETIOLOGY AND DIAGNOSIS

Pediculosis capitis is the term applied to infestation of the scalp by the human head louse, *Pediculus capitis*. Individual sites of feeding are difficult to see. There may be signs of irritation in the form of erythema, scaling, scabbing, pyoderma and the periphery of the hairy areas may exhibit linear excoriations. Pruritus is a common symptom in subjects who have had head lice for several weeks, but first-time infestations may not produce any symptoms. Individuals who have had previous episodes usually develop pruritus within 48 hours of exposure. Some conditions that can give a false diagnosis of pediculosis include contact or seborrheic dermatitis, insect and mite bites, eczema, psoriasis, or piedra.

Most cases of head louse infestation in schools are first detected by observations of one or more children scratching their heads. Closer scrutiny may reveal nits adherent to the hairs. Usually, these are the whitish to sandy-colored empty shells of eggs that have hatched. It is common for desquamated epithelial cells (DEC) or pseudonits (commonly known as "hair muffs" or hair casts) to be mistaken for eggs. Newly laid or viable intact eggs are more difficult to see, and may be tan to coffee-colored or darker with a black "eye spot".¹⁰ In colder climates viable nits will be found close to the scalp. However, this may not be true in warmer climates where body heat is not needed for incubation and may actually provide too much heat.¹⁰

As soon as a nit hatches, the 1st instar nymph, which is only 0.5 mm in length, will travel to the scalp to feed and stay for approximately 6 days. As it grows to adulthood, it becomes more adventurous and travels around the scalp and hair. The most definitive tool for diagnosis is the identification of live lice. However, because lice move quickly, avoid light, and tend to take on the hair color of their host (i.e. blonds will have lighter lice than brunettes), lice can be difficult to find. The most common places to find them are behind the ears and at the nape of the neck.¹¹

LIFE CYCLE

Just before hatching, the louse embryo uses its chitinous mouth parts to cut a hole in the operculum (the cap of the egg), which always faces away from the scalp. The newly emerged baby louse, also known as a nymph or “instar”, must feed on human blood shortly after hatching to avoid starvation or dehydration, and will feed on blood every 4 to 6 hours for the remainder of its life. Lice rarely live for more than 24 hours away from the host without a human blood meal.¹² The louse goes through three stages of development which each last 3 to 4 days, prior to reaching adulthood. During this development, the first, second and third instar stages, the louse molts, and casts off its exoskeleton to reveal a new one.

The sex is not determined until adulthood, approximately 9 to 12 days after hatching. The appearance and shape of the two different sexes are distinctively different. Females are usually 20% larger than males, although variations can occur. Females are not only usually longer, but wider and rounder than males, with a posterior portion that terminates in two protrusions, creating an invaginate V shape. The abdomen of females contains one to three fully formed eggs and the female head louse will lay 5 to 10 eggs a day throughout her lifetime of about 30 days. By contrast, the smaller male has a rounded posterior and brown bands across the back that darken with age. Adult lice are approximately the size of a sesame seed, ranging from 2.1 to 3.3 mm.¹¹

DISEASE TRANSMISSION

Unlike body lice, head lice, are not known to be vectors of disease. However, head lice have been shown to transmit *Staphylococcus aureus* and group A *Streptococcus pyogenes*.¹ In a homeless population in California, Bonilla et al. found that 25% of head lice-infested persons had lice pools infected with *Bartonella quintana* strain Fuller, the bacterium that causes trench fever in humans.¹³

TREATMENTS

Effective treatments to remove lice and nits include include nit-combing, brushing, and/or application of pediculicides (Table 29-1). Most pediculicide products currently

available in the United States kill lice but not their eggs. Therefore, if lice are present 8-12 days later, a second treatment should be applied to kill any nymphs that may have hatched from eggs that survived the first treatment.

The rise in head lice resistance to OTC products currently makes treatment options difficult. The active ingredients of the pediculicidal products currently available in the United States include lindane, natural pyrethrins, permethrin, and malathion. These and other alternative head lice treatments and emerging products are discussed in detail below.

Prescription Products

Benzyl Alcohol Lotion 5%

The non-pesticide asphyxiant, Benzyl Alcohol Lotion 5% (Ulesfia™) is the first head lice treatment to be approved by the Food and Drug Administration (FDA) since 1986. It is approved for two 10-minute treatments applied 1 week apart. Scanning electron micrographs (SEM) indicate that unlike other asphyxiants which cause the louse to simply close down its respiratory system, Benzyl Alcohol Lotion 5% (BAL 5%) suffocates lice by stunning the apparatus open allowing the vehicle to infiltrate and decimate the “honeycomb” structure lining the breathing spiracle.¹⁴ Clinical trials showed two treatments of BAL 5% to be 75% effective. This novel nontoxic pediculicide can be used on the most vulnerable populations including children as young as 6 months of age. This product is an easy to use water-based lotion with a consistency similar to hair conditioner.

Malathion

Malathion is an organophosphate and an irreversible cholinesterase inhibitor. Illnesses linked to agricultural use of this pesticide have raised concerns about its toxicity in humans. However, the high grade of malathion used for the treatment of human pediculosis is very different from the grade used for agricultural or veterinary purposes.¹⁵

In the United States, 0.5% malathion lotion (Ovide®; originally known as Prioderm®) is the quickest acting and most ovicidal of any pediculicide developed in the last 30 years.^{16,17}

Ironically, despite its quick action, Ovide® is labeled for a relatively long application time. Because the original malathion studies for FDA approval involved an 8-12 hour application, this became the recommended treatment protocol. The 78% isopropyl alcohol content, longer application time, and limited use to 6 years and older, are potentially undesirable attributes. We found that a reduced application time of 20 minutes is equally effective and is significantly more pediculicidal and ovicidal than Nix®.¹⁸

Resistance to malathion products other than Ovide® has been documented in many countries including England.¹⁹ In the UK and other countries where two products have been combined, such as malathion and permethrin, lice are still resistant. So far there are no documented cases of resistance in the United States. Lice in the USA may have remained sensitive to malathion because this product is not as readily available as it is in the UK and other countries, where it can be purchased over the counter. Also, the formula available in the United States is different than in other countries and incorporates a resistance strategy component.

Lindane

Lindane 1% (gamma-benzene hexachloride, GBH, GBHC, formerly known as Kwell®) has been available as a shampoo for the treatment of head lice for more than 50 years. Although 1% lindane shampoo is simple to use, with a recommended treatment time of only 4 minutes, it has serious drawbacks. Lindane belongs to the class of chemical insecticides called organochlorines, which also includes DDT. These insecticides do not degrade and thus persist in the environment for decades. Lindane rinsed off after use passes through the sewer system into creeks, rivers, lakes and oceans, where it can contaminate drinking water, the tissues of fish and wildlife, as well as farm soil. For these reasons, California banned the sale of all lindane products in that state beginning in 2002. Lindane not only persists in the environment but also accumulates in the body, especially the central nervous system, creating the potential for risk of serious neurotoxicity.^{20,21}

One disadvantage of lindane for treatment of head lice is its slow killing time which can last up to 6 hours. Additionally, lindane has a high treatment failure rate, because of tolerance or resistance in lice. In 2003 the Food and Drug Adminstration (FDA), "black boxed" lindane, meaning that its website and labeling warns against using the product because of toxicity, specifically for anyone under 110 lbs.²² In view of the many negative aspects of this pediculicide, it is difficult to see the advantage of future lindane use, particularly when several other less toxic and more effective treatments are available.

Carbaryl

Carbaryl (1-naphthyl N-methylcarbamate, marketed as Carylderm, Derbac, Sevin, and generics) is a prescription second line treatment for pediculosis capitis in the United Kingdom and Australia, where it is available in both a 0.5% lotion and a shampoo formulation. It is a reversible cholinesterase inhibitor with an objectionable odor. Like lindane, it has been banned for both human and agricultural uses in many countries.

Prescription Products Off-Label

Ivermectin

While the FDA has approved oral ivermectin for the treatment of internal parasitic infections onchocerciasis and strongyloidiasis, this drug does not have an FDA-approved indication for the treatment of head lice. However, ivermectin has been used "off label" for pediculosis treatment when all other treatments have failed. Since the half-life of ivermectin in the bloodstream is only 16 hours, it is necessary to give more than one dose in order to kill nymphs that hatched from the eggs. Ivermectin is not ovicidal.

Unpublished studies by Meinking et al.^{23,24} conclude that oral ivermectin is safe, well tolerated and most effective in killing head lice at the dose of 400 µg/kg, on days 1 and 8.

Cotrimoxazole

Reports have appeared suggesting that oral administration of cotrimoxazole (sulfamethoxazole/trimethoprim, TMPX, Septra, Septrin, Bactrim and different names in various countries) is an effective treatment for pediculosis capitis.^{25,26} Because lice are obligate blood feeders and are dependent on their symbiotic bacteria for survival, these reports may indeed have merit. However, this is not a fast-acting pediculicide and it should only be prescribed when pyoderma, ear infections, and other indications for this antibiotic warrant it.

Cotrimoxazole is a valuable antibiotic combination that should be reserved for significant infections. Also, in rare cases, this drug may produce harmful side effects, including allergic reactions, aplastic anemia, toxic epidermal necrolysis (TEN), and blood dyscrasias.

Prescription Products in Development

Topical Ivermectin

Topical ivermectin for the treatment of head lice was found to be effective in Alexandria, Egypt. 1% ivermectin lotion had a curative effect on head lice after a single application. Youssef et al.²⁷ reported that a single application of 0.8% ivermectin lotion was effective in treating head lice in all 25 patients treated with clearance of lice within 48 hours after application. A 0.8% ivermectin shampoo was more effective than a shampoo containing 1% lindane in 208 Columbian patients.²⁸ Even though more clinical trials are needed to confirm this efficacy, topical ivermectin provides a promising alternative therapy for head lice, particularly with resistance to current available topical treatments on the rise.²⁹

Spinosad

Spinosad has been approved by the Environmental Protection Agency (EPA) as a crop protection product in

TABLE 29-1—FDA-Approved Therapy for Head Lice Infestations

Approved Therapy	1% Lindane	0.5% malathion	Natural pyrethrins with PBO	1% permethrin	Ulesfia™ (benzyl alcohol) Lotion
Pediculicide Classification	Organochlorine	Organophosphate	Plant extract with synergist (piperonyl butoxide)	Synthetic pyrethroid	Asphyxiant
Recommended application time	4-10 minutes (two applications one week apart)	Package insert 8-12 hours, effective in 20 minutes	10 minutes (two applications one week apart)	10 minutes (two applications one week apart)	10 minutes (two applications one week apart)
Killing time	6-24 hours	5-20 minutes	3-28 hours	3-30 hours	10-30 minutes
% Ovicidal activity	10-24	98-100	30-60	30-70	70-80
Residual activity	No	Yes-only if applied for at least 6 hours (not recommended)	No	Yes-only in sensitive populations	No
Cosmetic acceptability	Fair	Poor	Good	Good	Excellent
LD 50 mg/kg (rats)					
Oral	88	2800	584 - 900	3185	1230 – 3200
Dermal	1000	4400	1500	Over 5000	NA*
Adverse properties	Banned in some states/countries due to contamination of drinking water, CNS toxicity, overuse due to ineffectiveness, delusions of parasitosis	Irreversible cholinesterase inhibitor, flammable, unpleasant odor	Allergic reactions in people with certain flower allergies	No substantial reports	No
Resistance Reported	Worldwide	Europe, Middle East, and other places worldwide (not USA)	USA and other countries worldwide	USA and other countries worldwide	No
Trade names	1% Lindane Shampoo	Ovide (USA only)	RID and generic versions (generics are more effective)	Nix crème rinse and generics	Ulesfia™ (benzyl alcohol) Lotion

*No dermal LD₅₀ were conducted in rats. In rabbits, 10% solution of benzyl alcohol did not produce dermal irritation after a single 24-hour exposure. The MTD of benzyl alcohol in rats when administered dermally was 1000 mg/kg/day.

the United States, Canada, and Australia, and has received provisional approval in the UK, Spain, and several other European Union countries. In 2002, the National Organic Standards Board approved Spinosad's use in the production of certified organic foods. The product is used to eliminate pests in crops. It is not based on a synthetic compound, but on bacteria that occurs naturally in soil in the Caribbean. Phase III trials found spinosad, without combing, well-tolerated and demonstrated superiority to 1% permethrin with combing. The results of the trial found a total of 84.6% (study 1) and 86.7% (study 2) spinosad-treated subjects lice-free 14 days after final treatment and the majority one treatment only.³⁰

Over-the-Counter Products

Pyrethrins (natural plant extracts)

Extracts of the flower heads of *Chrysanthemum cinerariaefolium* contain a mixture of active agents called natural

pyrethrins, which include pyrethrin I, pyrethrin II, jasmolin I, jasmolin II, cinerin I, and cinerin II. These extracts are available in lotion, shampoo, foam mousse, and gel formulations that also contain the synergist piperonyl butoxide (PBO; RID®) is a natural extract. All natural pyrethrin products manufactured since 1950 are combined with piperonyl butoxide (PBO), which has insecticidal properties of its own, greatly enhancing the activity of pyrethrins and reducing the amount necessary while providing the same activity. Originally, it was added purely for financial reasons but it has been found to block the mixed function oxidase (MFO) pathway of resistance. The active agents in the pyrethrum flowers are extracted with kerosene or petroleum distillates, which may cause eye irritation. The natural pyrethrins demonstrate low mammalian toxicity (600–900 mg/kg oral, 1500 mg/kg dermal calculated as LD₅₀). They suffer, however, from poor stability to heat and light and have no residual activity.

None of the natural pyrethrin pediculicides are totally ovicidal. Twenty to 30% of the eggs of the head lice remain

viable after treatment.^{16,31} This necessitates a second treatment 7–10 days later in order to kill newly emerged nymphs, hatched from eggs that survived the first treatment.

Apart from the inconvenience and expense of having to treat twice, there is no evidence that multiple treatments with pyrethrins is hazardous. As with all topical agents, repeated use invites the development of cutaneous allergic reactions, contact dermatitis, and dry itchy scalp, which may be mistaken as a treatment failure.

Permethrin (a synthetic pyrethroid)

By synthesizing and modifying the molecular structure of natural pyrethrins, chemists were able to develop compounds called pyrethroids. Permethrin (3-phenoxybenzyl(1, 2)-3-(2,2-dichlorovinyl)-2,2 dimethyl cyclopropane carboxylate), is the first heat and light-stable synthetic pyrethroid, and has even lower mammalian toxicity than natural pyrethrins. Based on oral studies in animals, this compound is about three times less toxic than natural pyrethrins and approximately 36 times less toxic than lindane.

In the United States, permethrin is available as a 1% cream rinse (Nix®, generics). In some other countries, preparations of both strengths are available over the counter. The 1% permethrin creme rinse (Nix) has been approved by the FDA for the treatment of pediculosis since 1986. This product has undergone more clinical trials and toxicology studies than any other pediculicide on the US market. Like the natural pyrethrin products, Nix® is not completely ovicidal; approximately 20–50% of viable eggs hatch after treatment. Also, although residual permethrin on the hair once killed nymphs soon after they hatched, this is no longer the case. They have become resistant to any residual effect. Data from the U.S. and numerous countries indicates that resistance has become a worldwide problem.³² Recent studies in the United States have not only confirmed the existence of permethrin resistance, but also traced this resistance to specific genetic mutations in lice.³³ Because of the prevalence of resistance, it has become necessary to apply Nix® two times, 1 week apart. However, even with two applications, Nix often is not effective in killing lice.¹⁸

Dimethicone

Dimethicone is a silicone-based treatment that is currently marketed in different concentrations and solutions in various parts of the world. Burgess³⁴ found that two applications of 4.0% dimethicone lotion cured 70% of study participants of head lice infestation. The product was kept on the hair for 8 hours or overnight. A second application is necessary because dimethicone is not ovicidal. Nymphs that hatch since the first application must be treated with a second application 1 week later. The product is applied to dry hair and shampooed or brushed out. Like benzyl

alcohol lotion 5%, dimethicone seems less irritating than existing treatments and has a physical action on lice that should not be affected by resistance to neurotoxic insecticides. However, it is not FDA approved and has not been tested for children younger than 4 years of age and because it is an emollient; very high concentrations of it are slippery, and special care should be taken to avoid spillage and injury from slips and falls.

Alternative Products

Since many frustrated parents and health professionals are reluctant to apply pesticides to children's heads, they have turned to alternative therapies to battle head lice.

Many claim to have successfully cured their infestations by using inexpensive, readily-available products from the grocery or health food store. There is no doubt that oily alternatives slow down the lice and make them easier to find and comb out. However, when these alternatives are rinsed off the next morning, the lice usually survives. Petroleum jelly (Vaseline) and mayonnaise are two alternative treatments that should be avoided, but for different reasons. Vaseline leaves behind a waxy residue that disguises the visual impact of nits. It also leaves the hair tacky, causing lint and other substances to stick to it. Mayonnaise, on the other hand can be dangerous. When left on the hair for a period of time, particularly in warm climates, it has been known to drip and get into the mouths of children, thus causing food poisoning.

Nit Picking

It is common practice to comb or “nit pick” through the hair after treatment to remove lice and nits. Nit removal is important for two main reasons. First, it removes an outwardly visible sign of head lice infestation, thus preventing stigmatization. Second, because no pediculicide kills 100% of eggs, manual nit removal is recommended to eliminate any nits that may have survived treatment.

However, many school authorities in the United States insist upon a “no nit” policy to ensure freedom from infestation and proof of adequate treatment. Under this policy, children with visible nits are sent home and parents are required to treat them so that they are nit-free before returning to school. However, this strategy does not work. Visible nits does not mean “viable” nits, nor does it necessarily mean the presence of live lice or an active infestation. Often what is identified by school officials as nits, are previously hatched out egg casings or displaced sebaceous plugs, also known as pseudonits. These desquamated epithelial cells encircle the hair and are usually the same size and color as a nit.

Neither the American Academy of Pediatrics (AAP), nor the Center for Disease Control (CDC)³⁵ recommends the “no nit” policy. In an AAP article, Frankowski et al.

What We Know

- Head lice are not a result of poor hygiene.
- The population most vulnerable to head lice infestation is children 3 to 11 years of age.
- Head lice are hemimetabolic in development, meaning that they do not go through a complete metamorphosis and that the larval stage of a louse merely looks like a baby adult. The life cycle of the louse is as follows:
 - It takes the egg 8 to 12 days to hatch,
 - The first “instar” or nymph takes 3 to 4 days to molt to the
 - Second “instar”, which then takes 3 to 4 days to molt to
 - The third “instar”, which takes 3 to 4 days to molt to
 - An adult (9 to 12 days after hatching) at which point its sex is determined,
- 2 days later it begins to copulate.
A louse lives approximately 30 days.
- Head lice have six legs and 14 breathing spiracles.
- Head lice do not fly.
- Unlike crab and body lice, head lice are not known for being vectors of disease, however they have been shown to transmit *Staphylococcus aureus* and group A *Streptococcus pyogenes*.¹ In a homeless population in California, Bonilla et al. found that 25% of head lice-infested persons had lice pools infected with *Bartonella quintana* strain Fuller, the bacterium that causes trench fever in humans.¹³
- Worldwide resistance has been a problem for decades. However, the introduction of new treatments seeking approval by the FDA offers hope of alleviating this problem for the future.
- Head lice can live 15 to 24 hours without a blood meal.

cited a study that followed 1729 school children screened for lice. Only 31% of the 91 children who had nits, also had live lice. And only 18% of those with nits alone developed to an active infestation over 14 days of observation.³⁶ Furthermore, banning children from attending school based on the presence of nits often results in parents missing work, which can create economic hardship for families. It is not necessary to cut long hair or shave the head to manage a head lice infestation. While such measures may ease the task of looking for and removing nits, the possible psychologic damage done by such shearing should override any potential benefits.

CONCLUSION

When head lice are found, parents often get angry or anxious and may even blame their child. Practitioners can help alleviate family anxiety and stigmatization by not only prescribing treatment, but easing blame and passing on some common sense. For example:

1. Head lice infestation is not caused by poor hygiene. It is most likely that the infestation occurred as a result of head-to-head contact, a sleep over, or a shared hat or batting helmet. Family members should be advised to avoid these behaviors in the future.
2. In addition to treating the family member(s), wash and dry their sheets, pillow cases, and towels.
3. Vacuum once.
4. Remember that lice do not last for more than 36 hours without a blood meal, nor do they fly. It is unlikely that lice will be found away from the hair on inanimate objects such as carpets or couches, and if they are, they will not live long. Don’t make yourself crazy cleaning.

Concentrate on monitoring the hair and scalp of the infested family member(s) and their siblings.

Treatment of Scabies

30

Hermann Feldmeier, M.D.

SEARCH METHODOLOGY

Data for this chapter were found through searches of Medline and Lilacs databases using the keywords "scabies" in combination with "treatment". Additionally, reference lists of retrieved articles were searched. No date restrictions were set in these searches. Articles in English, French, German, Spanish, and Portuguese were analyzed. References found in textbooks on parasitic skin diseases, and tropical medicine were also used. As a rule, only controlled clinical trials were included in this analysis.

INTRODUCTION

Scabies is an intensely pruritic skin disease caused by the infestation with *Sarcoptes scabiei var. hominis*. In industrial countries, the infestation occurs sporadically or in epidemics, such as in hospitals, nursing homes, or prisons. In the developing world, particularly in resource-poor urban and rural communities, the infestation is endemic. Globally, 300 million people are supposed to suffer from scabies.¹

Transmission of *Sarcoptes* mites requires intimate body contact such as between a mother and her child, during sexual intercourse, or when children play together with their body only partly covered by clothes. The role of fomites in transmission is discussed controversially.

TREATMENT OVERVIEW

Clinically, scabies presents in a variety of manifestations. There is reason to assume that scabies is an immune-mediated spectral disease with nodular scabies at one end of the spectrum and disseminated crusted (Norwegian) scabies at the other end². Depending on the immune competence of the host the propagation of the parasites is almost completely abrogated at one end of the spectrum (nodular scabies) and at the other end remains uncontrolled (disseminated scabies). Hence, for optimal treatment the immune competence of the patient has to be taken into consideration.

Immediate treatment of the patient, together with treatment of close contacts are the principles of case management. As contacts may be infested without presenting

signs or symptoms, they should be treated, independently whether scabies is suspected or not. Superinfection should be treated with a topical antibiotic.

Two to four weeks after treatment the patient has to be re-examined. Even after successful elimination of all mites, pruritic papules and nodules may persist for months. Another explanation of persisting itch and for eczema after effective therapy is the development of a contact dermatitis caused by the topical acaricide.

As compared to other parasitic skin diseases, evidence which treatment is optimal for a defined clinical condition or in a certain setting is rather scarce. A recent systematic review identified twenty small trials involving 2392 patients, the majority performed in developing countries.³ Methodologic quality varied considerably between trials. Only two trials described both adequate randomization sequence generation and adequate allocation concealment and the majority of the reports described neither adequately. The degree of blinding was unclear in eight of the 20 identified trials, and losses to follow-up were greater than 20% of the enrolled participants in three of the trials. The studies differed considerably with regard to setting, disease prevalence in the population, intensity of the infestation, outcome measure (such as parasitological cure, resolution of lesion, decrease of pruritus, etc.) and length of follow-up. This is of importance, since it may be expected that in an endemic area, reinfection is common and that reinfection may be indistinguishable from primary treatment failures.

Moreover, treatment regimen varied between the trial sites. For instance, benzyl benzoate was used in concentrations from 10% to 25%, and oral ivermectin was given in a single dose of 100 µg/kg, but also in two doses of 200 µg/kg given 8 to 10 days apart. Hence, although the studies analysed by Strong and Johnstone³ fulfilled the prerequisites of a randomized, controlled trial, reported cure rates have to be regarded with caution.

An overview of current treatment options is given in Table 30-1. Since the effectiveness of the various compounds seems to depend on the setting, treatment recommendations vary from country to country, and the selection of a drug is often based on the personal preference of the dermatologist, local availability of the drug and cost, rather than on sound evidence.

TABLE 30-1—Overview of Current Treatments for Scabies

Substance	Dosage	Advantages	Useful in Special situations	Resistance Known	Contraindications/disadvantages
Lindane	0.3-1% lotion or cream	Effective, inexpensive	No	Yes	Pregnant women, children/severe neurotoxic adverse events, particularly in children; substance is stored in fat cells and breast milk
Benzyl benzoate	10-25% ointment	Effective, inexpensive	Resource-poor settings	No	Pregnant women, infants/can cause severe skin irritation
Sulfur in petrolatum	2-10% liquid	Inexpensive	No	No	Infants, children/noxious and malodorous; may cause skin irritation; multiple treatments required; lack of safety and efficacy data
Crotamiton	10% ointment	Antipruritic and antibacterial activity; usually well tolerated	Infants	Yes	Multiple treatments necessary; efficacy questionable
Permethrin	5% cream	Effective	Infants, children, pregnancy; institutional settings	Yes	Previous sensitization against pyrethrins/neurotoxic adverse events; allergenic potential, may cause skin irritation; expensive
Ivermectin	Oral, 2×200 µg/kg 8-10 days apart	Effective; acts also against other ectoparasites and intestinal helminths	Resource-poor settings, institutional settings. Disseminated crusted scabies, patients with low immunocompetence;	Yes	Pregnant women, children <5 years/expensive; dose regimen has to be adjusted to infectious status

TOPICAL ACARICIDES

Based on the rationale that the mite is confined to the superficial layers of the epidermis, topical agents have been developed and used for decades. Initially, they held the promise of a high efficacy without the risk for adverse events. Problems associated with topical therapies, however, emerged rather soon after their introduction. The efficacy of the compounds varied from setting to setting and hints for the development of resistance became obvious.²

Topical therapies are laborious, require time-consuming applications, and some are even messy. The patient has to pay attention that the compound remains for the required time on his skin, must carefully wash off remaining cream or lotion, and eventually needs to apply a body cosmetic to counteract the irritating effect of the topical acaricide. Moreover, because *Sarcoptes* shares biochemical pathways with human⁴, and since most topical acaricides are actually pesticides with a neurotoxic mode of action, drug safety has become a matter of concern.⁵ In infants and small children the risk of toxic reactions is higher than in older individuals, because their body surface area is comparatively large and the scabicide may be licked off by the patient. As excoriations are common, the acaricide may penetrate into the blood circulation and cause systemic adverse events.

Various topical treatments are available. These include sulphur compounds which have been used for centuries; benzyl benzoate (first used in 1931); crotamiton (used

since the late 1970s); hexachlorocyclohexane, which is also known as gamma benzene hexachloride. The commercial purified form is lindane (available since 1948); malathion (used since the mid-1970s) and permethrin (in the USA first licensed in 1985).

Lindane

For more than 40 years, lindane has been the mainstay of therapy against scabies.

However, in only a few studies the efficacy of the substance has been assessed.

Amer et al.⁶ compared 1% topical lindane with 10% topical crotamiton and found a similar efficacy. In a study in Thailand, the efficacy of lindane was similar to that of 10% topical sulphur⁷. Five trials compared 1% topical lindane with 5% topical permethrin. The trials' combined estimate showed permethrin to be superior to lindane³. When compared with ivermectin, one study reported a similar efficacy and the other more treatment failures in the lindane group.^{8,9}

Serious adverse events may occur, particularly when the manufacturer's instructions are not followed rigorously. An application on altered skin or the use with a frequency greater than recommended, poses a health hazard to the patient.⁵ The danger of neurotoxic adverse events is particularly high in infants and young children.¹⁰ Toxic effects

include neurotoxic symptoms such as numbness, restlessness, anxiety, tremor and convulsions.¹¹ Accidental oral ingestion may lead to nervous system damage and death.⁵ Sudakin¹² reported a fatality after a single dermal application of lindane lotion. Oberoi et al.¹³ showed that the topical application of lindane causes oxidative stress in patients with scabies, as indicated by a significant increase in levels of malonaldehyde, superoxide dismutase and a decrease of blood glutathione.

Because of its potential neurotoxicity, lindane had always been contraindicated in infants, pregnant women, nursing mothers, and patients with seizures or other neurologic diseases. In the EU, lindane has been banned from use in agriculture since 2001 and from medical use in 2007. In 2002, California banned pharmaceutical use of lindane because of concerns about detrimental ecological consequences.¹⁴ Because of safety concerns and a rather low efficacy, lindane should no longer be used for the treatment of scabies.

Benzyl Benzoate

Benzyl benzoate was first known as a component of “balsam of Peru.” Hitherto, seven studies with an adequate study design are published. The concentration used varied between 10% and 25% and the efficacy between 48% and 91%.¹⁵⁻²¹ Benzyl benzoate performed similarly to topical sulphur in a study in India¹⁹ and to synergized natural pyrethrins in a study in Italy¹⁵. Three studies failed to observe a difference in cure rates after treatment with benzyl benzoate or oral ivermectin, whereas one study showed a superiority of ivermectin.^{16,18,20,21} Recently, in a study in the Senegal, benzyl benzoate was significantly more effective than a single dose of oral ivermectin (150-200 µg/kg).¹⁷ However, the dosage of ivermectin in the study was considered suboptimal.²²

Benzyl benzoate is a rapidly acting agent, but requires several applications, such as once to twice per day during 2 to 3 days; repeat after 10 days. Given its propensity to cause skin irritation, repeated applications should be performed with caution. The substance may produce a burning sensation, pruritus, and keratosis. The complicated regimen and the side effects reduce compliance. Mytton et al.²³ found no evidence of adverse events in pregnancy in a retrospective cohort study in Thailand.

Sulfur in Petrolatum

Sulfur in petrolatum has been used for centuries and it is still considered a first-line treatment in resource-poor settings. The substance needs to be applied for three consecutive nights and to be washed off thoroughly 24 hours after the last application.

Gulati 1978¹⁹ compared 25% topical sulphur ointment with topical benzyl benzoate. There was no difference between the two groups after 15 days. There was also

no difference between topical sulphur and 0.3% topical lindane.⁷

The substance is far from being cosmetically acceptable since it has a foul odor, it is messy and it stains clothing and bedding. It can also produce a toxic dermatitis. It had been considered safe, appropriate for infants younger than 2 months of age, and for pregnant women or lactating mothers.²⁴ However, Haustein²⁵ recently questioned the safety of the drug and considered its use obsolete in infants and small children because of its potential liver and kidney toxicity.

Crotamiton

Crotamiton (10% in a cream/lotion) is applied for 24 hours on 2 consecutive days. Since the compound is not very effective, some authors have suggested a 5-day application. In one study, crotamiton performed similar to 5% topical permethrin, in another study the compound was less effective.^{6,26}

The substance has an antipruritic effect but can induce an irritation of the skin and induce a contact dermatitis.^{27,28} Otherwise, crotamiton is considered safe for use in children and infants.

Malathion

There are still no published reports of randomized controlled trials that test the effectiveness of malathion against another drug, despite almost 30 years passing by since a noncontrolled study first suggested that the drug was effective. Malathion exists as a 0.5% alcoholic or aqueous solution. It is an organophosphate and inhibits the acetylcholinesterase irreversibly. The odour is quite objectionable, and inhaling the fumes can result in severe headaches.¹¹

Permethrin

Permethrin, a synthetic pyrethroid, is used in many countries as first line therapy. The recommended use is a single 10-hour application of a 5% cream. Hitherto, eight studies have assessed the efficacy of permethrin in comparison with other topical acaricides. When data of the different studies were combined in a meta-analysis, 5% topical permethrin was significantly more effective than 10% topical crotamiton or 1% lindane.³ Amerio et al.²⁹ compared 5% topical permethrin with 0.16% topical natural pyrethrins synergized with 1.65% pyperonil butoxide in a thermolabile foam. There were no treatment failures in either group after 28 days.

Permethrin is approved for use in infants >2 months of age. Mytton et al.²³ did not find any evidence of adverse effects of 4% permethrin on pregnancy.

Permethrin can cause a burning sensation, exanthema, pruritus and folliculitis.² Like other natural or synthetic

pyrethrins, permethrin has an allergic potential. Given its wide use in agriculture and gardening, previous sensitization of a child with scabies may have occurred. In this case, permethrin is contraindicated. Tomalik-Schäfer et al.³⁰ applied 5% permethrin cream to the skin of healthy adults and found that a substantial proportion of the substance is resorbed through intact skin. Presumably, in patients with scabies resorption is even higher because of the presence of multiple excoriations.

Since only low pyrethroid concentrations are necessary to modify sensory neurone function, neuromuscular adverse reactions may occur after a single application.³¹ The main adverse effect of dermal exposure is paraesthesia, presumably as a result of hyperactivity of cutaneous sensory nerve fibres. The face is affected most commonly and the paresthesiae are exacerbated by sensory stimulation such as heat, sunlight, scratching, sweating or the application of water.³¹ Coleman et al.³² reported a case of severe neck dystonia after topical application of 5% permethrin cream.

Natural pyrethrins applied in a thermolabile foam formulation seem to be better tolerated and reduced itching more rapidly than permethrin cream.²⁹

In other ectoparasites, such as head lice, permethrin resistance is widespread. This suggests that scabies mites may develop resistance, too. Anecdotal reports of failure in Australian remote communities may indicate emerging resistance.⁴ Furthermore, longitudinal studies conducted in northern Australia confirm increasing *in vitro* tolerance. In 1994, before widespread permethrin treatment was introduced, all mites were killed within 30 minutes of *in vitro* exposure to permethrin. By the year 2000, however, 35% of mites were alive after 3 hours of exposure and a significant proportion remained alive overnight. More recent analysis confirms increasing tolerance and shows that the permethrin is now the slowest acting acaricide *in vitro* in this region.⁴

HERBAL REMEDIES

Some essential oils kill sarcoptic mites. For example, tea tree (*Melaleuca alternifolia*) oil has been shown to be highly effective *in vitro*.³³ In an open clinical trial a paste composed of an extract of neem (*Azadirachta indica*) and of *Curcuma longa* (turmeric) cured 97% of patients with scabies.³⁴

Toto ointment and *Lippia multifolia* oil have been found to be useful in studies in Nigeria.^{35,36} Both treatments look promising, but randomized controlled trials making direct comparisons with the existing best treatments are needed to assess their true relative effectiveness and safety.

Ivermectin

The advent of ivermectin, a macrolytic lactone, has opened a new area in the treatment of scabies. Since the mid

1980s, ivermectin has been administered in humans, and until today several hundred million individuals have been treated with this drug in onchocerciasis and lymphatic filariasis control programs in Africa and South America. Owing to the possibility that the blood-brain barrier is incompletely developed in infants, raising the potential for ivermectin neurotoxicity, the drug is currently contraindicated in children less than 15 kg. It is also contraindicated in pregnant and lactating women. Despite these concerns, ivermectin has been used in large helminth control programs in these groups with no adverse effects, but because of a lack of comprehensive safety data, this barrier remains.⁴

In scabies studies, a single dose of ivermectin has been given. Based on the experience in endemic areas, we suggest two doses (200 µg/kg; repeat after 8–10 days). Comparative trials have shown that the efficacy is similar or better than that of topically applied lindane^{8,9} and is similar to that of benzyl benzoate.³ In a small study in India, Usha et al.³⁷ found more treatment failures in patients treated once with oral ivermectin compared to 5% topical permethrin. Alberici et al.³⁸ compared ivermectin and benzyl benzoate in HIV-associated crusted scabies. The investigators found that neither drug was effective when used in isolation and that combination therapy was the best option. Similarly, experience with crusted scabies patients in northern Australia strongly supports combination treatment, including multiple dose of ivermectin and topical acaricides.⁴ This indicates, that oral ivermectin may not replace topical substances entirely.

Ivermectin is considered to be a drug with an excellent safety profile.³⁹ Adverse events are rare, of minor importance and only of transient nature. At present, ivermectin is, except in a few countries such as in Mexico, Brasil, France, and the Netherlands, only approved for the treatment of helminth infections. However, off-label use on compassionate grounds for the treatment of simple and crusted scabies is common.⁴ If mass treatment is requested, such as during an epidemic, ivermectin is the drug of choice.⁴⁰

So far, resistance to oral ivermectin has been reported in two cases from Australia. These patients, aborigines with extremely severe crusted scabies, had received 30 to 58 doses of ivermectin over a period of 4 years.⁴¹

TREATMENT OF FOMITES

The treatment of clothing and bed linen (washing at 60°C, treatment with an antiscabietic lotion or putting it in a hermetically sealed bag for several days) is a frequent recommendation. However, this practice can be restricted to patients with multiple lesions or disseminated crusted scabies, since the risk of a reinfection through fomites seems to be low when the intensity of infestation is low.⁴²

TREATMENT FAILURE

Presumably, the majority of relapses are attributed to the lack of adherence to treatment protocols and a low compliance. Frequently, not all body parts are covered by the topical acaricide and particularly the head, the genitals or the periungual area are left untreated. In the case of treatment failure, a different compound should be used in order to avoid the development of resistance and/or cumulative toxicity. Resistance against neurotoxic acaricides is becoming a matter of concern and has been documented for crotamiton, lindane, and permethrin.⁴

CRUSTED SCABIES, IMMUNOCOMPROMISED PATIENTS

In crusted scabies, ivermectin is the drug of choice. Usually five to seven doses of oral ivermectin (200 µg/kg) have to be given. Some authors suggest a combination of ivermectin and topical permethrin.^{43,44} Ivermectin is also the drug of choice in scabies patients with innate or acquired immunodeficiency. Alberici et al.³⁸ suggest the combination of ivermectin and benzyl benzoate in HIV-associated crusted scabies.

Scabies in Children

The different treatment options currently in use are summarized in Table 30-2. As evidence is scarce, recommendations are based on reasonable best practice.

Scabies in Pregnancy

Due to safety concerns, how to treat scabies during pregnancy is a matter of debate (Table 30-2). Since ivermectin and lindane are contraindicated, only benzyl benzoate, crotamiton and permethrin remain as treatment options. Based on toxicologic considerations, Fölster-Holst et al.⁵ suggest the use of topical permethrin.

INSTITUTIONAL SETTINGS

The eradication of scabies epidemics in institutions requires careful planning and the collaboration between dermatologists, infections disease specialists, nurse staff, and the public health sector. Control is based on mass treatment of all residents irrespective of their infectious status, and should include the staff of the institutions and family contacts.⁴⁵ Mass treatment of the residents can be performed with oral ivermectin (two doses 200 µg/kg 1 week apart) or with 5% topical permethrin alone or in combination.^{46,47}

RESOURCE-POOR SETTINGS

In developing regions of the world, cost and availability of the acaricide are of obvious importance when selecting the most appropriate treatment for scabies. Ideally, the acaricide should be easy to apply, minimally absorbed through the skin, nontoxic for the host, and effective as a single-dose regimen. However, no drug currently fulfills all these criteria.

TABLE 30-2—Recommendations for Treatment of Scabies in Newborns, Infants and Children, During Pregnancy and Lactation^a

	Benzyl benzoate	Crotamiton	Permethrin	Malathion	Ivermectin
Newborn	Not recommended	Treatment only under strict medical supervision ^b	Treatment only under strict medical supervision ^b	Not recommended	Not recommended ^c
Infants	Treatment only under strict medical supervision ^b	Recommended ^d	Recommended ^d	Not recommended	Not recommended ^c
Children	Recommended ^e	Recommended ^d	Recommended ^d	Second line treatment ^f	Recommended
Pregnancy	Recommendation disputed ^g	Only in exceptional Cases	Treatment only under strict medical supervision	Not recommended	Not recommended ^h
Lactation	Treatment only under strict medical supervision ⁱ	Not recommended	Not recommended ^j	Not recommended	Not recommended ^h

^a Adapted from [2]

^b preferably in hospital setting

^c manufacturer does not recommend treatment in children less than 5 years or with less than 15 kg

^d only if skin is not excoriated or denuded; permethrin contraindicated if child is allergic against pyrethrins/pyrethroids

^e if child ≥ 6 years

^f an aqueous preparation should be used, because alcoholic preparations sting and cause wheeze

^g manufacturer allows prescription. In the USA, the prescription is prohibited as the embryo may develop a gasping syndrome⁵

^h by manufacturer. However, no adverse events were observed in thousands of women in inadvertently treated during pregnancy and lactation in helminth control programs

ⁱ do not apply on the breast and nipples

^j permethrin is present in breast milk

Because of its low cost, benzyl benzoate (10 to 25%) is commonly used in developing countries.

Mass treatment with ivermectin was successfully used to control scabies in resource-poor settings in Brazil and the Solomon Islands.^{40,48} In the latter study a single dose of ivermectin reduced prevalence from 25% to <1% for several months after intervention. Besides, the simultaneous elimination of the most common intestinal helminths, and of other ectoparasites by ivermectin is very much appreciated by polyparasitized patients typical in developing countries.

What We Know

- Scabies is an extremely itchy parasitic skin disease caused by the mite *Sarcopetes scabies var. hominis*. Transmission occurs mainly through direct contact from person to person. Fomites play only a minor role, except in disseminated crusted scabies.
- Scabies mimics many clinical conditions. The clinical manifestations depend on the age and the immunocompetence of the host.
- Treatment guidelines vary considerably between countries and are rarely based on evidence. Topically applicable compounds are sulfur in pretolatum, benzyl benzoate, crotamiton, permethrin, and malathion. Lindane should no more be used. All compounds require strict adherence to treatment protocols and some are potentially hazardous molecules. Resistance is emerging and is supposed to spread in the future. Oral ivermectin (200 µg/kg twice 8–10 days apart) is an excellent alternative and is the drug of choice in disseminated crusted scabies and in patients with altered immunocompetence.

Treatment of Onychomycosis

Aditya K. Gupta, M.D., Ph.D., F.A.A.D., F.R.C.P.(C), and William Brintnell, B.Sc., Ph.D.

BACKGROUND

DEFINITION

Onychomycosis is a fungal infection of the nail caused predominantly by anthropophilic dermatophytes, less commonly by yeast (*Candida* spp.), and by nondermatophyte mold infections.^{1–3} Onychomycosis may present with hyperkeratosis, subungual debris, thickening, or discoloration of the nail plate. Total nail dystrophy may also result when onychomycosis is advanced.³

INCIDENCE/PREVALENCE

Onychomycosis is the most common nail disorder in adults. It accounts for approximately 50% of all nail diseases^{4,5} and has increased in individuals over the last 80 years.³ In North American centers, the prevalence of onychomycosis is between approximately 6.5% and 13.8%.^{4,6–8} Onychomycosis affects predominantly toenails compared to fingernails. In some reports the ratio of toenail to fingernail onychomycosis ranges from 4:1 to 19:1.^{4,7,9,10}

ETIOLOGY/RISK FACTORS

Predisposing factors for onychomycosis include tinea pedis, positive family history, increasing age, male gender, trauma, immunosuppression, diabetes mellitus, poor peripheral arterial circulation, and smoking.^{3,4,6,7,11–17} Additionally, for fingernails persistent exposure to water, the use of artificial nails, and trauma induced by pushing back the cuticles and aggressive manicuring are predisposing factors.

PROGNOSIS

Onychomycosis may be treated with systemic and/or topical antifungal agents, and most recently, devices have been used to treat onychomycosis. Traditional systemic agents used to treat onychomycosis include griseofulvin and ketoconazole. The newer oral agents used to treat onychomycosis are terbinafine, itraconazole, and fluconazole.^{18–25}

Recent data suggests that posaconazole may have efficacy. A recent randomized, placebo and active controlled, parallel, multicenter, blinded study not yet published in its entirety, studied treatment of patients with dermatophyte

DLSO (n=36-37 per regimen) with variable doses of posaconazole (100, 200, 400 mg/day for 24 weeks), as well posaconazole 400 mg/day and terbinafine 250 mg/day (both for 12 weeks duration).²⁶ The placebo arm of the study was treated for 24 weeks in keeping with the posaconazole dosing regimen arms. The primary efficacy endpoint of complete cure at 48 weeks was identified in 23%, 54%, 46%, 20%, 37%, and 0% for the posaconazole 100, 200, 400 mg/day (24 week regimen), 400 mg/day posaconazole (12 week regimen), 250 mg/day terbinafine, and placebo arms respectively. Of equal importance to efficacy, the frequency of adverse events did not differ significantly between treatment arms and were primarily mild in severity. As posaconazole is more efficacious and similar in safety at increased dosing compared to terbinafine 250 mg/day, its' use may become more mainstream.

Other azoles that have been reported to have some efficacy include ravuconazole.²⁷ Currently published data relating to the efficacy of another azole (voriconazole) as a drug to treat onychomycosis is limited to several manuscripts describing in-vitro studies.^{28,29}

Topical treatments include ciclopirox and amorolfine nail lacquers.^{30,31} Only ciclopirox nail lacquer 8% has been approved in the United States for the treatment of onychomycosis.³²

Relapse of onychomycosis, especially of toenails, is not uncommon, particularly in predisposed individuals. Reasons why fingernail onychomycosis responds better than toenail disease may be related to the fact that perfusion of the upper extremity is generally better than the lower extremity; this may result in improved drug delivery to the fingers compared to the toes. In addition, fingernails have a faster rate of outgrowth compared to toenails (3 mm/month compared to 1 mm/month),³³ resulting in the infected fingernail growing out faster than its lower extremity counterpart does.

AIMS OF TREATMENT

Onychomycosis may be a cosmetic problem, especially when fingernails are infected.³⁴ The treatment objectives are to reduce the fungal burden within the nail, ultimately curing the fungal infection, and to promote healthy regrowth of affected nails. In some instances, when onychomycosis is symptomatic, for example, pain, discomfort, soft tissue

infection, a timely treatment may help to eliminate symptoms and prevent complications that could be associated with more severe consequences.³⁵

RELEVANT OUTCOMES

The most commonly reported therapeutic measure of efficacy is mycologic cure, which is defined, by most, as negative light microscopic examination and negative culture. There are several ways by which clinical improvement has been reported. Some studies have used the parameter of clinical success, which is defined as cleared or markedly improved (90-100% clear nail).³⁶ Others have defined clinical success as cure or improvement sufficient to reduce the involved area of the target nail to less than 25% at the end of therapy.³⁷ Another term that has been used is clinical effectiveness, which is taken to be mycologic cure and at least 5 mm of new clear toenail growth.³⁸ Clinical cure refers to the post-therapy nail appearing completely cured to the naked eye. Complete cure rate is the combined results of mycologic and clinical cure.

METHODS

To identify studies where oral treatments, itraconazole (continuous and pulse), fluconazole, terbinafine (continuous and pulse) and griseofulvin were used to treat adults with toe- or fingernail onychomycosis caused by dermatophytes, we searched MEDLINE (1966-2010) for randomized-controlled trials (RCTs). The reference sections of the published reports were also examined for potential studies not listed in the database. Some of the studies were excluded for the following reasons:

Open trials, studies conducted in a special population (e.g., diabetics, Down syndrome, transplant patients), reports where we were unable to extract the relevant data, double publications, non-English language studies, and retrospective studies were excluded.

Onychomycosis caused by *Candida* spp. and nondermatophyte moulds is less common and the management of onychomycosis caused primarily by these organisms will not be considered in this chapter.

The use of most nail lacquers to treat onychomycosis will not be considered with the exception being ciclopirox discussed briefly herein. Although heralded as a safer alternative to systemic antifungal therapy, currently approved topicals for a large part have reported modest cure rates at best. For example, two pivotal studies and a collection of data from various European studies reported contradictory but modest complete cure rates of 5.5%, 8.5%, and 26.2% after 48 weeks of therapy in two North American and European studies, respectively.³² More recently, a novel water soluble formulation of ciclopirox in a solution containing hydroxypropyl chitosan has also been published with complete cure rate of ~ 13% assessed in 157 patients after 12 months of treatment followed up for a further 12 weeks after completion of therapy³⁹.

There are many anecdotal reports of various topical agents being effective for the management of onychomycosis; however, published reports of the efficacy of topical agents in onychomycosis in the indexed, peer-reviewed literature are far fewer. Other clinical trials have included tioconazole 28% solution, bifonazole with urea, fungoid tincture, miconazole, and tea tree oil.

This chapter discusses the distal and lateral presentation of dermatophyte onychomycosis, which is the most common type; the treatment of the other types of onychomycosis is not considered.^{3,40}

Also excluded were studies that used nonstandard treatment dosage or duration for toenails (e.g., terbinafine therapy <3 months or >4 months, itraconazole [continuous] therapy <3 months or >4 months, <200 mg/day, itraconazole [pulse] therapy <3 pulses or >4 pulses, fluconazole dosage other than 150 mg per week, griseofulvin therapy <3 months), fingernails (terbinafine therapy >6 weeks, itraconazole [continuous] therapy >6 weeks, itraconazole [pulse] >2 pulses, fluconazole dosage other than 150 mg per week), or other nonstandard regimens, such as sequential or combination therapy.

We have not considered trials where ketoconazole has been used to treat onychomycosis, given the potential of this agent to cause hepatotoxicity and the availability of alternative agents.

The use of posaconazole, ravuconazole, and voriconazole for the management of onychomycosis are not being discussed further in this chapter because the information currently available is limited.²⁶⁻²⁹

Several devices have been reported in the management of onychomycosis. This includes the use of laser systems, photodynamic therapy and iontophoresis. In many cases, the studies are in the form of case reports or open studies without adequate controls. In other instances the efficacy data, mycologic cure and clinical cure, and total cure 1 year from the start of treatment are not available in a published, peer-reviewed format.

Evidence was graded using the quality of evidence scale system employed by Cox et al.⁴¹

- I: Evidence obtained from at least one properly designed randomized control trial
- II- i: Evidence obtained from well-designed control trials without randomization
- II- ii: Evidence obtained from well-designed cohort or case control analytic studies, preferably from more than one center or research group
- II- iii: Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments could also be included
- III: Options of respected authorities based on clinical experience, descriptive studies, or reports of expert committees
- IV: Evidence inadequate owing to problems of methodology (e.g., sample size, length of comprehensiveness of follow-up or conflicts in evidence)

What is the role of oral antifungal therapy in the management of dermatophyte onychomycosis in adults?

Griseofulvin was the first significant oral antifungal agent available to manage dermatomycoses. Over the years the use of griseofulvin in the treatment of onychomycosis has decreased; although, it is still used for the treatment of tinea capitis, in countries where this agent is available.⁴² Ketoconazole, an oral imidazole, is no longer recommended for the treatment of onychomycosis, which requires a long duration of therapy, because of the potential for hepatotoxicity.⁴² The introduction of the new oral antifungal agents, terbinafine, itraconazole, and fluconazole has lead to improved efficacy rates, decreased treatment duration, and fewer adverse events.

QUESTION: What are the effects of systemic treatments on fingernail and on toenail onychomycosis?

OPTION: Griseofulvin

The regimen for treating onychomycosis is continuous therapy using a dosage of 500 mg/day to 1 g/day, typically administered for 6 to 12 months in fingernail onychomycosis and for 9 to 18 months in toenail disease.

Fingernail: Quality of Evidence – I

One randomized double-blind study compared griseofulvin to terbinafine in the treatment of onychomycosis (Table 31-1).⁴³

Fingernail: Effectiveness

In a double-blind randomized-controlled study(RCTs),⁴³ griseofulvin was given at a dosage of 500 mg/day for 12 weeks. The mycologic cure rate and complete cure rate was 63% and 39%, respectively.

Toenail: Quality of Evidence – I

Three double-blind RCTs^{44–46} and one open RCT⁴⁷ compared griseofulvin to terbinafine (continuous) or itraconazole (continuous) in the treatment of onychomycosis (Table 31-2).

Toenail: Effectiveness

In the RCTs, 500 mg/day or 1 g/day of griseofulvin was administered to treat onychomycosis. In the double-blind RCTs, the mycologic cure rate ranged from 45 to 69% and complete cure occurred in 2 to 56% of patients. In the open RCT, 6% of patients were completely cured.

** Not defined; DB, double-blind; R, randomized; ITRC, itraconazole continuous; TERC, terbinafine continuous.

Drawbacks

The use of griseofulvin may be associated with adverse events such as gastrointestinal upset, nausea, diarrhea, headache, central nervous system symptoms, and urticaria.⁴⁸ No drugs are contraindicated with griseofulvin and few drug interactions are associated with griseofulvin therapy.

Comments

Griseofulvin was the first systemic agent used to treat onychomycosis on a widespread basis. Currently, the newer oral agents (itraconazole, terbinafine, and fluconazole) have been found to be more effective than griseofulvin; the duration of active therapy is also shorter with the more recently introduced antimycotics.^{49,50} Moreover, when griseofulvin is used to treat dermatophyte, toenail onychomycosis relapse rates may be higher (40 to 60%)⁵¹ compared to the newer oral antifungal agents.^{35,52–55}

OPTION: Continuous Terbinafine

The regimen for fingernail and toenail onychomycosis is 250 mg/day administered for 6 and 12 weeks, respectively.

Fingernails: Quality of Evidence – I

Two double-blind, RCTs evaluated subjects with fingernail onychomycosis only (Table 31-1). One study administered

terbinafine for 12 weeks and therefore was not included in this analysis.⁴³

Fingernails: Effectiveness

The double-blind, randomized, placebo-controlled study used terbinafine 250 mg/day for 6 weeks to treat fingernail onychomycosis (Table 31-1).⁵⁵ Mycologic cure was achieved in 79% of patients and complete cure in 59%.

Toenails: Quality of Evidence – I

The majority of studies were double-blind RCTs (Table 31-3). Terbinafine was administered at a dose of 250 mg/day terbinafine for 3 to 4 months.

Toenails: Effectiveness

Six double-blind RCTs compared terbinafine to placebo.^{36,55–59} Each study reported terbinafine 250 mg/day to be significantly more effective than placebo in treating onychomycosis.

Fifteen double-blind, randomized studies compared terbinafine (continuous) to other drug comparators^{38,46,60–72} with mycologic cure rates ranging from 46 to 95% and the corresponding clinical response rates being 39 to 97%.

Four open RCTs reported the efficacy of terbinafine (continuous) for 3 or 4 months.^{73–76} Mycologic cure ranged

between 75 and 94%. In one study, clinical response was reported to be 68%.⁷⁶ Complete cure ranged between 63 and 79% for reported studies.

Two randomized double-blind studies investigated the optimal duration for terbinafine therapy^{77,78}. Mycologic cure assessed at 48 weeks was identified in 41%, 71-82%, and 82% after 6, 12, or 24 weeks of treatment, respectively. Similarly, 40%, 59-71%, and 79% of patients achieved complete cure after 6, 12, or 24 weeks of treatment, respectively, when assessed at 48 weeks. Clearly 12 weeks of therapy is more efficacious than 6 weeks, but by extending the therapy to 24 weeks little additional effect is gained.

Drawbacks

Treatment of onychomycosis with terbinafine (continuous) is associated with a low frequency of adverse events^{49,79}. These adverse events are generally mild to moderate in severity, and reversible. The more common adverse events involve the gastrointestinal tract, skin, and central nervous system. Terbinafine should not be used in individuals with systemic lupus erythematosus and Stevens-Johnson syndrome.⁵⁵ Only a small proportion of patients discontinue treatment with terbinafine. Few drug interactions have been reported, some of these may be explained by the allylamine inhibiting cytochrome P450 2D6.^{80,81} In the United States and Canada, the package inserts^{55,82} state that pretreatment serum transaminase tests (alanine transaminase and aspartate transaminase) should be considered before initiating terbinafine therapy.

Comments

Terbinafine is effective and safe for the treatment of onychomycosis. Terbinafine is an allylamine, which inhibits squalene epoxidase, resulting in an accumulation of squalene and a deficiency of ergosterol. The accumulation of squalene may be associated with fungicidal action.⁸³ In one study the relapse rate ($\geq 90\%$ clear nail at any time and <90% at last visit) was recorded in 15% of patients when followed up for up to 96 weeks from the start of therapy.³⁶ There are a substantial number of high-quality studies that demonstrate the effectiveness of terbinafine (continuous) in the treatment of toenail onychomycosis, some of which have stated that this may be the most effective agent available for this indication.^{84,85}

OPTION: Terbinafine (Pulse)

Terbinafine (pulse) is administered as 250 mg twice a day for 1 week on, followed by 3 weeks off between successive pulses. Typically, two pulses are required to treat fingernail onychomycosis and three or four pulses for toenail disease.

Toenails: Quality of Evidence – I

Seven studies have reported the use of intermittent terbinafine therapy in the treatment of onychomycosis (Table 31-4). Each of the studies is randomized and against a comparator; two are open^{74,75} and three are single-blind,^{69,72,86} and two are double-blind.^{68,71} The duration of follow-up is approximately between 10 to 18 months.

Toenails: Effectiveness

Five blinded, randomized studies^{68,69,71,72,86} compared terbinafine pulse to various therapeutics and regimens for administration. The mycologic cure rate in the pulse terbinafine groups varied from 47% to 84%, and complete cure rates were reported between 22% and 42%.

In the two open, randomized comparative studies^{74,75} intermittent terbinafine therapy was associated with complete cure rates of 50% (N=20)⁷⁴ and 74% (N=23).⁷⁵ Furthermore, in the study by Tosti et al.⁷⁴ the mycologic cure rate was 80%.

Drawbacks

Intermittent terbinafine therapy has been associated with few adverse events. Adverse events are generally mild to moderate, and reversible. The spectrum of adverse effects is similar to that seen with the continuous terbinafine regimen. Terbinafine (pulse) regimen is not indicated for the treatment of onychomycosis, and therefore there are no monitoring guidelines in the United States.

Comment

The preferred regimen for the treatment of onychomycosis using terbinafine is continuous rather than pulse therapy. Compared to the continuous regimen, which has been well-studied, there are relatively less data available on both the efficacy and safety of the pulse regimen. More robust studies are needed to determine the most effective regimen for terbinafine pulse therapy.

OPTION: Pulse itraconazole

Itraconazole pulse is taken to be 200 mg twice a day for 1 week on, followed by 3 weeks off between successive pulses. Typically, two pulses are administered for fingernail onychomycosis and three or four pulses for toenail disease.

Fingernails: Quality of Evidence – I

One double-blind, placebo-controlled trial investigated the efficacy of itraconazole (pulse) treatment in fingernail onychomycosis.

Fingernails: Effectiveness

In the double-blind, placebo controlled study the mycologic cure and clinical response rates were 73% and 77%, respectively (Table 31-1).⁸⁷

Toenails: Quality of Evidence – I

Ten RCTs, five of which were double-blind and five open, evaluated itraconazole pulse in the treatment of toenail

onychomycosis (Table 31-5). Two further comparator studies investigated the efficacy of pulse itraconazole compared to other antifungal drugs, or differing dosing regimens (Table 31-5). More recently, in a study not yet published in its' entirety, the effectiveness of a 200 mg tablet has been evaluated. In a RCT, one group of patients received itraconazole 200 mg in tablet form with a daily dose of 400 mg per day for 1 week with 3 weeks off between successive pulses, for three pulses. The comparator group received itraconazole 100 mg capsules, the dosage being 200 mg

twice a day for 1 week pulse, with 3 weeks off between successive pulses.⁸⁸

Toenails: Effectiveness

One double-blind RCT compared three pulses of itraconazole to placebo.⁸⁹ A significant difference was present between the mycologic cure rate of itraconazole (62%) and placebo ($P<0.0001$). A significant difference also existed between the clinical response rate in the active treatment (65%) compared to the placebo group ($P<0.001$).

Four double-blind, randomized comparative studies evaluated itraconazole pulse treatment, three compared to continuous terbinafine treatment,^{8,60,61} and one compared to continuous itraconazole treatment.⁹⁰ The mycologic cure rates for the itraconazole pulse groups ranged between 13 and 69%. The corresponding range for clinical response rates were between 28 and 81%.

Five open, randomized comparative studies^{73,74,76,91,92} reported mycologic cure rates of itraconazole that ranged between 61 and 75%, and clinical response rates between 77 and 88%.

More recently, two comparator studies administering slight variations on the standard 400 mg/day itraconazole pulse regimen of 1 week per month for approximately 3 months duration reported mycologic cure rates between 57% and 74% in keeping with data from previous studies^{72,93}.

Drawbacks

Itraconazole (pulse) therapy is approved for fingernail, but not toenail, onychomycosis in the United States. Adverse events occur with a low frequency and are generally mild to moderate in severity, and reversible. These events include gastrointestinal upset, cutaneous eruption, and headache.⁹⁴ Studies report a low discontinuation rate as a result of an adverse event. Itraconazole can have an interaction with several drugs.^{54,80,71,95} There are several drugs that are contraindicated with itraconazole.^{50,92} In some cases the drug interaction may be explained on the basis of an inhibition of cytochrome P450 3A4 by itraconazole. Itraconazole is contraindicated in North America (USA and Canada) in patients with evidence of ventricular dysfunction, for example, congestive heart failure or a history of heart failure.^{54,96} Hepatic enzyme test values should be monitored in patients with pre-existing hepatic function abnormalities or those who have experienced liver toxicity with other medications. Hepatic enzyme test values should be monitored periodically in all patients receiving continuous treatment for more than 1 month, or at any time a patient develops signs or symptoms suggestive of liver dysfunction.^{54,96}

Comments

Itraconazole pulse therapy is effective and safe in onychomycosis. The pulse regimen used to treat toenail

onychomycosis decreases the itraconazole required by one-half compared to the continuous regimen with this triazole. This may result in monetary saving, increased compliance, and possibly reduce the frequency of adverse events.^{89,94,97-99} In fact, the pulse regimen is the preferred mode of drug delivery when using itraconazole. No significant difference was found between 3 and 4 pulse regimens of itraconazole for the primary efficacy parameters in the treatment of toenail onychomycosis.⁹² In one report, after the use of three pulses for the treatment of toenail onychomycosis, the relapse rate at follow-up, 12 months after the start of therapy, was 10.4%.⁹⁹ Two pulses of itraconazole should be effective and safe in fingernail onychomycosis. Itraconazole pulse therapy is not approved in the United States for the management of toenail onychomycosis, although it may be used off label in that manner to treat dermatophyte toenail onychomycosis.

OPTION: Continuous itraconazole

The regimen for fingernail and toenail onychomycosis is 200 mg/day administered for 6 and 12 weeks, respectively.

Fingernails: Quality of Evidence – I

One double-blind, randomized study compared itraconazole (continuous) with placebo in the treatment of fingernails only⁵⁰ (Table 31-1).

Fingernails: Effectiveness

The double-blind RCTs used a continuous regimen of itraconazole to treat fingernail onychomycosis.⁵⁴ The mycologic cure rate was 61% and the corresponding complete cure rate was 47%.

Toenails: Quality of Evidence – I

The majority of reported studies were double-blind RCTs (Table 31-6).

Toenails: Effectiveness

In the five double-blind RCTs that compared itraconazole (continuous) with placebo, significantly more patients receiving active treatment achieved mycologic cure and clinical response ($P<0.01$).^{54,100-102} The mycologic cure rates for the RCTs treating patients with itraconazole continuous ranged from 46 to 84%; the corresponding range for clinical response rates was 58 and 83%.

Seven miscellaneous comparative trials employed arms that studied the efficacy of continuous itraconazole therapy in treating dermatophyte onychomycosis and produced mycologic cure or complete cure rates varying between 46-84% or 23-76% respectively^{63-66,90,91,103}

^{†††} Mycologic cure (MC) defined as negative microscopy and culture unless indicated otherwise;^{††} MC defined as negative microscopy;[†]Clinical Response (CR) defined as cured or markedly improved unless indicated otherwise;[‡]CR variable definitions;[‡]Complete Cure (CC) defined as mycologic and clinical cure or improvement unless indicated otherwise;

** Not defined; MIC, miconazole; DB, double-blind; R, randomized; ITRP, itraconazole pulse; TERC, terbinafine continuous.

Recently, a novel formulation of itraconazole was developed and evaluated in a randomized, placebo-controlled, multicenter, parallel group, evaluator-blinded study; however, it has yet to be published in its' entirety.⁸⁸ This data from this study compared complete cure at 52 weeks in evaluable patients to dermatophyte DLSO treated for 12 weeks with itraconazole daily in either 1 × 200 mg formulation (n=496), 2 × 100 mg formulation (n=517), and placebo (n=156). Complete cure was achieved in 22.3%, 21.7%, and 1% of the 200 mg formulation, 100 mg formulation and placebo arms of the study, respectively⁸⁸.

Drawbacks

Adverse events associated with the use of continuous itraconazole for the treatment of onychomycosis are not common, and those experienced are generally mild to moderate in severity. Adverse events include gastrointestinal disorders (e.g., nausea, abdominal pain), rashes, and central nervous system effects (e.g., headache).^{90,94,97-99} Only a small proportion of patients discontinue treatment with the triazole. There are drugs that are contraindicated with itraconazole (see section on itraconazole pulse therapy above). In addition, the triazole has several drug interactions (see section above). Itraconazole is contraindicated in North America in patients with evidence of ventricular dysfunction, for example, congestive heart failure or a history of heart failure. The U.S. package insert suggests that liver function tests be performed in patients receiving continuous therapy for more than 1 month or at any time a patient develops signs and symptoms suggestive of liver disease.⁵⁴

Comments

Continuous itraconazole therapy is an effective and well-tolerated treatment of onychomycosis. Historically, treatment of onychomycosis with itraconazole was with the continuous regimen; later, work done by de Doncker et al.^{92,99} resulted in the widespread adaptation of pulse therapy for this indication. In the U.S. package insert, when patients with toenail onychomycosis were treated with itraconazole continuous therapy, 21% of the overall success group had a relapse (worsening of the global score or conversion of KOH or culture from negative to positive).⁵⁴

OPTION: Fluconazole

The treatment regimen of fluconazole for onychomycosis is 150 mg once weekly administered until the affected nail has grown out. Typically, the duration of therapy for fingernail and toenail disease has been 4 to 9 months and 9 to 15 months, respectively.¹⁰⁴

Fingernail: Quality of Evidence – I

One double-blind RCT assessed the efficacy of fluconazole in the treatment of fingernail onychomycosis (Table 31-1).

Fingernail: Effectiveness

The randomized, double-blind study¹⁰⁵ compared various regimens of fluconazole to each other and with placebo in the treatment of fingernail onychomycosis. Fluconazole 150 mg/week administered for up to 9 months, resulted in a mycologic cure rate of 90% and a clinical response rate of 88%.¹⁰⁵

Toenails: Quality of Evidence – I

Few double-blind RCTs have been reported.^{37,62} (Table 31-7).

Toenail: Effectiveness

In the double-blind RCTs^{37,62} mycologic cure ranged between 49 to 53%. The corresponding clinical response rates were 23 to 77%. In the open RCT, 31% of patients were mycologically cured.⁷³

Drawbacks

Fluconazole is not approved for the treatment of onychomycosis in North America. The more common adverse effects observed with fluconazole affect the gastrointestinal, cutaneous system, and central nervous system.^{81,104} Adverse events do not commonly occur, and those experienced are usually of mild to moderate severity, and reversible. Only a small proportion of patients discontinue treatment with fluconazole. The drugs contraindicated with fluconazole are cisapride and terfenadine. There are some drug interactions that may occur with the triazole; in certain cases, the drug interactions may be explained by fluconazole inhibiting cytochrome P450 2C9 and at higher doses the triazole may inhibit cytochrome P450 3A4.^{80,81}

Comments

Fluconazole is effective and safe in onychomycosis. Compared to terbinafine and itraconazole, there are relatively few studies that have evaluated the efficacy of fluconazole in the treatment of toenail onychomycosis. The preferred regimen for fluconazole is once weekly therapy; typically 150 mg per week administered for several months until the abnormal-appearing nail plate has grown out. In the study reported by Scher et al.³⁷ the clinical relapse rate over a 6 month follow-up was 4.4%.⁵² Studies evaluating the use of once weekly fluconazole at a higher dosage such as 300 mg or 450 once weekly,^{37,105} or continuous fluconazole

administration have not been discussed. It would be beneficial to have robust data on the relative efficacy of fluconazole 150 mg once weekly compared with 300 mg once weekly and 450 mg once weekly.

GENERAL COMMENTS

There have been several pharmacoeconomic analyses of the various oral treatments used in dermatophyte onychomycosis. These studies calculate the cost-effectiveness of each therapy based on the efficacy results of multiple clinical trials. The two most cost-effective regimens for the treatment of onychomycosis are terbinafine (continuous) and itraconazole (pulse).^{81,106–110} In the United States both terbinafine and itraconazole are available in generic formulations. Thus, the cost of these agents is not as much of an issue in the United States compared to the pregeneric era.

In certain nail presentations response to therapy may be improved by combining oral antifungal therapy with either an effective topical therapy or mechanical/chemical measures (e.g., mechanical avulsion, debridement, or chemical avulsion). For example, when there is lateral onychomycosis, a dermatophytoma, severe onycholysis, a thickened nail, or severe onychomycosis, it may be advantageous to consider a combination approach.^{111–116}

THERAPEUTIC DEVICES

Device-based therapy for onychomycosis is presently being developed in two manners. The first involves a device to

either deliver drug (iontophoresis), or in conjunction with a drug (photodynamic therapy). The second class of device for treating onychomycosis does not involve coadministration of drug but rather utilizes the device alone to provide therapy (lasers).

Iontophoresis

This type of device-based therapy utilizes a charged drug molecule, which is passed into and through the nail plate by means of a mild electric current in order to achieve greatly enhanced drug concentrations at the site of the infection. This is an improvement upon topical drug therapy (passive diffusion of drug) by substantially increasing the drug concentrations at the site of infection. Furthermore, the increased drug concentrations are achieved without an increased risk of adverse events such as are frequently encountered during systemic therapy.

Although several studies have been published using in-vitro models to test the efficacy of iontophoresis to deliver drug through a nail plate experimentally, only one study has carried out in-vivo work on onychomycosis patients. In this study patients were treated with 1% terbinafine HCL administered either actively by iontophoresis or passively through diffusion overnight, 5 days per week for 4 weeks and assessed 1 week later. Due to the short duration of the study, and the corresponding slow growth rate of the great toenail being treated, commonly measured efficacy rates were not feasibly studied. Instead, two parameters of efficacy were monitored: (1) clinical

improvement (outgrowth of ≥ 1.5 mm of new nail) and (2) mycologic improvement (reduced numbers of elements in the nail specimen). For clinical improvement, the percent of patients with ≥ 1.5 mm of clear nail growth treated by iontophoresis was 42% versus 18% of patients treated without iontophoresis. Similarly, after treatment with iontophoresis, significant improvement was seen as assessed by mycologic examination because 15% of patients tested had fungal elements in their nail specimens compared to 53% in those not treated with iontophoresis¹¹⁷.

Photodynamic Therapy (PDT)

PDT involves the use of visible light to activate drug in a lacquer format once applied and sufficient time has elapsed for the drug to penetrate the nail plate to the site of infection. As previously outlined in relation to iontophoresis, most studies to date involve in-vivo examination of drug efficacy using PDT.

However, one case report describes chemical avulsion of a patient's nail followed by drug administration and PDT activation with treatment being repeated twice at 15-day intervals. Mycology samples were positive after the third treatment, however, converted to negative 3 months later and were still negative when tested at a 12 months follow-up visit¹¹⁸.

Lasers

Lasers as a source of light are routinely used in medical procedures currently and are steadily increasing in their applications. Recently lasers as a device have begun to be studied as a means of providing non-drug related treatment for onychomycosis. However, despite a modest number of manuscripts having studied this from an in-vitro perspective, little or no firm data exists as to the mechanism of action involved in this therapy. Despite this fact, studies have been undertaken in-vivo to examine the efficacy of lasers in treating onychomycosis.

The first study by Bornstein et al. studied a small ($n=7$) number of patients with various fungal infections including *Trichophyton* species. Patients were treated with a laser using a dual wavelength exposure (870 nm/930 nm) for 4 minutes followed by single wavelength exposure (930 nm) for a further 2 minutes with a 1.5 cm spot size on days 1, 7, 14, and 60. During treatment, nail temperature was monitored and a physiologic temperature was maintained ($\leq 38^{\circ}\text{C}$) at the site, and by day 60, all patients had negative mycology test results¹¹⁹.

A second study of the efficacy of laser therapy on treating onychomycosis from Bornstein et al. performed a randomized-controlled study.¹²⁰ As with the previous study, patient population was not homogeneous in terms of clinical and mycologic presentation. In this study patients

What We Know

- The main oral antifungal agents used to treat onychomycosis are terbinafine, itraconazole, and fluconazole. Griseofulvin and ketoconazole are the traditional anti-fungal agents whose utility for onychomycosis has decreased substantially since the availability of the new oral antifungal agents. In addition, the use of ketoconazole for onychomycosis has diminished markedly given the potential for hepatotoxicity.
- The preferred regimens with the new oral antifungal agents are terbinafine (continuous), itraconazole (pulse), and fluconazole (once weekly). The duration of therapy with these agents for fingernail onychomycosis is typically: terbinafine continuous (6 weeks), itraconazole pulse (2 pulses), and fluconazole once weekly (6 to 9 months). The corresponding duration of therapy with these antifungal agents for toenail onychomycosis is 12 or 16 weeks, 3 or 4 pulses, and 9 to 15 months, respectively.
- RCTs have demonstrated that griseofulvin, terbinafine (continuous), itraconazole (pulse and continuous), and fluconazole are effective and safe for treatment of dermatophyte fingernail onychomycosis.
- RCTs have demonstrated that terbinafine (continuous), itraconazole (pulse and continuous), and fluconazole

are effective and safe for treatment of dermatophyte toenail onychomycosis.

- There are early studies looking at the role of devices such as laser therapy, and the combination of drugs and devices, for example, photodynamic therapy and iontophoresis. The published data available from these studies are often from open studies or small trials, thereby making it difficult to critically evaluate the place of these treatment modalities in the management of onychomycosis.
- There are several factors that need to be considered when deciding which agent to prescribe for onychomycosis; these include, efficacy, causative organism, regimen preference (e.g., continuous vs. pulse versus once weekly, expected duration of therapy), safety of antifungal agent, medical status of patient, potential for drug interactions, relapse rates, and cost of therapy.
- The efficacy of antifungal agents in the management of onychomycosis caused by *Candida* species and nondermatophyte molds is outside the scope of this chapter.
- None of the newer oral antifungal agents has been approved for the treatment of onychomycosis in children, where the disease occurs much less frequently.

(n=44) were treated on days 1, 14, 42, and 120 with treatment parameters identical to the previously described study.¹¹⁵ In the control arm, sham treatment (n=15) with no energy output was administered. After the final treatment, patients were followed out to day 180, however negative fungal culture was observed to be maximal on day 60 (75% of patients treated), and negative microscopy peaked on day 120 (64% of patients treated). At day 180, mycologic cure was observed in 30% of the patients treated. This data was not presented for the sham-treated patients.

In order that a comparison of efficacy can be performed between the oral agents, topical treatments, and devices (with or without a drug combination), it is important that the efficacy criteria remain the same, that is complete cure rate (complete clinical cure with mycologic cure [simultaneously negative light microscopy and culture]). Additionally, to best assess the efficacy of lasers to treat dermatophyte DLSO compared to drugs or the other class of devices, it is imperative that future studies be performed in a manner, whereby screening of patients is performed to assess the organisms involved and the extent of the disease present, rather than treating "all comers" which constitutes a homogeneous patient population.

Treatment of Leprosy (Hansen's Disease)

Danielle M. Miller, Ph.D., M.D., F.A.A.D., D.T.M. & H. and
Samuel L. Moschella, M.D., F.A.A.D., F.A.C.P.

INTRODUCTION

Leprosy, also known as Hansen's Disease, is caused by a chronic granulomatous immune response to infection of the skin, upper respiratory tract, eyes, nerves, and testes, with the acid fast bacteria *Mycobacterium leprae* and the recently described closely related bacteria *Mycobacterium lepromatosis*.¹ About 5% of the population in endemic areas is susceptible to infection, and recent studies have revealed a range of human lymphocyte antigen-D (HLA-D) related immune responses to the organism.

The diversity of clinical and histopathological host responses depends on the ability of the host to develop a cellular immune response to *M. leprae*.² Patients with relative good cell mediated immunity and a delayed type IV hypersensitivity reaction to *M. leprae* present with few well-demarcated hypoesthetic skin lesions. These individuals have tuberculoid leprosy (TT) and develop well-formed granulomas with few if any acid-fast bacilli in tissue. At the other end of the spectrum are individuals with no

immunity to *M. leprae*. They present with numerous skin lesions, have sheets of macrophages containing many bacilli on histology, and have lepromatous leprosy (LL). (Figure 32-1) The majority of patients fall in between these two polar forms of leprosy and have fluctuations in their immunity to the bacilli. Those who are immunologically closer to tuberculoid disease have borderline tuberculoid leprosy (BT) (Figure 32-2) and those closer to lepromatous disease have borderline lepromatous leprosy (BL). (Figure 32-3) Patients who have an absence of bacilli on skin-slit smear or biopsy are classified by the World Health Organization (WHO) as paucibacillary disease (PB) and those who have the presence of bacilli are multibacillary (MB). The WHO clinically classifies patients with five or less than five lesions as PB and those with more than five lesions as MB (Table 32-1).

A primary neuritic leprosy exists when no skin lesions are present but the patients have nerve damage³ (Figure 32-4). Histoid leprosy is a form of lepromatous leprosy in which the cutaneous lesions are firm, well-demarcated

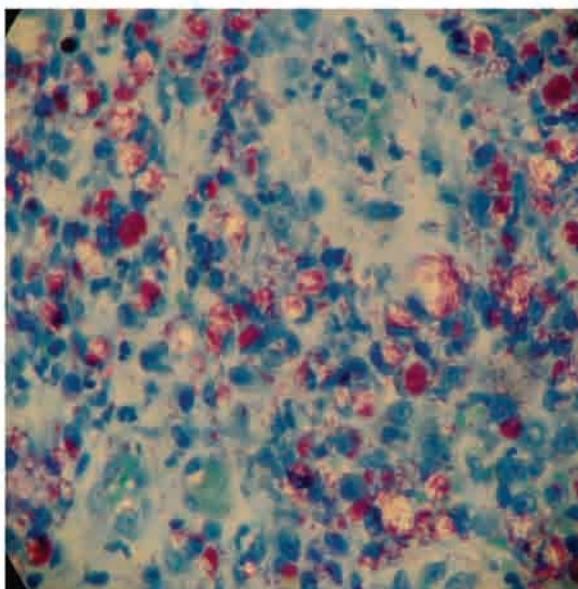

FIGURE 32-1 Histology of a lesional skin biopsy from a lepromatous leprosy case with Fite-Faraco modification of the carbol fuchsin stain showing acid-fast bacilli singly and in clumps (globi) within macrophages. (100x magnification)

FIGURE 32-2 A Tibetan patient with borderline tuberculoid leprosy who has well demarcated erythematous hypopigmented and anesthetic patches in an asymmetric distribution overlying the upper trunk.

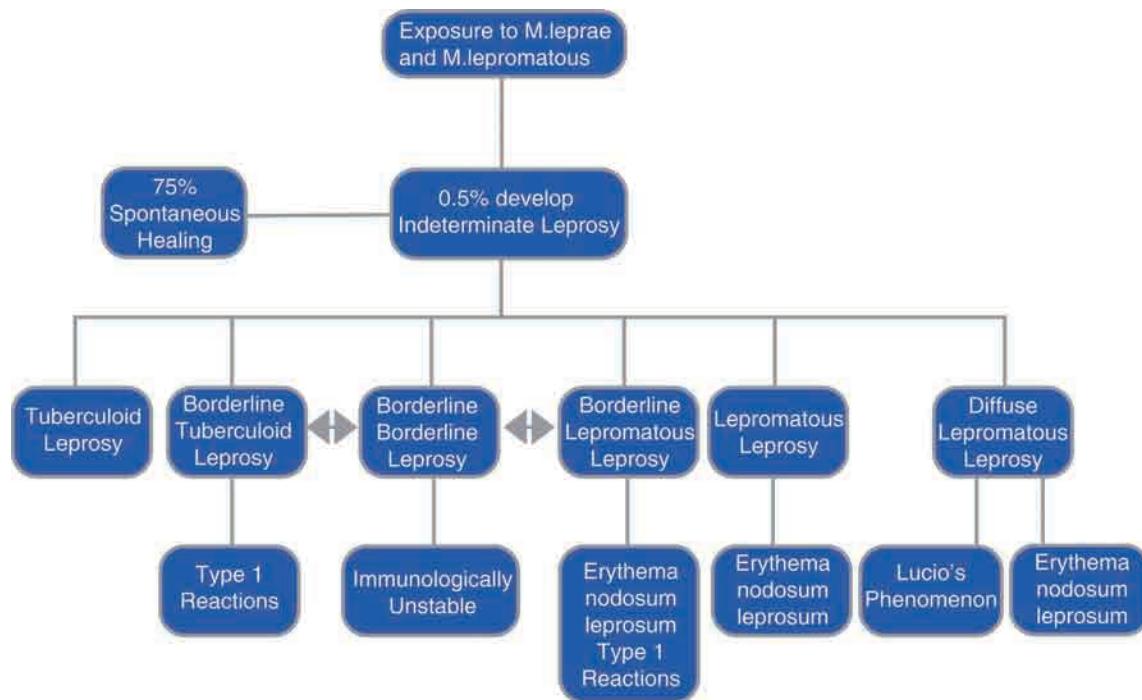

FIGURE 32-3 (A) Borderline lepromatous leprosy. This patient has madarosis, alopecia of the eyelashes, and bilateral ulnar nerve paralysis that has resulted in the claw hand deformity. (B) Borderline lepromatous leprosy consists of symmetrically located erythematous annular plaques with characteristic feathering of the edges and partial central clearing.

nodules reminiscent of dermatofibromas (Figure 32-5). Diffuse lepromatous leprosy may present with erythema nodosum leprosum and neuropathy without clinical evidence of skin lesions. Indeterminate leprosy is the earliest form of Hansen's disease and 75% of these individuals have an immunity that spontaneously clears the infection (Figure 32-6).

The WHO estimates that worldwide 2-3 million people live with physical disabilities secondary to leprosy.⁴ Neural damage results from the infectious granulomas created by *M. leprae* and by hypersensitivity reactions to the viable or dead bacilli. Early recognition and treatment of leprosy and its reactions is critical to reduce the degree of permanent neurological damage in these patients.

TABLE 32-1—Ridley-Jopling Classification Scheme

Ridley-Jopling Classification Scheme and the immunologic reactions, which are associated with the various forms of leprosy. The borderline category is immunologically unstable (double arrows) and these individuals can undergo upgrading of their immune status and move towards the tuberculoid pole, whereas a decrease in delayed hypersensitivity will cause a shift towards the lepromatous end of the spectrum.

FIGURE 32-4 Tenosynovitis of both dorsal hands in a patient with pure neural leprosy. There were no skin lesions but when biopsied demonstrated presence of bacilli, and also had arthralgias of the hands and decreased skin sensation of the hands and elbows.

EPIDEMIOLOGY

In 2009, the WHO reported the global registered prevalence of leprosy to be 213,036.⁴ The number of new cases detected in 2008 was 249,007.⁴ At this time the WHO reports that the number of new cases annually has remained relatively constant over the last 5 years with a decline of 3.54% per year since 2007. The majority of new cases were reported from India, Brazil, and Indonesia. About 3000 cases of relapse are reported worldwide annually after completing multidrug therapy (MDT). Some of these cases are felt to be due to under treatment of MB that has been misdiagnosed as PD.

MB patients may shed up to several million bacilli daily in their nasal secretions; hence, the nose is believed to be the major portal of exit.⁵ It is thus believed that the most likely portal of entry for the leprosy bacillus is the respiratory tract. There are some reports of transmission via penetrating wounds through intact skin, such as by thorns, fomites, and tattoos.⁶ Phenolic glycolipids (PGL-1), a component of the electron transparent zone of the cell envelope of *M. leprae*, have been isolated from soil and soil

FIGURE 32-6 Indeterminate leprosy in a patient who had emigrated from a leprosy endemic region. This patient had one well-circumscribed erythematous plaque on the face that was associated with decreased sensation. A biopsy revealed a granulomatous infiltrate surrounding adnexal structures and cutaneous nerves.

may also be a source of infection.² Untreated multibacillary patients represent the major source of infection and chemotherapy renders the nasal discharge bacteriologically negative within several days. Humans are the major host and reservoir for *M. leprae*. Natural infections are also reported in wild armadillos in Texas, Louisiana, and Brazil, as well as in chimpanzees and Mangabey monkeys. In adults, men are twice as likely to contract infection with *M. leprae*, and reactions are generally more common in men. In women, lepromatous reactions are seen more frequently during the third trimester of pregnancy and the post-partum period. The incidence of conjugal leprosy is around 5%.⁷

Children and infants are more susceptible to leprosy than adults are, and children are an indicator of the prevalence of the disease in the general population. Up to 60% of children will develop evidence of disease upon exposure to infectious family members in endemic areas and 75% have a positive Fluorescent Leprosy Antibody Absorption Technique (FLA-ABS).⁸ The average incubation period is 2-7 years and the peak incidence is between 5 to 9 years of age. Up to 20% of children born to mothers with leprosy in endemic areas will develop the disease by puberty. In endemic regions, most children will present with tuberculoid or

FIGURE 32-5 (A) Histoid leprosy, a form of lepromatous leprosy, consists of firm, fixed, shiny nodules that are most numerous on the face and extremities. (B) The cutaneous lesions in histoid leprosy often present with a central umbilication.

indeterminate skin lesions (70%). Fortunately, the majority of cases of early leprosy in children are self-healing. Two thirds of children with HD will have neural involvement, yet reactional states in children are less frequently reported than in adult populations. Due to the long incubation period, leprosy is most often diagnosed in adults, at which time the patients may already have significant disabilities. Leprosy in children under one year of age is rare but has been reported, the youngest being 2-3 months old, and 57% of infants have a history of contact with an infected individual, the mother being the most common source.⁹

Household contacts of patients with PB disease have a two-fold increased risk for developing HD and household contacts of MB disease have a 5 to 8-fold risk of the disease. Up to 30% of household contacts may develop the disease and there is a predilection for males and younger individuals.¹⁰ Since treatment has become more available, advanced cases of lepromatous leprosy are rare. Ulcerative ENL, amyloidosis, nephrotic syndrome and death are uncommon complications following implementation of MDT by the WHO.^{2,5}

Pregnancy, in the absence of treatment, is generally associated with worsening disease.⁷ However, reversal reactions are more common in the puerperium and erythema nodosum leprosum (ENL) occurs more frequently in the third trimester and following parturition. Both types of reactions can reoccur throughout lactation. Fifty six percent of women experienced immunologic flaring of their disease during their third trimester, 50% developed Type 1 lepra reactions during the first six months of lactation, and 68% developed Type 2 lepra reactions during the third trimester and the first six months of lactation. The leprosy reactions are caused by fluctuations in cell mediated and humoral immunity secondary to hormonal changes and women with HD require close supervision with frequent follow-up visits during pregnancy and lactation. There is decreased placental size, intrauterine growth retardation, delayed growth and development, and an increased risk for infections and mortality in infants born to mothers with leprosy, and these findings were more severe in mothers with LL.

DIAGNOSIS

The clinical picture of Leprosy is comprised of skin manifestations and ocular and peripheral nerve damage. Skin lesions consist of hypopigmented patches, papules, and plaques overlying the cooler parts of the body such as the face, ears, and extremities. The cutaneous lesions generally have reduced sensation to light touch. Nerve damage commonly follows a pattern of mononeuritis multiplex, presenting with sensory and motor deficits as well as autonomic dysfunction. The patients have peripheral numbness or anesthesia, paresthesia, dysesthesia or allodynia, muscle weakness or paralysis, and anhydrosis, cutis laxa, and alopecia.¹¹ Alopecia is due to the destruction of follicles by

the leprous granulomatous process. A characteristic presentation is the loss of the lateral eyebrows (Figure 32-7a), called madarosis. Epistaxis is common secondary to involvement of the nasal mucosa, which may progress to destruction of the nasal bone; the sinuses may also be involved. Granulomatous infiltration of the oropharynx presents with hoarseness (Figure 32-7b).

In tuberculoid leprosy the patients present with one or a few isolated well-demarcated infiltrated anesthetic patches; these are sometimes associated with a palpable proximal superficial nerve.⁵⁻⁷ In BT the patches are more numerous, but still well demarcated and tend to be distributed asymmetrically (Figure 32-2). BL has more widespread and more symmetrical skin lesions, which may or may not have associated anesthesia. The cutaneous lesions have less well-defined borders and are less anesthetic. (Figure 32-3a and 3b) LL results in diffusely infiltrated skin, which subsequently presents as shiny papules or plaques. These lesions favor the cooler parts of the body, where the density of bacilli is greater. (Figure 32-7a-7d) The early skin lesions do not have decreased sensation but do so later in the disease. Combined large nerve involvement, such as the ulnar and median and the common peroneal and posterior tibial, create the glove and stocking anesthesia of hands and feet. In some cases of LL the skin is diffusely infiltrated without evident skin lesions, and the first presenting sign of HD may be neuropathy or ENL.

There are no serologic tests or skin tests (other than histology) with the sensitivity and specificity to allow for routine use in the clinical setting to diagnose Hansen's disease. To make a diagnosis of leprosy, one must have at least one of the following: skin lesions with an abnormal sensory perception, enlarged peripheral nerves, and/or the presence of acid fast bacilli in skin biopsy or peripheral skin smears.¹² The presence of all three cardinal signs has a sensitivity of 97% and a positive predictive value of 98%.

Although sensory impairment is easily detected in skin lesions, 30% of cutaneous lesions in MB do not have associated anesthesia. There is also considerable variation in clinician's abilities to detect enlarged peripheral nerves, which may occur in other diseases such as neurofibromatosis, entrapment neuropathies, and genetic sensorimotor neuropathies.¹³ Slit skin smear examination, although highly specific, have a low sensitivity secondary to sampling error from the skin sites selected for testing.¹⁴ The slit skin smear examination can be used to quantify the number of acid-fast bacilli in infected skin lesions as well as to follow patients before and after treatment. The reliability of this test is dependent on the ability of the clinician to perform and inspect the histology of the slit skin smear.

In PB disease, where bacilli may be difficult to find on histology, polymerase chain reaction analysis may be performed on tissue sections to assist in the detection of *M. leprae*. Serologic testing for PGL-1 antibodies may also be helpful in supporting the diagnosis of lepromatous leprosy, but neither test is approved in the United States for routine clinical use.¹⁵

FIGURE 32-7 (A) Lepromatous leprosy. Diffuse infiltrated plaques on the ears, nose, eyebrows, cheeks and chin with associated Clofazimine hyperpigmentation. There are leonine faces, madarosis, and large pendulous ears. (B) Lepromatous leprosy patient who presented with hoarseness secondary to involvement of the oropharynx, here the infiltrated palate lesions are accentuated by Clofazimine hyperpigmentation. (C) Lepromatous Leprosy showing typical diffusely and symmetrically distributed shiny nodules over the back with relative sparing over the spine. (D) Patient with a long history of untreated lepromatous leprosy, stocking-glove anesthesia, and mitten hand deformity.

A full thickness skin biopsy from the edge of a skin lesion is still the “gold standard” to diagnose leprosy. The tissue is fixed in neutral buffered formalin and embedded in paraffin. Histological sections are stained with hematoxylin and eosin to identify the host response and the Fite-Faraco modification of the carbol fuchsin stain or Gomori methenamine silver stain to identify acid-fast bacilli in dermis and nerves^{2,16} (Figure 32-1).

CLASSIFICATION OF LEPROSY

The clinical, pathological, and immunological features of Hansen's disease present with a wide range of clinical and pathological manifestations. In 1873, Dr. Gerhard Henrik Armauer Hansen (1841-1912), a Norwegian physician, discovered that the causative agent of leprosy was *M. leprae*. Until the time of his discovery, leprosy was thought to be hereditary or a disease imposed on individuals as a curse from god, and those afflicted suffered discrimination and persecution.¹⁷

There are two classifications of leprosy: the Ridley-Jopling scheme and the WHO classification. The Ridley-Jopling

scheme classifies leprosy on a scale from tuberculoid to lepromatous leprosy. The WHO classification consists of paucibacillary disease and multibacillary disease² (Table 32-2).

William Jopling (1911-1997), a leprologist at the Jordon Leprosy Hospital in England, together with D. S. Ridley, a pathologist, proposed a classification of leprosy taking into account the Lepromin reaction of the patient and the number of *M. leprae* bacilli in tissue (Table 32-3).¹⁸ The Lepromin skin test was developed by Dr. Kenuke Mitsuda in 1919 and involves a subcutaneous injection of a standardized extract of inactivated leprosy bacillus.¹⁹ The injection site is examined 3 and 28 days after injection. The Fernandez reaction occurs 24-48 hours after injection and represents a type IV delayed type hypersensitivity reaction to soluble leprosy antigens. The Mitsuda reaction occurs about 21 days after injection, reflecting cell mediated immunity and is represented by a cutaneous granuloma 4 mm or greater in diameter. A positive Lepromin test is seen in individuals able to mount a strong immune response to one of the antigens found in the leprosy bacilli (human, athymic mice, or armadillo derived).¹⁹ A positive Mitsuda reaction may also be seen in the majority

TABLE 32-2—Summary of the Immunologic Responses and Treatments Used for Leprosy

Ridley-Jopling Classification	Indeterminate Leprosy	Tuberculoid Leprosy	Borderline Tuberculoid Leprosy	Borderline and Mid-Borderline Leprosy	Borderline Lepromatous Leprosy	Lepromatous Leprosy
Clinical Classification	One skin lesion with decreased sensation	One to three asymmetrically located well demarcated patches and plaques with xerosis, decreased sensation, and alopecia	More numerous skin lesions and less well demarcated than in TT, asymmetric enlargement of peripheral nerves	Numerous skin lesions, often with a targetoid appearance (erythematous edges with a pale center), skin lesions more or less symmetrically located, multiple peripheral nerve trunks involved	Numerous symmetrically located macules and papules, symmetrical involvement of nerve trunks, lesions often have preserved sensation	Widespread involvement of skin and other organs, shiny nodules and plaques symmetrically distributed with coarsening of facial features (Leoneine facies) and loss of lateral eyebrows (madarosis), nasomaxillary and laryngeal involvement, ocular keratitis and iritis
Mitsuda Skin Reaction	- / - + / +	+++ / ++++	++ / ++	- / +	- / +	-
Burden of Bacilli in Tissue	- / (+)	- / +	- / +	++	+++	++++
NHDP Treatment	<ul style="list-style-type: none"> - Rifampicin 600 mg once - Ofloxacin 400 mg once - Minocycline 100 mg once (ROM) 	<ul style="list-style-type: none"> - Dapsone 100 mg daily × 2 years (children 1-2 mg/kg) - Rifampicin 300 mg daily × 2 years (children 10 mg/kg) - Clofazimine 50 mg daily × 2 years (children 1-2 mg/kg) 				
Cytokine profile	Type 1 reactions - IL-2, IFN-γ, TNF (stimulates macrophage activity)			Type 2 reactions - IL-4, IL-5, IL-10, IL-13 (suppresses macrophage activity)		
Host Immunity	Th1 CD4+ T-cell response - cell mediated immunity - Type IV hypersensitivity reaction			Th2 CD4+ T-cell response - Antibody response - Immune complex formation - Neutrophilic dermatosis (Sweet's like) - Erythema nodosum leprosum		
Reactions	None	Rare RR	RR	RR / ENL	RR / ENL	ENL
WHO MDT	<ul style="list-style-type: none"> - Rifampicin 600 mg once - Ofloxacin 400 mg once - Minocycline 100 mg once (ROM) 	<ul style="list-style-type: none"> - Dapsone 100 mg daily × 6 months (children 1-2 mg/kg) - Rifampicin 600 mg once per month supervised × 2 years (children 10 mg/kg) - Clofazimine 300 mg once per month supervised and 50 mg daily × 2 years (children 1-2 mg/kg for both monthly and daily doses) - If Clofazimine pigmentation is objectionable, it may be replaced by daily ethionamide or prothionamide 				
Slit Skin Smear, number of bacilli	-	- / +		+ (bacillary index equal to or greater than 2)		
WHO-clinical classification	One skin lesion with decreased sensation	Less than 6 skin lesions with sensory disturbance		Six or more skin lesions		
WHO Classification	Indeterminate	Paucibacillary		Multibacillary		

Summary of the immunologic responses and treatments used for leprosy. The Ridley-Jopling Scheme is at the top of the chart with the corresponding clinical findings seen in the different forms of leprosy.^{11,18} At the bottom of the chart is the corresponding classification used by the World Health Organization (WHO).² The host immunity ranges from a strong cell-mediated response to *M. leprae* at the left side of the chart to no immunity at the right of the chart. The National Hansen's Disease Program (NHDP) differs from the Multi Drug Therapy (MDT) program recommended by the WHO. The NHDP is longer, with two drugs administered daily for one year for Tuberculoid Leprosy (TL) and triple therapy daily for two years in both borderline disease and Lepromatous Leprosy (LL). The WHO organization administers one monthly-supervised dose of Rifampicin to reduce the cost of treatment. PB disease is treated with two drugs for 6 months and MB disease is treated with three drugs for two years. PB disease is associated with a strong Th1 CD4+ T-cell response and reversal reactions (RR).^{35,36} MB disease, on the other hand, has a predominantly Th2 CD4+ T-cell response and is associated with RR and Erythema nodosum leprosum (ENL).^{6,7,35,48} Indeterminate leprosy is treated with a single dose of Rifampicin, Ofloxacin, and Minocycline (ROM). The bacillary burden in tissue increases on both histology and slit skin smear as the host immunity decreases.^{12,16} The Mitsuda skin reaction is more pronounced in the setting of a good cell mediated immunity of *M. leprae*.^{18,19}

of people from non-endemic areas and in contactants to patients with leprosy, as well as in patients with tuberculoid leprosy. Negative reactions are seen in lepromatous leprosy and weakly positive reactions are seen in the borderline spectrum of HD (Table 32-2).

For diagnosis of leprosy in endemic countries, where there is a risk for transmission of other infectious diseases such as Human Immunodeficiency Virus (HIV) and Hepatitis B from unsanitary surgical instruments used for skin biopsies and slit skin smears, as well in the field lack of equipment to read and personnel capable of interpreting the results, the WHO has decided to train medical personnel to classify leprosy by counting the number of skin lesions instead of performing invasive procedures. For practical reasons, the WHO has redefined the classification of HD as follows: a single hypopigmented lesion Indeterminate Leprosy, 1-5 skin lesions Paucibacillary Disease (PBD), and more than five skin lesions as Multibacillary disease (MBD).²

MICROBIOLOGY

M. leprae is an acid-fast staining, microaerophilic, nonmotile, non-spore forming, obligate intracellular curved or straight bacterium that grows and divides inside Schwann cells and macrophages. It favors temperatures around 27-30°C and has an estimated in vivo replication time of every 12-14 days. It is weakly acid fast and appears as red rods when stained with the Fite Faraco method.²⁰ The cell wall consists of chains of alternating N-acetylglucosamine and N-glycolylmuramate linked by peptide cross-bridges. These in turn are linked to a galactan layer by arabinoglycan and the galactan layer is linked to three branched chains of arabinan, making up the electron-dense zone surrounding *M. leprae*.²¹ Arabinan is linked to galactan and forms the inner leaflet of the pseudolipid bilayer. The outer leaflet, also called the electron-transparent zone, is composed of mycolic acids, mycoserosic acids, trehalose monomycolic acid, phthiocerol dimycocerosaic acid, and phenolic glycolipids (PGL-1).

The primary lipid in the bacterial cell wall is PGL-1 and interacts with laminin of Schwann cells, resulting in inflammation and nerve damage.²² *M. leprae* has never been grown in artificial medium and is propagated in animal models; mice (normal, euthymic and gene knockout) and the nine banded armadillo (*Dasypus novemcinctus*) for research purposes and for testing drug resistance of the bacillus.^{23,24} The mouse footpad model is an in vivo system that allows research on *M. leprae* by inoculating a suspension containing the bacilli into the footpads of BALB/C and CBA mice. After 6 months a biopsy obtained from the inoculated tissue is evaluated to characterize the host-parasite relationship of leprosy. This animal model has been also used to determine viability of *M. leprae* organisms, to test for drug effectiveness and resistance, and to develop new forms of chemotherapy.²⁴ The MDT for leprosy was developed with information derived from the mouse footpad system. The armadillo is a natural host for *M. leprae*, and with its lower

body temperature, the bacilli replicate readily and large numbers of organisms can be isolated for biochemical and immunologic research such as vaccine development and investigation of the leprous neuritis.²³

TREATMENT OF LEPROSY

From as early as 600 B.C., through the writings of Sushtra from India, there is evidence of Hydnocarpus Oil being used to treat leprosy and an Egyptian physician is reported to have used the oil back in ancient times. Until the 1940s, Chaulmoogra oil had been the treatment for leprosy. It was relatively ineffective and caused significant injection site reactions.²⁵ In 1943, based on reports that promin was successful in the treatment of *Mycobacterium tuberculosis*, Guy Henry Faget and coworkers treated several Hansen's patients in Carville, Louisiana with promin resulting in regression of skin lesions and cures. Until this time there had been no effective treatment and this success was called "The Miracle at Carville" and published in the book with the same title by Betty Martin. In 1946 and 1947, Robert Cochrane (in an injected formulation) and John Lowe (in an oral formulation) respectively, used a related drug called Dapsone to treat HD and found it to be better tolerated than promin. Dapsone became widely used for the treatment of leprosy in the 1950s, yet it is only bacteriostatic, and in time this monotherapy resulted in the development of Dapsone-resistant bacilli.²⁶

It became essential to develop new and more powerful drugs to treat leprosy. This led to the development of Clofazimine, a dye, which is mainly bacteriostatic and mildly bactericidal as well as anti-inflammatory, and was first used by Stanley G. Browne to treat HD. In 1962, Clofazimine was added to Dapsone to treat lepromatous patients. In the early 1970s, Rifampicin emerged as the first bactericidal drug to treat leprosy, and in 1982 the WHO recommended a MDT regimen using all three drugs to treat and cure all MB disease patients² (Tables 32-3 and 32-4).

TABLE 32-3—Ridley's Logarithmic Scale

Ridley's Logarithmic Scale	Bacillary Burden per 100 magnification of the Histologic Field
6+	>1000 bacilli in an average field
5+	100-1000 bacilli in an average field
4+	1-100 bacilli in an average field
3+	1-10 in an average field
2+	1-10 in 10 fields
1+	1-10 in 100 fields
0	No bacilli seen after screening 200 fields

Ridley's Logarithmic Scale used in the Ridley-Jopling classification scheme.¹⁸ The numbers of bacilli are quantified in skin specimens, and the numbers increase logarithmically with decreasing cell-mediated immunity. Following treatment of leprosy with MDT, the cell wall remnants are cleared slowly by the immune system; approximately half to one log per year. This explains why LL patients may continue with ENL up to 10 years after completion of treatment.⁴⁸

TABLE 32-4—Summary of Commonly Used Medications in the Treatment of Leprosy and its Reactions⁷⁰

Drug	Dose	Mechanism of action	Laboratory Monitoring	Side effects
Non-reactive disease therapy				
Dapsone	100 mg daily	- Bacteriostatic - Inhibits bacterial synthesis of dihydrofolate reductase - Anti inflammatory: inhibits myeloperoxidase	- Check for G-6-PD deficiency - Complete Blood Count - Liver Function Tests	- Dapsone Hypersensitivity syndrome - Toxic hepatitis - Methemoglobinemia - Hemolytic anemia - Agranulocytosis
Rifampicin	300 mg daily	- Bactericidal - Inhibits bacterial RNA-polymerase	- Liver function tests	- Hepatotoxicity - Flu like symptoms - Orange discoloration of body fluids
Clofazimine	50 mg daily	- Binds bacterial guanine bases - Inhibits macrophages and neutrophil mobility	- Liver Function Tests	- Brown-purple skin pigmentation - Accumulation of crystalline Clofazimine in lymph tissue (may lead to intestinal obstruction) - ichthyosis
Floxacillin	400 mg daily	- Bactericidal - Inhibits DNA-gyrase	- Liver Function Tests	- Spontaneous tendon rupture - Hepatitis - Peripheral neuropathy - Psychiatric disturbances
Minocycline	100 mg daily	- Bactericidal: binds 30S ribosomal subunit - Anti-inflammatory: inhibits 5-lipoxygenase - Apoptosis	- Liver Function Tests	- Vertigo - Dizziness - Autoimmune hepatitis - Drug induced lupus - Pseudotumor cerebri - Expired medication is nephrotoxic - Blue-grey pigmentation of the skin and mucous membranes
Clarithromycin	dose: 500 mg daily	- Bactericidal: binds 50S ribosomal subunit	-Liver Function Tests	- Dizziness - Creatinine - Diarrhea - Caution in patients with QT prolongation or taking Buspirone
Reaction therapy				
Thalidomide	100-300 mg daily	- Inhibits TNF- α	- Pregnancy test in females	- Teratogenic-contraindicated in pregnancy - Increases risk for thromboembolism - Peripheral neuropathy
Prednisone	10-80 mg daily	- Immunosuppressant	- Blood glucose - With long term use consider bone density testing and - <i>Pneumocystis carinii</i> prophylaxis	- Adrenal suppression and Cushingoid features - Increases risk for diabetes and osteoporosis - Insomnia - Osteoporosis - Glaucoma
Colchicine	dose: 0.6 -1.2 mg daily	- Anti-inflammatory - Binds tubulin - Inhibits mitosis - Inhibits neutrophil motility and activity	- Complete Blood Count	- Contraindicated in renal failure - Bone marrow suppression - Diarrhea
Pentoxifylline	400-800 mg three times daily	- Anti-inflammatory - Inhibits TNF- α and leukotriene	- None	- Gastrointestinal upset
Azathioprine	50-150 mg daily	- Inhibits purine synthesis	- Complete Blood count - Alkaline Phosphatase	- Bone marrow suppression - Increased opportunistic infections - Increased risk of malignancies

	Dose	Mechanism of action	Laboratory Monitoring	Side effects
Methotrexate	10-20 mg weekly	- Antimetabolite - Inhibits dihydrofolate reductase - Add folate supplementation to reduce risk for toxicity	- Complete Blood Count - Liver Function Tests - Pregnancy test in females	- Teratogenic, contraindicated in pregnancy and in men trying to get their partner pregnant - Hepatotoxic - Contraindicated in renal disease
Cyclosporine	300 mg daily	- Calcineurin inhibitor - Inhibits interleukin-2	- Complete Blood Count - Renal Function Tests - Liver Function Tests - Blood pressure	- Nephrotoxic - Hepatotoxic - Hyperplasia of the gingiva - Increased opportunistic infections and malignancies
Acedapsone	225 mg intramuscular injection daily	- Bacteriostatic: Prodrug of Dapsone	- Check for G-6-PD deficiency - Complete Blood Count - Liver Function Tests	- Dapsone Hypersensitivity syndrome - Toxic hepatitis - Methemoglobinemia - Hemolytic anemia - Agranulocytosis
Ethionamide	250 mg twice daily	- Bactericidal - Inhibits synthesis of mycolic acid	- Liver Function Tests - Thyroid Function Tests - Blood Glucose	- Gastrointestinal intolerance - Depression - Neuritis, reduced by coadministration of pyridoxine - Hepatitis - Hypoglycemia - Teratogenic
Prothionamide	500 mg daily	- Bactericidal - Inhibits synthesis of mycolic acid	- Liver Function Tests - Thyroid Function Tests - Blood Glucose	- Hepatotoxic, increased risk when administered with Rifampicin - Hypothyroidism - Hypoglycemia - Peripheral and optic neuropathy - Metallic taste - Depression
Etanercept	50 mg injected twice weekly	- Inhibits TNF- α	- Liver Function Tests - Rule out infection with tuberculosis and hepatitis B	- Increased risk of infections - Contraindicated in tuberculosis and hepatitis B infection

Summary of commonly used medications in the treatment of leprosy and its reactions.⁷⁰ The mechanisms of action, appropriate laboratory monitoring, and most common side effects are described.

IMMUNOLOGY, VACCINES, AND CHEMOPROPHYLAXIS

The host immunity determines the clinical manifestation of infection with *M. leprae*. A robust Th-1 type cytokine production is seen in TT and a suboptimal pro-inflammatory response with predominate Th-2 type cytokines is seen in lepromatous leprosy. HLA studies in a southern Brazilian population revealed that HLA-DRB1*1601 was associated with susceptibility to borderline leprosy, HLA-DRB1*08 was associated with susceptibility to lepromatous leprosy, and HLA-DRB1*04 was associated with resistance to infection.²⁷

The role of vaccines in leprosy is to induce a cellular immunity and to induce the differentiation of memory CD8+ cytotoxic T cells.^{28,29} The Bacillus Calmette–Guérin (BCG) vaccine, initially developed to induce protection against tuberculosis (TB), was found to convey some protection

against leprosy, but its effectiveness varies, depending on the report. A past meta-analysis did not provide evidence of its efficacy due to the heterogeneity of the methods and results, yet a more recent meta-analysis revealed that there might be some efficacy when controlled for the age at the time of vaccination, the clinical form of leprosy, as well as the number of doses administered. Genetic variations in the BCG vaccine strain and genetic variations in test subjects also lead to variable efficacy.²⁸ Isolated studies reported from the Indian experience using the BCG-Galaxo, BCG-Japan, and BCG-French-Danish vaccine strains, revealed a protective effect in children, but some of these were not randomized controlled trials (RCT). The effectiveness in prevention varied from 20-80%. Type 1 and type 2 lepra reactions were 13.2% less frequent in those who had received a BCG vaccine.^{29,30} Vaccination was found to be more effective in females and those less than 20 years of age, as well as in individuals with a BCG scar less than or equal to

5 mm in diameter.³¹ Some of the current research supports the use of BCG vaccine in endemic areas for the prevention of leprosy in children and more research is required to develop this method of leprosy control in the future.

In addition to the development of better vaccines to reduce the spread of Hansen's disease, chemoprophylaxis in contacts of patients with leprosy has also been employed as a method of control. A review of 320 references was carried out and revealed seven RCT, with a total of 66,311 participants, using either single dose rifampicin, dapsone twice weekly for 2 years, or acedapsone every 10 weeks for 7 months, with follow up ranging from 2-4 years.³² In all studies chemoprophylaxis was superior to placebo. A single dose of rifampicin administered to contacts of newly diagnosed leprosy patients was 57% effective in preventing the development of HD after 2 years of follow up. Acedapsone administration reduced the rate of leprosy in contacts by 67%, and Dapsone reduced the rate by 30-40%. The studies did not report adverse events and a significant number of participants were lost to follow up. Rifampin, Ofloxacin, and Minocycline (ROM) has been used as chemical prophylaxis, reducing the serological response development of antibodies to *M. leprae*, but the data was found to only be statistically significant in adults.³³

Treatment of Reactions: Type 1 Reactions

Acute inflammatory reactions may occur in treated and untreated Hansen's disease, and may present as medical emergencies since injury to the nerves develops rapidly, resulting loss of sensation, paralysis (Figure 32-8), and deformities (see Figure 32-3a), and ocular involvement ultimately results in severe visual impairment.³⁴ Chemotherapy for leprosy is not discontinued in the setting of reactions because of its added anti inflammatory effect (Table 32-5).

Type 1 reactions, also known as reversal reactions, occurs in 15-30% of BL, BB and BT leprosy, and are believed to be a result of increased antigen excess resulting in an upgrading of delayed type hypersensitivity.³⁵ Patients present with erythema and edema of existing skin lesions, acral edema, and painful neuritis, which may become severe and last weeks to months.³⁴ Reversal reactions have also been observed following immunization, with other mycobacterial infections, pregnancy, and both physical and emotional stress.³⁵

Corticosteroids have been the first-line treatment and are effective in reducing inflammation and edema of nerves. Prompt treatment with prednisone 1 mg/kg/day is required to prevent irreversible nerve damage.³⁶ The dose of prednisone is increased if there is no response within 24-48 hours and tapered slowly to prevent relapse. High dose steroids are often required for a prolonged period of time and carry a significant risk for serious side effects. The earlier that treatment with corticosteroids is instituted after onset of nerve damage, the greater the likelihood of preventing permanent nerve impairment. Irreversible nerve damage

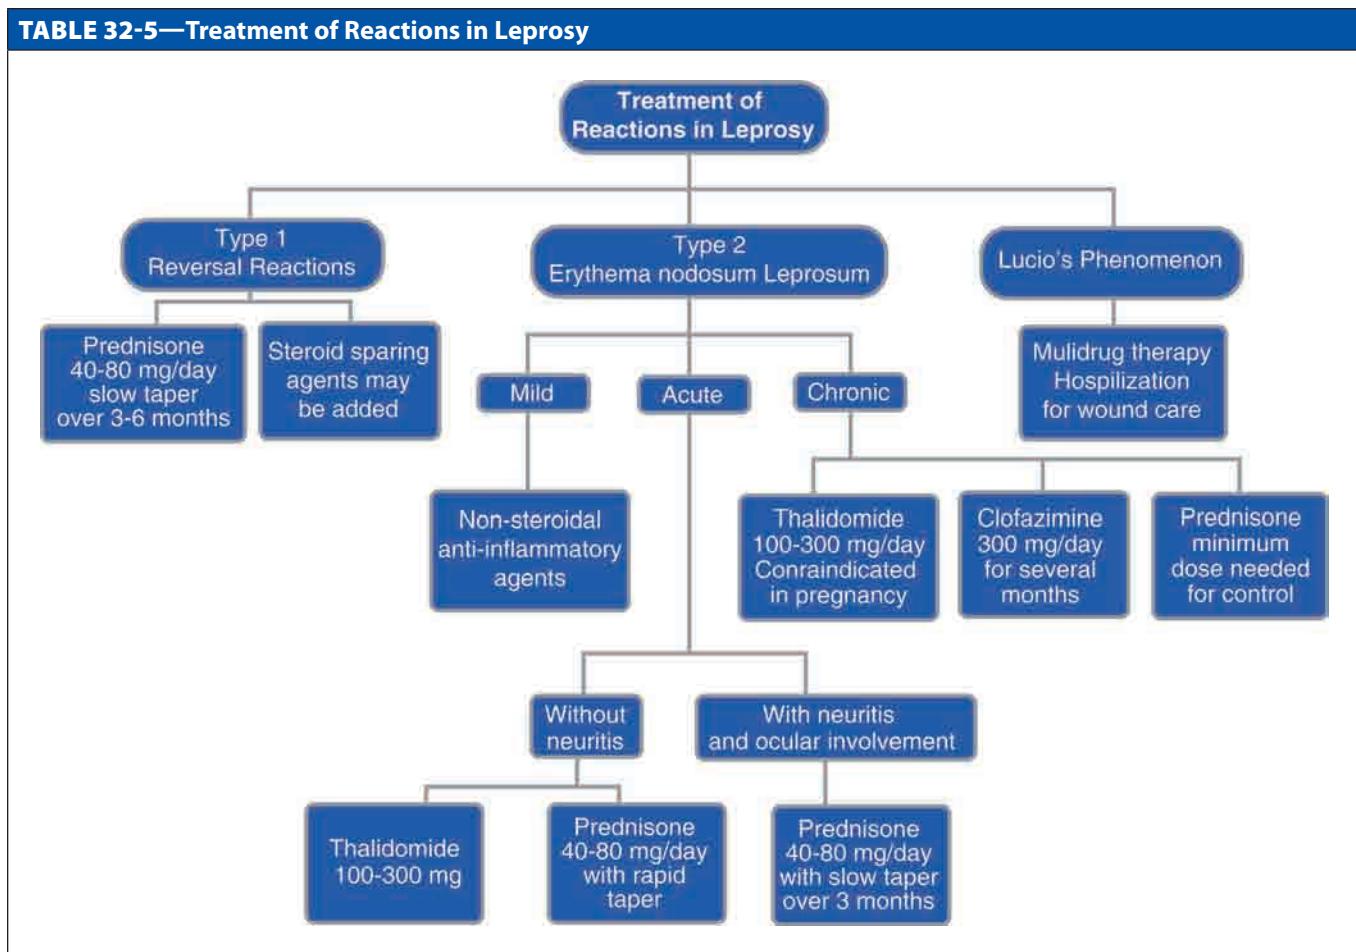

FIGURE 32-8 Borderline lepromatous leprosy patient with acute neuritis of the radial nerve and new rare onset right wrist drop.

can ensue within hours to days and steroids only have a 60% success rate in salvaging nerve function when started early and given over an extended period of time.³⁷

A number of steroid sparing agents have been investigated but the clinical trials are small and more studies are needed to further investigate the role of steroid sparing agents in the treatment of leprosy reactions. Pro-inflammatory cytokine gene expression, such as Interferon (IFN)-gamma, Tumor necrosis factor (TNF)-alpha, Interleukin (IL)-1, IL-2, IL-12, are increased during type 1 reactions.³⁸ Although Thalidomide inhibits TNF-alpha, it was found to have no benefit in treating reversal reactions.³⁹ Cyclosporine, which blocks the transcription of IL-2 and suppresses cellular immunity, has been used successfully to treat reversal reactions but is not as effective as corticosteroids and larger clinical trials are needed to further evaluate its potential use.^{40,41} Pentoxifylline and azathioprim have shown conflicting results. There is one case report using methotrexate to successfully treat a reversal reaction, and there have been no studies investigating the use of mycophenolate mofetil in the treatment of type 1 reactions.⁴²

Several studies have looked at using prednisolone as prophylaxis for neural damage. The results have shown that corticosteroids fail to improve the status of motor and sensory nerves when used as a prophylaxis.⁴³ Furthermore, the studies revealed that nerve conduction studies were abnormal at the onset of treatment, indicating that peripheral nerve damage is more extensive at the time of presentation than had previously been recognized.

Longitudinal epineurotomy, by incising the thickened epineurium and burying the nerve in deeper and warmer tissues, medial epicondylectomy, and decompressive surgery, are frequently used to treat neuritis.⁴⁴ Surgical intervention is always used in combination with medical therapy. Indications for surgery include nerve function impairment, nerve pain, and nerve abscesses; however, the long-term benefits are not well substantiated. There are three randomized controlled trials comparing medial epicondylectomy and corticosteroids with corticosteroids

TABLE 32-5—Treatment of Reactions in Leprosy

Treatment of reactions in leprosy. Type 1 reversal reactions require high dose steroids with a slow taper to preserve nerve function and reduce the risk for relapse. Steroid sparing agents may also be beneficial, but more research is needed to identify effective agents.^{35,36} Type 2 reactions are treated according to their severity and duration with anti-inflammatory agents such as nonsteroidal anti-inflammatory drugs, Clofazimine, Thalidomide, and steroids in severe cases.⁴⁸ The Lucio's phenomenon requires hospitalization and supportive medical care. These patients very rarely present with ENL.⁵⁶

alone in patients that had ulnar nerve neuritis of less than six months duration.⁴⁴⁻⁴⁶ The outcomes for the surgical group and the medical treatment group did not show any significant difference in outcome after one year of follow up. The studies did not report on surgical complications and adverse outcomes, making the data insufficient to draw sound conclusions regarding surgery for treating nerve damage in Hansen's disease. The claw hand deformity on the other hand (Figure 3a), which develops from damage to the ulnar nerve, can be successfully corrected thru surgical intervention with tendon transfers, resulting in a more functional hand and reducing one of the most common stigmas associated with HD.⁵

Treatment of Reactions: Type 2 Reactions

Erythema nodosum leprosum, or type 2 leprae reaction, affects 9% of borderline lepromatous leprosy and 49.4% of lepromatous leprosy patients (Figure 32-9). ENL affects men more frequently than women.⁴⁷ The prevalence of ENL has decreased significantly since the introduction of MDT for MB. The patients present with fever, malaise, painful red nodules affecting the skin, iritis,

myalgias, periosteal inflammation and dactylitis, arthralgias, lymphadenopathy, mastitis, and orchitis.^{6,7} Patients may also develop acute neuritis as a result of antibody-antigen immune complex deposition, dysregulation of macrophages and T-cells, and overproduction of TNF- α . Histology is characterized by a neutrophilic infiltrate in acute lesions. There are randomized clinical trials evaluating the treatment of ENL, however, they are difficult to compare due to the heterogeneity of treatments and small sample sizes used in the trials.⁴⁸ Clofazimine, which has an anti-inflammatory effect, appears to reduce the frequency and severity of Type 2 reactions. One trial compared thalidomide to acetylsalicylic acid and found that treatment with thalidomide resulted in fewer lesions.⁴⁹ Other trials revealed that clofazimine at higher therapeutic dosage had a long-term benefit with fewer recurrences and greater treatment success when compared to thalidomide and prednisolone respectively.^{50,51} There are no trials comparing thalidomide to prednisone for the treatment of type 2 reactions.

There are a number of non-randomized clinical trials that showed that thalidomide was quite effective in the treatment of ENL, its use, however, is limited due to its

FIGURE 32-9 Borderline lepromatous leprosy undergoing MDT presenting with acute erythema nodosum leprosum, consisting of tender erythematous nodules on the arms, which was associated with constitutional symptoms.

teratogenicity, and a potential increase in thromboembolisms, and neuropathy.⁵² Prednisone is also highly beneficial for type 2 reactions and methotrexate, azathioprim, cyclosporine, pentoxifylline, and etanercept are reported to reduce ENL in a number of case reports.⁵³

LUCIO'S PHENOMENON

Antibodies to cardiolipin and SS-B can be seen in lepromatous leprosy. Patients may develop antiphospholipid antibody syndrome characterized by necrosis of the skin and digits secondary to hypercoagulability. This may be misdiagnosed as Lucio's phenomenon (LP).⁵⁴ The LP is a rare acute necrotizing endotheliitis with thrombosis that has been primarily described in patients of Mexican ancestry.⁵⁵ This serious complication has a high morbidity and high mortality rate. The patients present with painful stellate skin ulcerations that have overlying black eschar and involve the face, trunk, and extremities. They have arthralgias, fever, anemia, and cachexia. These patients all have the so-called primary diffuse lepromatous leprosy, "La lepra bonita", they have madarosis, and they may have high levels of cryoglobulins in addition to high levels of *M. leprae* antigens. A retrospective study of 200 skin biopsy specimens from patients with LP revealed five common features: Endothelial cells are heavily laden with acid-fast bacilli, vascular endothelial cell proliferation resulting in vessel wall thickening and obliteration of the

vascular lumen, vascular ectasia, angiogenesis, and thrombosis of cutaneous vessels.⁵⁶ LP requires intensive inpatient management for wounds and supportive medical care, such as that provided by a burn unit, in addition to MDT. The condition carries a 50% mortality, even with advanced medical care and systemic corticosteroids.

COMORBIDITIES

In the United States, 85% of the leprosy cases detected are in immigrants. In the past the majority of cases were identified in refugees and immigrants from Cambodia, Laos, and Vietnam. In the last 10 years the demographics have changed with most patients coming from Brazil. Patients frequently have infectious and parasitic diseases that include tuberculosis, hepatitis B, strongyloides, schistosomiasis, HIV, and the incidence depends on the region from where they have emigrated.⁵⁷ Appropriate serologic testing for HIV, strongyloides and schistosomiasis, in addition to PPD placement, should be carried out at initial presentation. These comorbidities require treatment prior to initiating therapy with immunosuppressive agents.

FOOT CARE

Treatment of the insensitive foot in leprosy is analogous to treatment of the diabetic foot and remains a challenge in HD. A comprehensive treatment plan includes healing ulcerations and reducing the rate of recurrent ulcerations.⁵⁸ Regular debridement of calluses is necessary to reduce the risk for the development of perforating ulcers. (Figure 32-10) Damage to autonomic and sensory nerve fibers of the skin leads to dry skin, the inability to sweat, and loss of local sensation. Dry skin is prone to cracking, ulceration, and secondary infection. Loss of sensation leads to

FIGURE 32-10 The insensitive foot with calluses and neuropathic ulcers. The patient has already lost a number of toes secondary to infected traumatic ulcerations and osteomyelitis.

misuse, callus formation, injury, and secondary infection with development of osteomyelitis and resultant joint deformation. The Gillis W. Long Hansen's Disease Center has developed methods of fabricating cutout sandals (also known as the Carville sandal), walking splints, and walking casts that are used in conjunction with special footwear and patient education to treat and prevent plantar ulcers successfully.

A meta-analysis of interventions for skin changes caused by nerve damage in leprosy was done, but the various trials are difficult to compare due to diverse interventions and outcome measures in the studies.⁵⁹ Zinc tape showed some benefit over other traditional dressings, although the difference was not statistically significant. Casting of the foot and other methods of fixation of the foot aids in the healing of ulcerations. Polyvinyl chloride boots were slightly less effective as canvas shoes, and there was no significant difference in below the knee plasters and double rocker bottom shoes in promoting wound healing. None of the studies commented on complications and RCT are needed to further define best treatment practices for ulcer management and prevention in leprosy.

Additional measures to reduce ulcerations and improve the healing of existing ulcerations include avoidance of long distance walking, reduction of manual workload, and patient education of self-foot care. Patient and family education programs in self-care are effective in reducing ulcer rates by 41% at the end of one year and consistent use of orthotic shoes reduce the ulcer rates by 43%.⁶⁰

Infections and osteomyelitis are common complications of foot ulcerations. The most common bacteria isolated from local wound infections were *Staphylococcus aureus* and *Pseudomonas aeruginosa*.^{58,60} Soft tissue infections require administration of antibiotics and osteomyelitis requires long term antibiotic therapy. Frequently surgical debridement of the infected bone and amputation is necessary to control the infection.

Surgical management of deformities is helpful in reducing the stigma of HD familiar to people living in endemic areas and improving the quality of life of patients. Damage to the peroneal nerve may result in foot drop and the ankle may be stabilized with orthoses or surgical intervention with arthrodesis to allow for better ambulation.⁵⁸

MENTAL HEALTH

Mental illnesses are seen more frequently among patients treated for or with a history of leprosy. The rate of depression is three times higher among Hansen's patients than in patients suffering from other skin conditions such as *Tinea versicolor*.⁶¹ A study from an outpatient leprosy clinic in Ethiopia revealed an even greater increased risk with 52.4% of Hansen's patients reporting as having mental distress when compared to 34.6% of patients suffering from other skin conditions, yet the symptoms were not further classified into specific psychiatric diagnoses. The sex distribution

in this study was equal.⁶² Overall, the data available regarding mental illness in HD is sparse, yet the studies that are published indicate a need to investigate the psychosocial needs of this patient population further in order to integrate the appropriate psychiatric management into our current medical management.

OCULAR COMPLICATIONS IN LEPROSY

There is an increased prevalence in eye diseases among patients with MB disease, some of which may lead to blindness. *M. leprae* prefers the cooler parts of the body, which includes the anterior chamber of the eye. The inflammatory response to the bacillus, scleritis and iritis, may result in posterior synechia and cataracts.⁶³ The iritis is managed with steroid eye drops or oral prednisone. ENL may also affect and damage the eye.

Neuritis of the fifth and seventh cranial nerves can result in insensitivity of the cornea and paralytic lagophthalmus.^{3,5} Data from patients in India with treated MB disease revealed that ocular disease was more frequent when compared to the general population. The prevalence of bilateral blindness was 1.04% (95% confidence interval (CI)), unilateral blindness was 8.55% (95% CI), glaucoma with a mean intraocular pressure of 12 mm HG was 3.6% (95% CI), and cataracts occurred three times more frequently.⁶³

Damage to the ophthalmic division of the fifth cranial nerve results in anesthesia of the cornea and loosing the blink reflex, preventing the patient from noticing if the eyes are dry or if there is something in the eye.^{3,5} Eye drops and antibiotic ointments are helpful in protecting the cornea. If the zygomatic branch of the seventh cranial nerve that innervates the orbicularis muscle is damaged, paralysis and lagophthalmus can ensue, leaving the cornea exposed during sleep and leading to an exposure keratitis and corneal ulceration that will ultimately lead to blindness. Medial and lateral tarsorrhaphy can surgically correct the deformity so that the eyelid can close and protect the cornea.

DETECTION AND TREATMENT OF NEUROPATHY

Early detection and treatment of neuropathy in HD is important in decreasing the degree of permanent sensory and motor impairment. Peripheral nerves and superficial cutaneous nerves are most commonly involved.³ The peripheral nerves become enlarged and tender, and are palpable on examination. These nerves include the greater auricular nerve (Figure 32-11), supraclavicular nerves as they cross the clavicle, the ulnar nerve proximal to the elbow, the dorsal cutaneous branches of the ulnar nerve at the wrist, the median nerve, superficial radial nerves, common peroneal (lateral popliteal) nerves as they course around the neck of the fibula, the superficial peroneal nerves of the anterior ankle, posterior tibial nerve below

FIGURE 32-11 Borderline tuberculoid leprosy patient with an enlarged palpable nerve of the neck.

the medial malleolus, and the sural nerve. The ulnar nerve is the most commonly enlarged and tender nerve.

Monofilament testing (MFT) (Figure 32-12) is the most commonly employed technique to detect and grade the severity of sensory neuropathy. Studies looking at the sensitivity and specificity of the various clinical tools available to assess peripheral nerve function have shown that the sensitivity of MFT was between 35-44% and voluntary muscle testing (VMT) was quite low at 4-5%, although testing of the ulnar nerve was higher at 25%.⁶⁴ By combining nerve palpation with MFT, the sensitivity was increased to greater than 60 % and the combination of the two tests are the most practical methods employed when assessing and treating patients in the field. The sensitivity varied with the nerves palpated: all nerves ranged from 71-88%, with the exception of the sural nerve (59%) and the median nerve (43%). The specificity of nerve palpation was greater than 60% for all nerves, except for the common peroneal nerve (40%) and the ulnar nerve (34%). Thus nerve palpation

is more sensitive but less specific than VMT and MFT in assessing peripheral nerve function in Leprosy since palpable nerves may be present in unrelated medical conditions.

Subclinical neuropathy is quite common in patients and ranges from 20-50%.⁶⁵ Sensory perception was most frequently affected, followed by warmth detection thresholds (WDT) and cold perception thresholds (CPT). In random testing of HD patients, nerve conduction studies of the ulnar nerve revealed that 29% of patients had decreased WDT and 13% had decreased CPT.

The International Federation of Anti-Leprosy Associations (ILEP) Nerve Function Impairment & Reaction (INFIR) Cohort Study in India performed a small study looking at the inter-tester reliability of MFT and VMT.⁶⁶ Good to very good reliability was noted with MFT and moderate reliability was noted with VMT, with individual testers varying up to one grade from the gold standard value. With additional review and correction of discrepancies of the techniques used by the physiotherapists, good reliability was achieved, highlighting the importance of formal training and review of the techniques employed to obtain reliable and consistent results.

Despite successful completion of treatment and no evidence of lepromatous reactions, some patients have a silent neuropathy with asymptomatic progression of sensory and motor loss. The mechanism of this progression is poorly understood and there are no RCT investigating treatments for this type of neuropathy.

NEUROPATHIC PAIN

It is the general belief of both lay people and health care providers that leprosy patients feel no pain. Neuropathic pain is more common than previously recognized and is a rising problem in leprosy. As part of a relapse study carried out in Ethiopia in patients 10 years after completing MDT, 29% reported symptoms consistent with neuropathic pain

FIGURE 32-12 (A) Sensory testing can be carried out using nylon filaments of different diameter, allowing to grade the degree of loss of sensation. (B) Monofilament testing of the acral surface of the left foot.

that was described as being severe.⁶⁷ The neuropathic pain is generally refractory to analgesics such as non-steroidal anti-inflammatory drugs and opioids.

Proposed mechanisms of the development of neuropathic pain include spinal sensitization, sprouting of A beta nerve fibers in the superficial layer of the dorsal horn, and ectopic discharge in the dorsal root ganglion or in a neuroma of a nerve stump.⁶⁸ The ectopic discharge is mediated by sodium channels can be blocked by anticonvulsants and lidocaine. The emphasis has been on leprosy control programs and worldwide distribution of multi drug therapy and little attention has been given to the treatment of pain associated with HD. Treatment is limited to gabapentin, amitriptyline, and serotonin reuptake inhibitors and no RCT evaluating their efficacy have been carried out. Research is needed to address this treatment challenge.

NEW BACTERIA CAUSING LEPROSY

In 2009, a new bacterium, called *Mycobacterium lepromatosis*, causing leprosy was described and characterized.⁶⁹ It shares 90.9% homology with *M. leprae* and represents a divergent species. The new bacterium was isolated from two patients in Mexico with diffuse lepromatous leprosy who died from their disease. It has been proposed that this new species is associated with LL and perhaps LP, which may explain regional differences in HD and the increased incidence of LP in Mexico. At this time the treatment for *M. lepromatosis* is the same as employed for *M. leprae*.

CONCLUSION

The two important events in the history of treatment of leprosy was; the Miracle at Carville with the discovery of promin's ability to cure HD, and the development of MDT by the WHO in greatly reducing the number of active cases of leprosy to just over 200,000 annually world-wide since the 1980's. More than 15 million people with leprosy have been cured using MDT. Although the WHO does not count those individuals who have completed MDT, these patients continue to suffer significant morbidity secondary

to ocular and nerve involvement, due to ongoing reactions, which in the case of LL can last up to 10 years after treatment until the immune system has been able to clear all bacterial remnants from tissues. The insensitive feet and hands are continuously subject to trauma and infections, resulting in deformities. Consequently, these patients require life-long ongoing medical care.

The number of annual new cases of leprosy has not decreased significantly over the last 10 years and new efforts directed to control transmission thru vaccines and chemoprophylaxis have been explored, but due to the long incubation period before disease becomes evident (average 2-7 years), and the challenge in collecting appropriate data, large multicenter long-term trials have been difficult to conduct.

Lepromatous reactions and their treatment are complex and their immunological mechanisms are still poorly understood. RCT are needed to identify additional treatment options available and to explore steroid sparing agents that can control reactions and preserve nerve function. There has been a lack of funding for trials of this nature as most of the efforts by the WHO have been dedicated to the WHO Leprosy elimination program to reduce the prevalence of leprosy cases to less than 1 per 10,000 people with their MDT program. Hansen's disease is a good research model for granulomatous diseases. Clinical trials are also needed to evaluate the psychological needs of patients with HD and how to better treat neuropathic pain; both problems have been under recognized.

The results of existing trials in the field of leprosy are difficult to interpret and compare due to the heterogeneous treatments used, small sample size of patients, and often a lack of reporting of adverse events and outcomes. Future trends in treatment and management of leprosy includes the treatment of contacts and vaccines to reduce transmission. The relapse rate of leprosy remains low, but existing cases may be secondary to the under diagnosis of MB by merely counting skin lesions, and treating all HD patients with MDT for two years would eliminate this problem. The rate of resistance of bacilli to MDT also remains low and the treatment of choice for leprosy is MDT as recommended by the NHDP and the WHO.

What We Know

- There are two bacteria that cause leprosy: *Mycobacterium leprae* and *Mycobacterium lepromatosis*.
- MDT as recommended by the NHDP and the WHO is an effective treatment to cure leprosy. The relapse and resistance rates remain low with this treatment.
- Early recognition and treatment of HD is the most important factor in reducing the degree of neuropathy and disability that the patient may ultimately develop.
- BCG vaccines are effective in reducing the infection rates with leprosy in children by 20-80%. Vaccination also reduces the rate of lepromatous reactions in patients with HD by 13.2%. The benefit of BCG vaccination is greatest in children and women.
- Chemoprophylaxis in contacts of patients with leprosy is effective in decreasing the rate of development of HD in these contacts by 30-67%. Treatment was most effective with Acedapsone, followed by Rifampicin, Dapsone, Minocycline and ROM.

(Continued)

What We Know (Continued)

- The insensitive foot requires wearing orthotic shoes daily, which will reduce the risk for the development of plantar ulcers by 43%. Patient self-care education programs are effective in healing of existing ulcers and in decreasing ulcer formation of the feet by 41%.
- Type 1 reactions occur in 15-30% of borderline leprosy patients and prednisone 1 mg/kg/day is effective in controlling neuritis, but must be tapered slowly to prevent relapse. Prompt recognition and treatment is essential to reduce the neuropathy and deformities associated with damage to the involved nerves. Even with aggressive treatment, the neuropathy progresses in 60% of patients.
- Type 2 reactions occur in 9% of borderline leprosy patients and in 49.4% of LL patients. Clofazimine and Thalidomide are helpful in controlling ENL, as is prednisone. The medications are titrated to the lowest dose required to control the reaction.
- Pregnancy is associated with an increased frequency of reactions: 50% will develop Type 1 reactions during the postpartum and lactation period, and 68% will develop Type 2 reactions during the third trimester and the postpartum and lactation period.
- The Lucio's phenomenon is a vasculopathy associated with diffuse LL and is most common in patients of Mexican ancestry. The disease carries a 50% mortality rate and requires intensive supportive medical care and wound management.
- Ocular disease is common in HD and requires specialty care to manage and reduce morbidity and the risk for blindness.
- Both mental illness and neuropathic pain are seen with increased frequency in HD and RCT are needed to address the treatment of these conditions.
- Surgical correction of deformities are beneficial in improving functionality of the hands and feet, the quality of life of those with HD, and also are important in reducing the stigma associated with this disease and its socio-economic impact.

ACKNOWLEDGEMENTS

We should like to thank Vinald Francis, Medical Illustrator, for his assistance in creating the tables for this manuscript.

Treatment of Cutaneous Lupus Erythematosus

Nicole Fett, M.D., and Victoria P. Werth, M.D.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease capable of damaging all organ systems, resulting in a myriad of clinical presentations. The diagnosis of SLE, for research purposes, is defined by the 1982 American College of Rheumatology criteria.¹ Cutaneous manifestations of disease are seen in up to 90% of patients with SLE.² These cutaneous findings have been categorized into lupus-specific and lupus nonspecific lesions, based on their histologic appearance.³ Lupus-specific lesions are also broadly referred to as cutaneous lupus erythematosus (CLE). CLE has been further subcategorized based on the clinical morphology of the lesions and their average duration.³ The subcategories of CLE are chronic cutaneous lupus erythematosus (CCLE), subacute cutaneous lupus erythematosus (SCLE), and acute cutaneous lupus erythematosus (ACLE).³ Chronic cutaneous lupus erythematosus (CCLE) is further divided into the following subsets: classic discoid lupus erythematosus (DLE), generalized DLE, hypertrophic DLE, lupus profundus, lupus erythematosus tumidus, and chilblain lupus. Limited DLE is the most common form of CLE. When confined to the head and neck, it is rarely associated with SLE. DLE resolves with scarring and dyspigmentation. SCLE presents with photodistributed erythematous polycyclic patches or psoriasiform lesions. SCLE is transient and heals without scarring. SCLE is commonly associated with anti-SS-A antibodies and photosensitivity. Approximately 50% of patients with SCLE will meet ACR criteria for SLE.⁴ Acute cutaneous lupus erythematosus (ACLE) most often presents as an erythematous malar rash, although a generalized variant can occur. Close to 100% of patients with ACLE have SLE, making it the most specific cutaneous marker of systemic disease.^{4,5} It is also important to note that not all patients with CLE have SLE. CLE is two to three times more prevalent than SLE.⁴ Quality of life measures reveal that CLE is associated with significant morbidity.⁶

EPIDEMIOLOGY

A recent study by Durosaro et al.⁷ in a predominantly Caucasian population estimated the incidence of CLE as 4.3 per 100,000. A study of SLE in a similar population revealed an incidence of 3.06 per 100,000.⁸ Prior authors

have estimated that CLE is two to three times more prevalent than SLE.⁴ Both CLE and SLE are most prevalent in blacks, and in women of childbearing age.

ETIOLOGY

The etiology of CLE remains unknown. It is hypothesized that a unique combination of genetic predisposition, ultraviolet light (UVL) exposure, and immunologic factors results in the cutaneous, and possibly systemic, manifestations of the disease.^{9,10} Recently, several reviews of the pathophysiology of cutaneous lupus have been published^{9–11} A brief summary of these reviews follows. Multiple genes have been associated with the formation of CLE. Particularly, polymorphisms in genes encoding HLA subtype, tumor necrosis factor α , and complement molecules have been described. UVL exposure has an important role in pathogenesis. UVL is known to cause suprabasilar keratinocyte apoptosis. During apoptosis, these suprabasilar keratinocytes form outer membrane blebs full of self-antigens. Noninflammatory clearance of these apoptotic cells is impaired in patients with CLE, likely secondary to complement abnormalities, particularly a decrease in C1q. These apoptotic keratinocytes are thus phagocytosed, and the blebs that contain self-antigen are then presented to the host immune system, resulting in the formation of autoantibodies. The cellular debris of the UVL-induced apoptotic cells is also able to induce plasmacytoid dendritic cells, through Toll-like receptors 7 and 9, to make IFN- α . IFN- α induces cytokines involved in lymphocyte recruitment (CXCL9, CXCL10, CXCL11). These lymphocytes, once recruited to the skin, participate in cell-mediated destruction of the basement membrane. Lymphocytes are further recruited by the UVL induced production of cytokines IL-1 and TNF- α , and adhesion molecules ICAM-1, VCAM-1, E-selectin. This cascade, induced by UVL and propagated by the immune dysregulation in the patient, explains the combination of humoral and cell-mediated autoimmunity seen in CLE.

OUTCOMES MEASURES

Prior studies evaluating therapeutic options for CLE are difficult to interpret given the relative rarity of the disease, and the lack of a uniform outcome measure. Prior

investigators have used SLE activity indices such as the Systemic Lupus Activity Measure (SLAM) or the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) to monitor patient improvement (for review of activity indices see.¹²) However, neither of these indices are sensitive or specific for cutaneous improvement. Case reports and case series generally report subjective improvement by the investigator. This inability to measure outcomes made multicenter trials and systematic reviews impossible to conduct. In 2005, the Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) was introduced as an outcome instrument for CLE¹³. The CLASI reports two separate numerical scores: one for disease activity, and one for damage. The CLASI is a validated measure for both Dermatologists and Rheumatologists¹⁴ and will hopefully transform our ability to conduct meaningful objective studies of CLE.

SEARCH METHODOLOGY

We searched the Cochrane Library (Issue 3, 2009), Medline and Embase from inception until September of 2009, as well as the reference lists of relevant reviews.

RESEARCH QUESTIONS

Are Antimalarials Effective in the Treatment of Cutaneous Lupus?

During World War II, it was observed that soldiers with rheumatoid arthritis and systemic lupus erythematosus had less disease activity while on antimalarials.¹⁵ Since that time, antimalarials have been used for both SLE and CLE. Antimalarial efficacy is postulated to be associated with their photoprotective abilities, lysosomal stabilization, antigen presentation suppression, effects on toll receptors, and inhibition of prostaglandin and cytokine synthesis.^{15,16} Antimalarials also decrease TNF- α expression.¹⁷

Landmark studies for the use of antimalarials in SLE include the Canadian withdrawal trial published in 1998,¹⁸ and a recent systematic review of the effects of antimalarials on SLE outcomes.¹⁹ Ruiz-Irastorza et al. found that patients with SLE treated with antimalarials had significantly fewer lupus flares, increased survival, decreased thrombosis, and increased protection against irreversible organ damage (Ruiz-Irastorza, Ramos-Casals et al. 2009). Studies assessing use of antimalarials in CLE are limited.

We found two double-blind randomized controlled trials involving antimalarials.

The first, published by Ruzicka et al. in 1992 assessed the efficacy of acitretin compared to hydroxychloroquine in the treatment of CLE. 58 patients were randomized to either receive acitretin (28 patients) or hydroxychloroquine (30 patients). The patients were treated for 8 weeks. The outcome was defined as subjective improvement by a blinded investigator. Four patients in the acitretin

arm dropped out because of side effects. Three patients in the hydroxychloroquine group dropped out because of complete clearing of their cutaneous lesions. Thirteen out of 28 (46.4%) of patients treated with acitretin improved compared to 15 out of 30 (50%) patients treated with hydroxychloroquine. The difference in the results is not statistically significant. Patients reported increased side effects with acitretin compared to hydroxychloroquine. This study is limited by its short treatment period. Hydroxychloroquine is not at peak levels until 12 weeks of therapy.²⁰

The second, published by Bezerra et al. in 2005, assessed the efficacy of clofazimine in comparison to chloroquine. Thirty-three patients with CLE who met criteria for SLE were enrolled. Sixteen patients were randomized to receive clofazimine and 17 patients were randomized to receive chloroquine. The patients were followed for 6 months. Patient improvement was measured via the Mexican version of the SLEDAI (MEX-SLEDAI). The MEX-SLEDAI is a modified version of SLEDAI that does not include immunotesting. Scores are reported as 0 to 101, with only two possible points for rash assessment. Improvement was defined as an increase in the SLEDAI score by 5 overall. The study was conducted with intention to treat analysis. Five patients in the clofazimine group, and one patient in the chloroquine group dropped out of the study secondary to flares of their SLE. Twelve out of 16 (75%) of patients in the clofazimine group improved. Fourteen out of 17 (82.4%) patients in the chloroquine group improved. There was not a statistically significant difference in outcome between the clofazimine group and the chloroquine group. Clofazimine causes significant skin discoloration, which limits its use. One patient in the clofazimine group had a significant systemic flare.²¹

Kraak et al. published a double blind nonrandomized trial comparing hydroxychloroquine to placebo in patients with DLE. A total of 49 patients were treated for 1 year. Twenty-four patients received hydroxychloroquine, and 25 patients received placebo. At the end of 1 year, based on a subjective examination performed by an investigator, patients on hydroxychloroquine were improved over placebo.²²

Multiple case series have also been published supporting the use of antimalarials in CLE. In 1957, Christiansen published a review of multiple case series, totaling 414 patients with CLE treated with chloroquine. He reported that 265 of the patients (64%) had an improvement on the high dose (500 to 750 mg) of chloroquine used at that time (Christiansen 1957).

A case series published by Callen in 1982 reported 30/34 (88%) of patients with DLE improved on hydroxychloroquine (Callen 1982).

Kreuter et al. published a retrospective review of 36 patients with tumid lupus treated with antimalarials. They reviewed the charts of twenty-six patients treated with chloroquine and ten treated with hydroxychloroquine.

Improvement was scored with a retrospective CLASI. The authors do not describe how they determined the retrospective CLASI score. They report 61% of patients exhibited complete or almost complete clearance of lesions with CLASI scores of 0 to 1. They found no difference in the efficacy of chloroquine compared to hydroxychloroquine. Only those patients on chloroquine reported side effects of headache, dizziness and nausea.²³

We found two studies looking at the addition of quinacrine in refractory patients. Toubi et al. retrospectively evaluated the addition of quinacrine to plaquenil in six patients with refractory SLE. Three of the six patients had skin involvement at the beginning of study. All six patients had been on plaquenil for approximately 2 years, as well as low dose steroids and methotrexate or azathioprine. All six patients had SLEDAI scores over 5. Quinacrine, 100 mg per day, was added to the current therapy. Five out of six patients had improvement in their SLEDAI scores. All three patients with CLE had improvement in their SLEDAI scores, but the authors do not report if this was secondary to improvement in their cutaneous findings. Two out of the three patients with CLE stopped the quinacrine during the study for a pregnancy. Both flared with quinacrine cessation, and both had improvement in their SLEDAI scores with reinstitution of the medication after delivery.²⁴

Cavazzana et al. conducted a retrospective cohort analysis of 34 patients looking at the addition of quinacrine in patients with skin disease unresponsive to hydroxychloroquine. Two different doses of quinacrine were used (50 mg/d in 5 patients and 100 mg/day in 29 patients). Responses were graded by a retrospective CLASI score. Complete response was defined as no remaining lesions. Partial response was defined as at least a 50% reduction in CLASI. Twenty-five out of 34 patients (73.5%) had a partial response. The dose of quinacrine did not affect the response, but higher doses of quinacrine did result in a statistically significant more rapid improvement. Side effects were reported in ten of 30 patients (8.8%) and included yellow discoloration and a hepatitis flare in a patient with underlying Hepatitis C. Eighteen out of 34 patients (52.9%) stopped quinacrine (nine because of no response, two because of a clinical remission, three because of side effects, three "voluntarily stopped", and one because of pregnancy). This study is limited by its retrospective nature, the small sample size, and the high drop out rate. Quinacrine induced a partial response in patients' refractory to hydroxychloroquine in approximately 75% of patients, but was not tolerated by some patients.²⁵

TOXICITY

The most commonly reported side effects of antimalarials are nausea, gastrointestinal upset, and headache. Hydroxychloroquine can cause blue-grey discoloration of the skin. Quinacrine causes yellow discoloration of the skin and sclera. The risk of retinal toxicity is minimized with

ideal body weight-based dosing (less than 6.5 mg/kg/day for hydroxychloroquine and less than 3.5 mg/kg/day for chloroquine).²⁶ Chloroquine has a higher risk of retinal toxicity than hydroxychloroquine, particularly if given for prolonged periods.²⁷ Two systematic reviews support the safety of hydroxychloroquine use during pregnancy.^{19,28}

CONCLUSIONS

There are no randomized controlled trials of antimalarials compared to placebo in the treatment of CLE. Randomized controlled trials comparing antimalarial efficacy in comparison to acitretin and clofazimine reveal 50% of patients on hydroxychloroquine improve at 8 weeks, and approximately 82% of patients on chloroquine improve by 6 months. These percentages are supported by a large case series of patients with CLE treated with antimalarials. Systematic reviews reveal obvious benefits of antimalarials in treating SLE. Chloroquine may be more efficacious than hydroxychloroquine, but chloroquine is less well tolerated. Addition of quinacrine appears to be helpful for refractory patients, but may be rarely limited by side effects. There is little evidence of toxicity from antimalarials.

Are systemic Steroids Effective in the Treatment of Cutaneous Lupus?

We did not find any RCT of oral steroids in the treatment of cutaneous lupus. As part of an observational study of patients with DLE,²⁹ reported that 2/25 patients responded to systemic steroids.²⁹

Toxicity

The adverse effects of systemic corticosteroids are well known. Systemic corticosteroids increase blood pressure and blood glucose levels, and predispose patients to osteoporosis, avascular necrosis of the hip, weight gain, depression, and glaucoma.

CONCLUSIONS

There is insufficient evidence to recommend systemic corticosteroids in the treatment of CLE.

Are systemic Retinoids Effective in the Treatment of Cutaneous Lupus?

We did not find any randomized controlled trials assessing the efficacy of systemic retinoids in CLE compared to placebo. One randomized controlled trial assessing the efficacy of acitretin compared to hydroxychloroquine was covered in the antimalarial section above.²⁰ This study is limited by its lack of placebo arm, as well as its short duration of 8 weeks. Hydroxychloroquine has not reached full

efficacy by 8 weeks. Acitretin was found to be as effective as hydroxychloroquine at 8 weeks, but was less well tolerated.

Prior to the publication of their 1992 randomized controlled trial, Ruzicka et al. conducted an open pilot study of acitretin in the treatment of CLE. Twenty patients with CLE were treated with acitretin (10 mg to 50 mg per day) for 4 to 12 weeks. Fifteen of the 20 patients (75%) showed an excellent or good response, defined as complete clearing or moderate clearing of residual lesions.³⁰

Ruzicka et al. also published a case series of 19 patients with CLE treated with etretinate. They reported 11 of 16 patients (69%) improved over a course of 2 to 6 weeks.³¹

Shornick et al. published a case series of 6 patients with CLE refractory to systemic corticosteroids and antimalarial therapy treated with 1 mg/kg/day isotretinoin. They reported clinical improvement in all 6 cases, and disease recurrence with medication withdrawal.³²

Multiple additional case reports of clinical improvement of CLE treated with systemic retinoids have been published. Case reports are limited by selection bias, because negative results are frequently not reported^{33–38}.

Toxicity

Retinoids are well known teratogens. The cutaneous side effects of retinoids are well known and consist of drying of the mucous membranes and skin, hair loss, and pruritus. Retinoids require monthly lab monitoring for pregnancy, decrease in blood counts, and elevations in triglycerides and transaminases.

CONCLUSIONS

There is insufficient evidence to recommend the use of systemic retinoids in the treatment of CLE.

Is Thalidomide Effective in the Treatment of Cutaneous Lupus?

We did not find any randomized controlled trials to support the use of thalidomide.

There are a multitude of case series (defined as greater than five patients) that support the efficacy of thalidomide. Gorrhans and Illy reviewed and summarized all published case series of CLE treated with thalidomide prior to 1984. They described benefit in approximately 90% of 156 patients treated with 100 to 200 mg of thalidomide per day.³⁹

Since this initial case series, 14 additional case series of patients with CLE refractory to other accepted treatment modalities (antimalarials, topical and systemic steroids, methotrexate) have been published. These 14 case series total 361 patients, 308 of whom responded to thalidomide therapy (85%). The treatment length varied from months to years. Many of the case series include a subset of patients

who were weaned off the thalidomide once clinical remission was obtained, and subsequently had disease flares. The patients who flared when weaned off thalidomide universally improved once the medication was reinstated.^{40–53}

Toxicity

The most common side effect reported, in up to 77% of patients, was drowsiness and constipation.⁴⁹ Reports of peripheral neuropathy ranged from 0% to 57% of patients. Thalidomide is a teratogen, causing phocomelia if taken during gestation. Rarely, women of childbearing age have been reported to experience premature ovarian failure while on thalidomide. For this reason, women who are considering having a family should refrain from taking thalidomide.^{54,55}

CONCLUSION

No randomized controlled trials exist to support the use of thalidomide in CLE. Thalidomide has been reported to be successful in the treatment of more than 400 patients with CLE refractory to accepted first line therapies. Randomized-controlled trials are needed to better elucidate the benefits of thalidomide in CLE, particularly given the well-documented severe risks of this medication.

Is Methotrexate Effective in the Treatment of Cutaneous Lupus?

We did not find any randomized-controlled trials of methotrexate in the treatment of CLE.

A double-blind randomized-controlled trial of methotrexate in the treatment of SLE was conducted by Carneiro et al. Forty-one patients with SLE were enrolled. Twenty patients were randomized to receive methotrexate (15 to 20 mg/week) and 21 patients were randomized to the placebo arm. Outcomes were defined as a decrease in SLEDAI scores, a decrease in scores for the visual analog for articular pain, and a decrease in prednisone dose. Baseline numbers for patients with CLE were not recorded. At the end of the study, 16 of the 21 patients (76%) in the placebo arm had cutaneous lesions, whereas only 3 of the 20 patients (15%) in the methotrexate arm had cutaneous lesions. Patients in the methotrexate arm had significantly decreased pain scores, SLEDAI scores, and prednisone doses.⁵⁶

Two retrospective studies of methotrexate treatment of CLE have been published.

Boehm et al. retrospectively reviewed methotrexate use in 12 patients with CLE who failed oral steroids and antimalarials. All patients received 10 to 25 mg of methotrexate (orally or intravenously) weekly. Ten of twelve patients were reported to have improved (six with complete clearing, and four with partial clearing). One patient each was

treated with concomitant oral and topical steroids. The methotrexate was well tolerated, with mention of only mild increases in transaminases. The number of patients who experienced this side effect was not reported.⁵⁷

Wenzel et al. retrospectively reviewed 43 patients with CLE treated with methotrexate. The investigators used a clinical activity index (CLAI) with parameters of extent of skin involvement, inflammation, and clinical course, to assign patients a baseline score, and a score after 2 to 3 months of treatment. Methotrexate was given at a dose of 15 to 25 mg intravenously weekly. Based on CLAI scores, 42 out of 43 patients (98%) improved on weekly intravenous methotrexate. Seven of the 43 patients (16%) stopped the methotrexate secondary to side effects or lab abnormalities (four for elevated transaminases, one because of fatigue, one for pancytopenia, and two patients did not have described reasons for cessation). Gastrointestinal symptoms and fatigue were commonly reported side effects. Moderate elevation in liver enzymes occurred in 23 of 43 patients (54%).⁵⁸

Multiple case reports of improvement of CLE treated with methotrexate exist in the literature.⁵⁹⁻⁶³

Toxicity

Methotrexate is incompatible with pregnancy. It is generally well tolerated with changes in transaminases, headache, fatigue, and gastrointestinal upset; the most commonly reported side effects.

CONCLUSIONS

There are no randomized-controlled trials assessing the use of methotrexate in the treatment of CLE. There is insufficient evidence to guide the use of methotrexate in CLE at this time.

Is Mycophenolate Mofetil Effective in the Treatment of Cutaneous Lupus?

We did not find any randomized-controlled trials using mycophenolate as a therapy for CLE.

Kreuter et al. recently published a prospective nonrandomized open pilot study using mycophenolate sodium in the treatment of ten patients with SCLE resistant to at least one standard therapy. Mycophenolate sodium was given at a dose of 1440 mg per day (which is equivalent to 2000 mg of mycophenolate mofetil per day) to all ten patients for a duration of 3 months. CLASI scores and use of 20MHz ultrasound combined with colorimetry were used to assess outcomes. There was a statistically significant decrease in the mean CLASI score, ultrasound assessment revealed a return to normal thickness, and colorimetric measurement showed statistically significant decrease in erythema⁶⁴.

There are six prior case reports showing improvement in all subtypes of CLE in 11 of 19 patients treated with mycophenolate mofetil⁶⁵⁻⁷⁰.

Toxicity
